Reliability is another important issue that needs to be addressed, especially for telecommunication applications where these types of components have to pass high quality standards such as the Telecordia qualification in the USA.

Other PWL Systems

Many of the PWLs to date have been developed using Er doping, which emits light in the range of interest for telecommunications (the C-band and even the L-band). Here, Yb can be added as a co-dopant to improve power conversion efficiency. Other fluorescing ions have also been used: Nd, Tm, Ho, and Cr. Several research teams have successfully demonstrated Nd-YAG PWLs, in particular. Ridge waveguide lasers have been made using semiconductor materials InGaAs/InP heterojunctions in both Fabry–Perot and DFB configurations. These systems are electrically pumped. DFB PWLs have also been made using dye doped polymers.

It must be mentioned that there are other ways to use waveguides to make lasers. The primary example is a configuration where the waveguide resonator is external to the active region. Designs, such as ring resonator lasers and an external cavity lasers, fall in this category.

Future research and development of PWLs would undoubtedly utilize photonic crystal structures. These structures have a periodic fluctuation in the index of refraction in two or three dimensions. Owing to the resultant Bragg reflections, specific allowed and forbidden states are created which can be used to control the confinement of light. Hitherto, these structures have been used to form mirrors or hexagonal ring resonators. These more sophisticated laser designs are likely to enable new functions such as tunability of the output spectrum.

Summary

Planar waveguide lasers are a special class of laser where light is confined to a waveguide. They have distinctive advantages that include high optical gains, low laser thresholds, narrow linewidths in the kHz range, and optimal thermal management. Significantly, they afford a platform that can be readily expanded to include an array of lasers, each with an unique output, and can ultimately be combined with multiple optical components on the same chip. Such compact integrated devices are bound to take photonics to a new high level of capability.

List of Units and Nomenclature

a	integer denoting number of laser modes
E	electric field
k_z	propagation constant for travel in z direction
L_c	length of laser cavity
L_G	length of grating
m	order of the grating, an integer
n	refractive index of the medium
$\bar{n}$	modal effective refractive index
R	reflectance
V	normalized frequency or the V parameter of the waveguide
Δn_{eff}	modulation of the effective index of the grating
η	confinement factor or fraction of the light confined in the region of interest
λ	wavelength of the lightwave
λ_B	resonant wavelength of a Bragg grating or Bragg wavelength
Λ	grating pitch
Φ	electric field distribution

Introduction

This article discusses the principle of operation and the basic material engineering aspects for the design of semiconductor lasers. The physics of the gain medium is analyzed in detail and the role of many-body effects due to the Coulomb interaction of the carriers for the optical properties of the active semiconductor material is demonstrated. The two main types of laser resonators for diode lasers, Fabry–Perot resonators and vertical cavity structures, are described. Finally, the dynamics of semiconductor lasers, including the principles of short pulse generation and nonequilibrium gain dynamics, is addressed.

Basic Principles

The optical emission from semiconductor lasers arises from the radiative recombination of charge carrier pairs, i.e., electrons and holes in the active area of the device. The conduction-band electron fills the valence-band hole by simultaneously transferring the energy difference to the light field. This is called radiative recombination. Hence, the frequency of the laser light is mainly determined by the bandgap of the semiconductor laser material. In order to achieve lasing, one needs carrier inversion, i.e., a sufficient number of electrons in the conduction band so that the probability of light absorption is lower than the probability of emission.

It has been shown that a large variety of semiconductor materials is suited for semiconductor lasers. The most stringent requirement for the material is that it has a direct bandgap. In other words, the maximum of the valence band and the minimum of the conduction band have to be at the same position in k-space (in the center of the Brillouin zone). The elemental semiconductors silicon and germanium do not fulfill this condition and therefore cannot be used for semiconductor lasers.

In order to achieve carrier inversion, it is necessary to pump the semiconductor laser, i.e., to excite a sufficient number of electrons from the valence band into the conduction band. Even though this pumping in semiconductors, as in other solid state laser materials, can be done optically, the large technological impact of semiconductor lasers is at least in part due to the possibility of electrical pumping with a few tens of milli-amperes at low voltages.

The original version of such a semiconductor laser device is shown in Figure 1, The laser structure consists of a GaAs-based p-n junction which is biased in the forward direction. Electrons are injected from the n region and holes from the p region, respectively. Due to the diode characteristics of the p-n junction, semiconductor lasers are often also called laser diodes. In the device shown in Figure 1, the laser mirrors are formed by the cleaved facets of the semiconductor crystal. Because of the high refractive index of GaAs, the semiconductor–air interface provides a reflectivity of about 32% which is sufficient for laser emission.

However, the early type of laser, the so-called homojunction device, was not very efficient because of the low carrier density in the active area and because of the weak overlap between the inverted region and the optical mode. Considerable improvement towards room-temperature continuous wave (cw) operation was achieved by the introduction of the so-called double heterostructure. Its principle is shown in Figure 2.

The basic idea behind the double heterostructure laser is that the active material (e.g., GaAs) is embedded in another semiconductor with a slightly larger bandgap (e.g., (AlGa)As). This causes a potential well in which electrons and holes are confined in order to achieve high carrier densities in the active area. Moreover, the smaller refractive index of the surrounding high-bandgap material helps to guide the optical field within the region of highest inversion. Additional ridge-shaped lateral structuring is frequently used to form a complete optical waveguide.

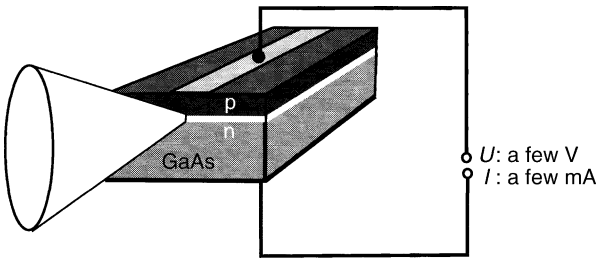

Figure 1 Principle of operation of a semiconductor laser.

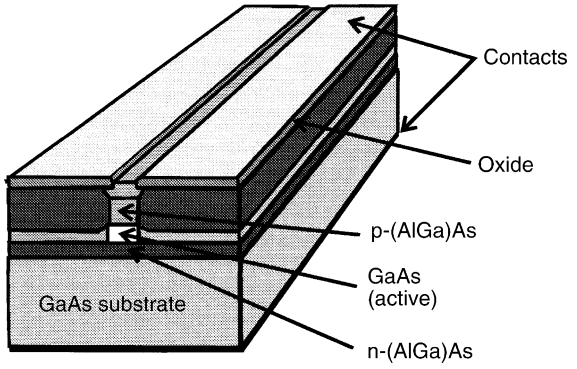

Figure 2 Double heterostructure laser diode.

Nowadays, even more advanced laser structures can be fabricated, as modern crystal growth techniques such as molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD) have become available. These techniques allow the grower not only to determine the composition of the semiconductors with remarkable precision, but also to define the shape virtually on an atomic scale. In particular, it is now possible to grow microstructures so small that their electronic and optical properties deviate substantially from those of the corresponding bulk materials. So-called quantum-well (QW) structures, in particular, turned out to be superior to bulk materials in many respects and are currently the active medium in most commercial semiconductor lasers. The gain medium in QW laser structures consists of one or more films with a thickness of a few atomic monolayers. These are embedded in a barrier material with a larger bandgap that serves to confine the carriers to the wells. In QWs the quantum confinement restricts the free carrier motion to the two dimensions within the plane of the films, since the well thickness is comparable to or less than the thermal wavelength of the carriers. Hence, one speaks of quasi-two-dimensional structures where no free motion perpendicular to the films is possible. The corresponding energy states of the carriers are quantized, i.e., only discrete values are allowed for that part of the carrier kinetic energy which is related to the confined direction.

A major consequence of this restriction of the carrier motion to two dimensions is a change in the (single particle) density of states. This density of states is altered in QWs in comparison to bulk material. The density of states for bulk material is zero at the bandgap energy and rises with the square root of the energy for higher energies. In contrast, the density of states for a two-dimensional carrier system in a QW is a step-like function with a density of states different from zero at the QW-well bandgap (the bandgap energy of the active material plus the quantization energies of electrons and holes in the well). This increase of the density of states at the bandgap promises important advantages of QW structures over bulk material. Most importantly, the number of states that have to be occupied before inversion is obtained is considerably reduced in QW structures. This reduces the threshold current and increases the modulation speed of the laser structures. Accordingly, most of the modern laser structures are QW structures.

These arguments have encouraged many researchers to develop structures with further increased carrier confinement in two dimensions (quantum wires) and three dimensions (quantum dots). The single-particle density of states is even more favorable in quantum wires and quantum dots than in QWs: in both cases the single-particle density of states peaks at the effective bandgap energy. This argument seems to promise even better performance of quantum wire and quantum dot lasers as compared to QW devices. However, the single-particle density of states description completely neglects the Coulomb interaction of the carriers which strongly influences the optical and electronic properties of semiconductor structures. The absorption is modified by excitonic effects that lead to additional resonances below the bandgap and to changes of the continuum absorption. These changes are often quantified by the so-called Sommerfeld factor, which depends on the dimensionality of the system, i.e., it differs for bulk, QW, quantum wire and quantum dot structures. For example, the Sommerfeld factor completely suppresses the singularity of the density of states at the bandgap of quantum wire structures. Accordingly, with inclusion of Coulomb effects, the benefit of the quantum confinement is much less than expected from the single-particle density of states.

The use of quantum wire and quantum dot structures as a semiconductor laser gain medium is still in its infancy even though they can be grown with various degrees of precision. However, quantum dot structures, especially, hold great promise for the future, since they can be grown in large numbers using techniques similar to those already used for QWs. The possibility of layer growth under strained conditions, such as QWs between barrier material with a slightly different atomic lattice constant, also results in a greater flexibility to design the laser gain medium with the desired emission wavelength.

In principle, the emission wavelength of a semiconductor laser can be roughly designed by the choice of the material. Different semiconductors have different bandgaps between the valence band and conduction band and the bandgap energy determines the spectral range of the emission. One can tune the bandgap and thus the spectral range of

the emission by fabricating semiconductor alloys as, e.g., (GaIn)As or (AlGa)As. Presently, a large variety of different materials is commercially available covering, for example, the red ((AlGaIn)P), the near infrared ((AlGa)As, (GaIn)As), the telecom ((GaIn)(AsP)) and even the blue–ultraviolet range ((GaIn)N).

Great care has to be taken that the crystal used for a semiconductor laser is of almost perfect quality. Dislocations in the crystal, for example, have to be avoided as well as any kinds of defects since they act as nonradiative recombination centers. Nonradiative recombination competes with the radiative recombination that is essential for the laser process. Nonradiative recombination effects include Auger recombination and recombination via defects. Auger recombination is the process where an electron and a hole recombine and completely transfer the energy difference to another carrier (electron or hole) which is excited to a higher state. This is an intrinsic effect that depends mainly on the band structure and the relevant values of the transition probabilities (transition matrix elements). The probability for Auger recombination is temperature- and carrier-density-dependent and can be minimized, e.g., by properly cooling the device and by keeping the carrier densities as low as possible.

Nonradiative recombination via defects is an extrinsic effect that depends on the material quality and can thus be minimized by optimized growth. However, trying to avoid dislocations limits the choice of materials for laser structures severely. The growth processes require 'host' crystals, so-called substrates, on which the real structure can be grown. GaAs, InP, SiC and sapphire wafers are available in sufficient quality as standard substrates for optoelectronic applications. The epitaxially grown material adapts to the crystal structure of the substrate which implies that the lattice constant of the substrate and structure material should be very similar. If the lattice constants do not agree, i.e., if there is a structural mismatch, a certain amount of strain develops which increases with increasing lattice mismatch. Too much strain leads to the formation of dislocations which are detrimental to laser applications. Control of the dislocation density is currently one of the critical issues for the wide-gap III–V materials, such as GaN, because no substrate is available that matches the GaN lattice constant. However, a small amount of strain is often even desirable as long as it does not cause dislocations. Strain influences the band structure of the material in a predictable way and can therefore be used to tailor the laser emission properties.

Thus laser materials for a certain desired wavelength range have to fulfill two important requirements: first, the bandgap of the material has to fit the desired photon energy; and second, and more crucial, an appropriate substrate with the right lattice constant has to be available. This second condition excludes many material compositions from laser applications. In many cases, both conditions can only be simultaneously met with quaternary semiconductor alloys (for example (GaIn)(AsP) on InP substrates).

Physics of the Gain Medium

From a material physics point of view, the important structural aspects of a certain laser material are summarized in the band structure of the gain medium, i.e., in the quantum mechanically allowed energy states of the material electrons. The calculation of the band structure of a particular gain medium is therefore a crucial aspect of semiconductor laser modelling. Additionally, however, one has to understand the relevant properties of the excited electron–hole plasma in the active region of the laser.

In its ground state, i.e., without excitation and at very low temperatures, a perfect semiconductor is an insulator where no electrons are in the conduction-band states. The presence of a population inversion, i.e., occupied conduction band and empty valence band states in a certain range of frequencies, is, however, a requirement for obtaining optical gain and light amplification from a semiconductor. Sufficiently strong pumping leads to the generation of an electron–hole plasma, where the term 'electron' specifically refers to conduction-band electrons and 'holes' to the missing electrons in the originally full valence bands. Holes are also quasiparticles, just as the electrons. Electrons in a solid are quasiparticles with an effective mass that is considerably different from the free-electron mass in vacuum and that is determined by the band structure, i.e., the interaction with all the ions of the solid. The properties of the missing electrons, such as a positive charge for the missing negative electron charge, a spin opposite to that of the missing electron, etc., are attributed to the holes. As a consequence of their electrical charges, the excited electrons and holes interact via the Coulomb potential which is repulsive for equal charges (electron–electron, hole–hole) and attractive for opposite charges (electron–hole). Furthermore, electrons and holes obey Fermi–Dirac statistics and the Pauli exclusion principle that forbids two Fermions from occupying the same quantum state. The consequences of the Pauli principle are often referred to as 'band-filling effects' in the physics of semiconductor lasers.

The theory therefore has to account not only for the band-structure but also for this band filling, i.e., the detailed population of the electron and hole states. Taking into account only the band structure and band filling leads to a so-called free-carrier theory. But the electron–hole plasma in a semiconductor gain medium is an interacting many-body system because of the carrier interactions and the exclusion principle. In a many-body system the properties of any one carrier are influenced by all the other carriers in their respective quantum states. Generally, advanced many-body techniques are needed to systematically analyze such an interacting electron–hole plasma and to compute the resulting optical properties, such as gain, absorption or refractive index, all of which are changing in a characteristic way with the changing electron–hole density.

It is often helpful to investigate the characteristic time-scales and the most direct consequences of the various interaction effects even though the consequences of the different many-body effects are in general not additive. The fastest interaction, under typical laser conditions, is the carrier–carrier Coulomb scattering that acts on scales of femto- to picoseconds to establish Fermi–Dirac distributions of the carriers within their bands. These distributions are often referred to as 'quasi-equilibrium distributions' since they describe electrons and holes in the conduction and valence bands which may be characterized by an 'electronic temperature' or 'plasma temperature.' The plasma temperature is a measure for the mean kinetic energy of the respective carrier ensemble and relaxes towards the lattice temperature as a consequence of electron–phonon (= quantized lattice vibration) coupling, i.e., the carriers can emit or absorb phonons. The coupling to longitudinal optical phonons in polar materials is especially strong with scattering times in the picosecond range. The corresponding times for the electron–acoustic phonon scattering are in the nanosecond range. Generally, the carrier–phonon interaction provides an exchange of kinetic energy of the carriers with the crystal lattice in addition to the relaxation of the initial nonequilibrium distribution. Deviations between plasma and lattice temperature may occur, especially when lasers are subject to strong pumping or rapid dynamic changes.

The Coulomb interaction not only causes rapid carrier scattering but also directly influences the laser gain spectrum. Gain, i.e., negative absorption, occurs in the spectral region of population inversion, in other words, where the net probability for a test photon to be absorbed is lower than the probability to be amplified by stimulated electron–hole recombination. Energetically, the gain region is bounded from below by the effective (or renormalized) semiconductor bandgap and from above by the electron–hole chemical potential. Here, the chemical potential is the energy at which neither absorption nor amplification occurs, i.e., where the semiconductor medium is effectively transparent.

The effective bandgap energy for elevated carrier densities is significantly below the fundamental absorption edge of an unexcited semiconductor. This 'bandgap renormalization' is a consequence of the fact that the Pauli exclusion principle reduces the repulsive Coulomb interaction between carriers of equal charge. Furthermore, the Coulomb screening, i.e., the density-dependent weakening of the effective Coulomb interaction potential, contributes to the reduction of the bandgap.

Another many-body effect originates in the Coulomb attraction between an electron and a hole, and leads to an excitonic or Coulomb enhancement of the interband transition probability. All these effects contribute to the detailed characteristics of the optical spectra of a semicondcutor gain medium. Figure 3 shows an example of calculated spectra in comparison to experimental data.

The example demonstrates that the microscopic theory correctly accounts for the changes in the gain spectrum with changing carrier density by means of a consistent treatment of band structure, band-filling, and many-body Coulomb effects.

The Resonator

In addition to a gain medium, a laser needs a positive feedback process for the amplified stimulated emission. Hence, the inverted medium has to be

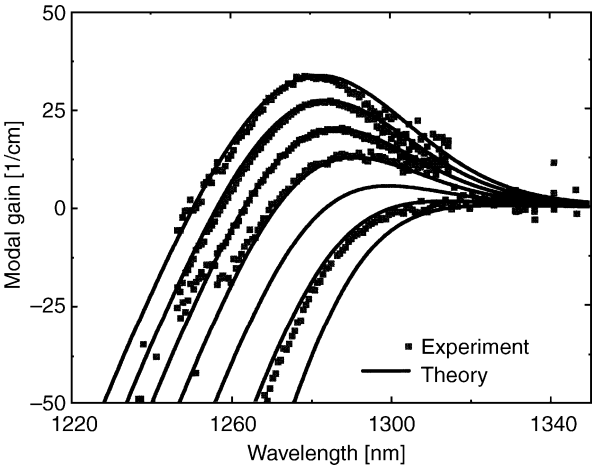

Figure 3 Comparison of experimental and theoretical gain spectra of a (GaIn)(Nas)/GaAs laser.

embedded into a resonator. One of the conceptually simplest versions of such a resonator is a so-called Fabry–Perot resonator which consists of two parallel plane mirrors. A double heterostructure Fabry–Perot laser is shown in Figure 2. Such Fabry–Perot resonators are very easy to fabricate for semiconductor lasers: the semiconductor crystal is cleaved perpendicular to the optical waveguide. The cleaved edges provide a reflectivity of about 32% due to the high refractive index of the semiconductor. This is sufficient to provide enough feedback for laser operation.

However, despite its conceptual simplicity, the cleaved-edge Fabry–Perot concept also introduces a number of problems. First, the light output occurs on two sides of the laser, whereas for most applications all the output power should be emitted out of one facet only. For practical applications, this problem can be solved by depositing coatings onto the cleaved facets of the structure. For example, deposition of a 10% reflectivity coating on one facet and of a 90% reflectivity coating on the other facet concentrates the laser emission almost completely to the facet of lower reflectivity. Antireflection coatings with reflectivities below 10^{-4} are used when laser diodes are coupled to external cavities, e.g., in tunable lasers.

A second problem with Fabry–Perot lasers is that the emission wavelength is often not well defined. A Fabry–Perot resonator of length L (optical length nL) has transmission maxima – so-called modes – at all multiples of $c/2nL$ where c is the speed of light and n the refractive index. That means that for typical devices with a length of 500 μm, hundreds of modes are present even within the limited gain bandwidth of a semiconductor. These modes often compete with each other resulting in multimode emission which may become particularly complex and uncontrollable when the laser is modulated for high-speed operation.

This problem can be overcome in so-called distributed feedback (DFB) lasers. In these devices, the refractive index is periodically modulated along the waveguide. In a simplified picture, this periodic pattern causes multiple reflections at different locations within the waveguide. For certain wavelengths, these multiple reflections interfere constructively to provide enough 'distributed' feedback for laser operation. With the DFB concept, single-mode emission can be realized even for high-speed modulation of the lasers. Alternatively, the region of distributed feedback can be separated from the region of amplification in so-called distributed Bragg reflector (DBR) lasers. These are devices with multiple sections where one section is responsible for the optical gain and another section (the DBR section) is responsible for the optical feedback.

So far, we have discussed so-called edge emitting lasers where the light emission is in the plane of the active area of the device. The lengths of these lasers are typically hundreds of microns and thus correspond to a few hundreds of optical wavelengths. This causes one of the major disadvantages of edge emitters – the multimode emission. Another disadvantage is the poor elliptic beam profile due to diffraction at the small rectangular output aperture. Finally, the fabrication procedure of edge emitters is complex since it requires multiple steps of cleaving before it is even possible to test the laser.

A novel alternative semiconductor laser concept was realized in the early 1990s: the vertical-cavity surface-emitting laser (VCSEL). A typical VCSEL structure is shown in Figure 4. In VCSELs, the light emission is parallel to the growth direction, i.e. perpendicular to the epitaxial layers of the structure. The cavity length of a VCSEL is in the order of a few (1–5) multiples of half the wavelength of the emitted light in the material. These small dimensions imply that the interaction length between the active medium and the light field in the resonator is very short. Therefore, the mirrors of a VCSEL have to be of very good quality; reflectivities of more than 99% are required in most configurations.

Very high reflectivities can be achieved with dielectric multilayer structures, so-called Bragg reflectors. Bragg reflectors consist of a series of pairs of layers of different refractive indices, where each layer has the thickness of a quarter of the emission wavelength. Most preferably, Bragg reflectors are epitaxially grown together with the active area of the device in only one growth process.

Small VCSEL resonators with Bragg reflectors at both ends of the cavity are called microcavities. They are designed in such a way that only one longitudinal mode is present in the region of the semiconductor gain spectrum. Accordingly, VCSELs are well suited to provide single-mode characteristics. Moreover, a round aperture for light emission can be realized with a diameter of a few micrometers so that

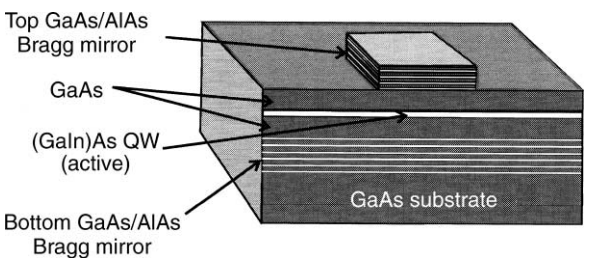

Figure 4 Vertical-cavity surface-emitting laser (VCSEL).

diffraction is weak and the beam profile is almost perfect.

VCSELs can be tested on wafer without further processing and can be arranged in two-dimensional arrays. A major disadvantage of VCSELs is their temperature dependence. The bandgap of the active material and the cavity mode depend on temperature in such a way that the cavity mode shifts away from the region of maximum gain when the temperature is varied. This severely limits the temperature range of operation for VCSELs.

Semiconductor Laser Dynamics

The dynamical behavior of semiconductor lasers is rather complex because of the coupled electron–hole and light dynamics in the active material. Like other laser materials, semiconductor lasers exhibit a typical threshold behavior when the pump intensity is increased. For weak pumping, the emission is low and spectrally broad; the device operates below threshold and shows (amplified) spontaneous emission. At threshold, the optical gain compensates the losses in the resonator (i.e., internal losses and mirror losses) and lasing action starts. Ideally the output power increases linearly with the injection current above threshold. The derivative of this curve is proportional to the differential quantum efficiency. The differential quantum efficiency can reach values close to unity and even the overall efficiency of the diode laser, i.e., the conversion rate from electrical power into optical power, can be as high as 60% which is far higher than for any other laser material.

Ideally, the laser emission is single mode above threshold. However, as discussed above, edge-emitting diode lasers tend to emit on multiple longitudinal modes and the competition of these modes can lead to complex dynamical behavior which is significantly enhanced as soon as the laser receives small amounts of optical feedback. Semiconductor lasers are extremely sensitive to feedback and tend to show dynamically unstable, often even chaotic, behavior under certain feedback conditions.

Like other lasers, semiconductor lasers respond with relaxation oscillations when they are suddenly switched on or disturbed in stationary operation. Relaxation oscillations are the damped periodic response of the total carrier density and the optical output intensity as a dynamically coupled system. Both are important for many aspects of semiconductor laser dynamics. The relaxation oscillation frequency determines the maximum modulation frequency of diode lasers. This frequency is strongly governed by the differential gain in the active material, i.e., by the variation of the optical gain with carrier density.

An important application of relaxation oscillations is short pulse generation by gain switching of laser diodes. The idea of gain switching is to inject a short and intense current pulse or an optical pump pulse into the laser structure. This pulse initiates relaxation oscillations but it is so short that already the second oscillation maximum is not amplified. As a consequence, only one intense pulse is emitted. The shortest pulse widths achieved with this scheme so far are in the few picoseconds range. For short pulse generation, a further complexity of the diode laser comes into play. The emitted pulses are observed to be strongly chirped, i.e., the center frequency changes during the pulse. This complex self-phase-modulation is a result of the strong coupling of the real and the imaginary parts of the susceptibility in the semiconductor. If the gain (which is basically given by the imaginary part of the susceptibility) changes during a pulse emission, the refractive index (basically the real part of the susceptibilty) also changes considerably. This leads to a self-phase-modulation if a strong optical pulse is emitted. This strong phase–amplitude coupling is also responsible for the high feedback sensitivity of diode lasers, for complex spatio-temporal dynamics (e.g., self-focusing, filamentation), and for a considerable broadening of the emission linewidth. The phase–amplitude coupling is often quantified with the so-called linewidth enhancement or α factor. This parameter, however, is a function of carrier density, photon wavelength, and temperature.

Diode lasers are also suited for the generation or amplification of extremely short pulses with durations below 1 picosecond. The concept used for such extremely short pulse generation is called mode-locking. The idea of mode-locking is to synchronize the longitudinal modes of the laser so that their superposition is a sequence of short pulses. The most successful concept to achieve mode-locking of diode lasers is to introduce a saturable absorber into the laser cavity and to additionally modulate the injection current synchronously to the cavity roundtrip frequency. A saturable absorber exhibits nonlinear absorption characteristics: the absorption is high for weak intensities and weak for high intensities so that high peak power pulses are supported. Such absorbers can be integrated as a separate section into multiple-section diode lasers which have already been successfully used for subpicosecond pulse generation. Furthermore, electro-absorption modulators, passive waveguide sections, and tunable DBR segments for wavelength tuning can also be integrated into such multiple-section devices.

However, when subpicosecond pulses are generated or amplified in semiconductor laser amplifiers the dynamics of the pulse generation or pulse amplification is strongly governed by complex nonequilibrium carrier dynamics in the semiconductor. The most prominent effects are spectral hole burning and carrier heating. Spectral hole burning occurs if an intense laser field removes carriers from a certain area in k-space faster than carrier–carrier scattering can compensate for. This leads to nonthermal carrier distributions and a gain suppression in certain energy regimes. As mentioned above, a nonthermal carrier distribution relaxes quickly (100 femtoseconds) into a thermal (quasi-equilibrium) distribution if the intense laser field is switched off, but this carrier distribution may have a plasma temperature much higher than the lattice temperature. This effect, which is referred to as carrier heating, also leads to a transient reduction of the gain on a few picoseconds timescale until the carrier distributions have cooled down to the lattice temperature by interactions with phonons. These ultrafast effects are of course particularly important for amplification and generation of short pulses but they generally influence the whole dynamical behavior of diode lasers including, e.g., the modulation behavior.

Up-Conversion Lasers

A Brenier, University of Lyon, Villeurbanne, France

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Under photoluminescence excitation, a luminescent center located inside a transparent material usually emits at a longer wavelength than the excitation. This is because of the existence of de-excitation losses inside the material. Thus, efficient down-conversion lasers can be built, for example, the commercial Nd^{3+}:$Y_3Al_5O_{12}$ laser which works at 1064 nm, under usual pumping near 800 nm. More surprisingly, it has been demonstrated that fluorescence can also be emitted at shorter wavelength than the excitation. This is possible if the losses are reduced and overcome by so-called 'up conversion mechanisms'. Generally speaking, a laser emitting at a shorter wavelength than the excitation is classified as an up-conversion laser.

These lasers are able to generate coherent light in the red, green, blue, and uv spectral ranges. A point of practical importance is that some of them can be pumped in the near-infrared range (around 800 nm or 980 nm) by commercially available laser diodes. They can be based on all-solid-state technology and share its advantages: compactness of devices, low maintenance, and efficiency. They are needed for a variety of applications: color displays, high density optical data storage, laser printing, biotechnology, submarine communications, gas-laser replacement, etc.

Because the emitted photons have higher energy than the excitation ones, more than one pump photon is needed to generate a single laser photon, so the physical processes involved in the up-conversion laser are essentially nonlinear. Two kinds of laser devices can be considered. In the first one, the excitation of the luminescent center up-migrates through the electronic levels and reaches the initial laser level. This step is due to some luminescence mechanisms. Then, in a second step, lasing at a short wavelength occurs through a transition towards the final laser level. In the second kind of device, the pump excitation activates a down-conversion lasing, but

the laser wave is maintained inside the cavity, cannot escape, and is up-converted in short wavelengths by the second-order nonlinear susceptibility of the crystal host. This requires bifunctional nonlinear optical and laser crystals. The device is thus a self-frequency doubling laser or a self-sum frequency mixing laser. If the nonlinearity is not an intrinsic property of the laser crystal but is due to a second nonlinear optical crystal located inside or outside the cavity, the device operates intracavity or extracavity up conversion.

Up-Conversion from Luminescence Mechanisms

The numerous $^{2S+1}L_J$ energy levels ($4f^n$ configuration) of the trivalent rare earth ions, inserted in crystals or glasses, offer many possibilities for up conversion, particularly from long-lived intermediate levels that can be populated with infrared pumping. Crystal field induced transitions between them are comprised of sharp lines, because the $4f^n$ electrons are protected from external electric fields by the $5s^2p^6$ electrons. Their fluorescence spectra can exhibit cross-sections high enough (10^{-19} cm^2) to lead to laser operation in the visible range. For up-conversion purposes, the most popular ions are Er^{3+}, Pr^{3+}, Tm^{3+}, Ho^{3+}, and Nd^{3+}. Up conversion in Er^{3+} was used for the first time in 1959, to detect infrared radiation.

Energy Transfers

Two ions in close proximity interact electrostatically (Coulomb interaction) and can exchange energy. The ion which gives energy is called the sensitizer S or donor, and the energy receiving ion is the activator A or acceptor. Two examples discussed below are shown in Figure 1. The most typical case of such nonradiative energy transfer in trivalent rare earth ions in insulating materials is due to electrical dipole–dipole interaction. For the latter, the transition probability $W(s^{-1})$ takes the form:

$$W = \frac{3\hbar^4 c^4}{4\pi n^4}\frac{1}{R^6}\frac{Q_A}{\tau_{rad}}\int \frac{f_A(E)f_S(E)}{E^4}dE \qquad [1]$$

where R is the S–A distance, E is the photon energy of the transition operated by each ion, n the refractive index, and Q_A is the integrated absorption cross-section of the A-transition:

$$Q_A = \int \sigma_A(E)dE, \qquad f_A = \frac{\sigma_A}{Q_A} \qquad [2]$$

In eqn [1], τ_{rad} is the radiative emission probability of S for the involved transition calculated from the emission probability A_S:

$$\frac{1}{\tau_{rad}} = \int A_S(E)dE, \qquad f_S = \tau_{rad}A_S \qquad [3]$$

The integral in eqn [1] is called the overlap integral and shows that the transfer is efficient if the luminescence spectrum of S is resonant with the absorption spectrum of A (corresponding to the S and A transitions involved in the nonradiative transfer). The transitions are often not in perfect resonance but remain efficient enough to be used in practice. Then the energy mismatch is compensated by phonons, and the energy transfer is said to be phonon-assisted.

The energy transfer visualized in Figure 1a is an up-conversion cross-relaxation. It is often met in the rare earth ions cited above when they are sufficiently concentrated in the material. The S and A ions can be of the same or of different chemical species. Successive energy transfers can promote the activator from its ground state towards higher energy levels, up to the one from which lasing can occur. This is the so-called 'Addition de Photons par Transferts d'Energie', sometimes appointed 'APTE'. Yb^{3+} is the most used ion as sensitizer and leads to the following transfers in examples of Er^{3+} or Ho^{3+} co-doping:

$$\begin{aligned} {}^2F_{5/2}(Yb) + {}^4I_{15/2}(Er) &\rightarrow {}^2F_{7/2}(Yb) + {}^4I_{11/2}(Er) \\ {}^2F_{5/2}(Yb) + {}^4I_{11/2}(Er) &\rightarrow {}^2F_{7/2}(Yb) + {}^4F_{7/2}(Er) \end{aligned} \qquad [4]$$

$$\begin{aligned} {}^2F_{5/2}(Yb) + {}^5I_8(Ho) &\rightarrow {}^2F_{7/2}(Yb) + {}^5I_6(Ho) \\ {}^2F_{5/2}(Yb) + {}^5I_6(Ho) &\rightarrow {}^2F_{7/2}(Yb) + {}^5S_2(Ho) \end{aligned} \qquad [5]$$

If several sensitizers give their energy simultaneously to a single activator, promoting it directly from its ground state towards a high energy level without intermediate levels, the sensitization is said to be 'cooperative'.

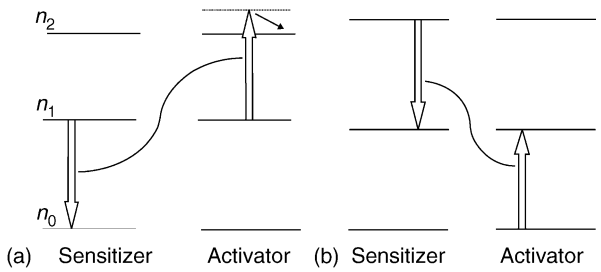

Figure 1 (a) Up-conversion cross-relaxation energy transfer. (b) Down-conversion cross-relaxation energy transfer. The example in (a) is phonon assisted, the example in (b) is resonant.

The energy transfer shown in Figure 1b is a down-conversion cross-relaxation. It is the inverse of the previous one. At first sight it is, of course, undesirable in an up-conversion laser. However, we notice that one ion in the upper level will lead to two ions in the intermediate level. This fact can be exploited in special conditions (see below) and be beneficial for up conversion.

The dynamical study of the energy transfers, starting from the microscopic point of view contained in eqn [1], is very complicated because of the random locations of the ions or because of other processes, such as energy migration among sensitizers and back transfers. A popular method leading to useful predictions in practice is the rate equation analysis dealing with average parameters. The time evolution of the population densities n_i of the various levels i are described by first-order coupled equations, solved with adequate initial conditions and including the pumping rate. As an example, the rate equations for levels 1 and 2 in Figure 1a take the form:

$$\frac{dn_1}{dt} = -\frac{n_1}{\tau_1} - 2kn_1^2 + \frac{\beta_{21}}{\tau_2}n_2 + W \qquad [6]$$

$$\frac{dn_2}{dt} = -\frac{n_2}{\tau_2} + kn_1^2 \qquad [7]$$

$$n_0 + n_1 + n_2 = 1 \qquad [8]$$

where $\tau_{1,2}$ are the lifetimes of levels 1 and 2, k is the up-conversion transfer rate, β_{21} is the branching ratio for the $2 \rightarrow 1$ transition, and W is the pump rate (not shown in Figure 1).

Sequential Two-Photon Absorption

Pumping the ground state of a luminescent ion (Figure 2a) with a wave at angular frequency ω, leads to population with density n_1 of an excited state in a first step. Because the rare earth ions have numerous energy levels, it is possible for the pump to also be resonant with the transition from level 1 towards a higher energy level 2, and is further absorbed. Such a process leading to n_2 up-conversion population is a sequential two-photon absorption. If there is no $1 \rightarrow 2$ resonant transition for the ω frequency, it is possible to use a second pump wave at a different angular frequency ω' resonant with the $1 \rightarrow 2$ transition (Figure 2b). Of course, in practice, it is advantageous when a single pump beam is required for up conversion.

Let us show the relevant terms of the rate equation analysis describing the process in Figure 2a:

$$\frac{dn_1}{dt} = -\frac{n_1}{\tau_1} + I\sigma_0 n_0 - I\sigma_1 n_1 + \frac{\beta_{21}}{\tau_2}n_2 \qquad [9]$$

$$\frac{dn_2}{dt} = -\frac{n_2}{\tau_2} + I\sigma_1 n_1 \qquad [10]$$

$$n_0 + n_1 + n_2 = 1 \qquad [11]$$

where I is the photon density of the pump (photons $s^{-1}\,cm^{-2}$) and σ_0 and σ_1 are the absorption cross-sections (cm^2) of the $0 \rightarrow 1$ and $1 \rightarrow 2$ transitions, respectively. The n_2 population density shows a nonlinear I dependence, most often close to I^2.

Photon Avalanche

In rare earth doped materials, an up-conversion emission, intense enough for visible lasing, can result from a more complex mechanism. In this case, absorption of the pump is not resonant with a transition from the ground state (weak ground-state absorption), but on the contrary, the photon pump energy matches the gap between two excited states (high excited state absorption). These levels are labeled 1 and 2 in Figure 3. Level 1 generally has a rather long lifetime in order to accumulate

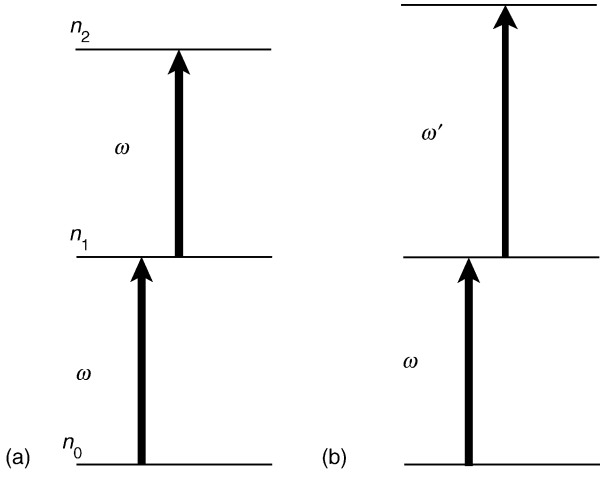

Figure 2 Two-photon absorption up-conversion.

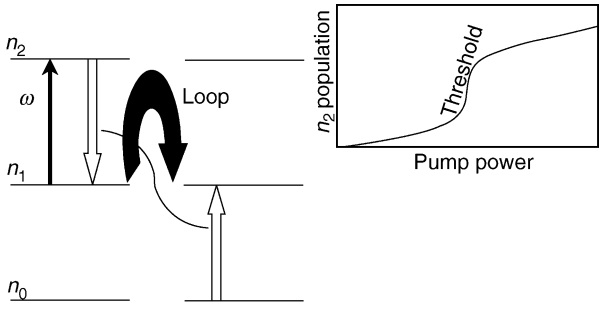

Figure 3 Photon avalanche up-conversion.

population and level 2 is the initial up-conversion laser level. When the pump light is turned on, the populations of levels 1 and 2 first grow slowly, and then can accelerate exponentially. This is generally referred to as 'photon avalanche'. The term 'looping mechanism' also applies, because we can see in Figure 3 that the excited state absorption $1 \rightarrow 2$ is followed by a cross-relaxation energy transfer (quantum efficiency up to two) that returns the system back to level 1. So after one loop, the n_1 population density has been amplified, and is further increased after successive loops. This pumping scheme was discovered in 1979, with $LaCl_3:Pr^{3+}$ crystal used as an infrared photon counter.

The rate equation analysis applied to the three-level system in Figure 3 leads to the following time evolutions:

$$\frac{dn_1}{dt} = -\frac{n_1}{\tau_1} + I\sigma_0 n_0 - I\sigma_1 n_1 + \frac{\beta_{21}}{\tau_2} n_2 + 2kn_0 n_2 \qquad [12]$$

$$\frac{dn_2}{dt} = -\frac{n_2}{\tau_2} + I\sigma_1 n_1 - kn_0 n_2 \qquad [13]$$

$$n_0 + n_1 + n_2 = 1 \qquad [14]$$

where the parameters have the same meaning as in eqns [6]–[11].

The steady state limit of the populations at infinite time, upon continuous excitation starting at $t = 0$, can be obtained from canceling the time derivative in the left-hand side of the equation. Let us point out the interesting result. Two different dynamical regimes and analytical expressions for $n_2(\infty)$ are obtained. In the usual case of low pumping rate in the ground state and if the parameters of the systems satisfy: $k < \frac{1-\beta_{21}}{\tau_2}$, then the first regime is observed, whatever the pumping rate $I\sigma_1$ in the excited state.

If the parameters satisfy:

$$k > \frac{1 - \beta_{21}}{\tau_2} \qquad [15]$$

the first regime is still observed at low pumping rate $I\sigma_1$ in the excited state, more precisely at pumping rate low enough such that

$$I\sigma_1 < \frac{\left(k + \frac{1}{\tau_2}\right)\frac{1}{\tau_1}}{k - \frac{(1 - b_{21})}{\tau_2}}$$

But interestingly, the second regime, the so-called photon avalanche, is obtained at high pumping rate $I\sigma_1$ in the excited state, that is to say if:

$$I\sigma_1 > \frac{\left(k + \frac{1}{\tau_2}\right)\frac{1}{\tau_1}}{k - \frac{(1 - b_{21})}{\tau_2}} \qquad [16]$$

So the right-hand side of eqn [16] appears to be a pump threshold separating two dynamical regimes when the condition in eqn [15] is satisfied, as the insert in Figure 3 shows.

Another way to distinguish between the two regimes is given by linearization of the system of eqns [12]–[14] ($n_0 \cong 1$). Then the description will only be valid close to $t = 0$. We know from standard mathematical methods that the solutions of eqns [12]–[14] are then a combination of $\exp(\alpha t)$ terms. If the threshold condition in eqn [16] is satisfied, a parameter α in the combination becomes positive, so the population of level 2 increases exponentially (photon avalanche) at early times and the dynamics of the system is unstable.

The physical meaning of eqns [15] and [16] is clarified by introducing the yield η_{CR} of the cross-relaxation process:

$$\eta_{CR} = \frac{k}{k + 1/\tau_2} \qquad [17]$$

and the yield η of the $2 \rightarrow 1$ de-excitation:

$$\eta = \frac{b_{21}/\tau_2}{k + 1/\tau_2} \qquad [18]$$

Then, the threshold condition in eqn [16] can be written as:

$$\left(\frac{I\sigma_1}{I\sigma_1 + 1/\tau_1}\right)(2\eta_{CR} + \eta) > 1 \qquad [19]$$

Starting with one ion in level 1, the first parenthesis in eqn [19] is the yield with which it will be promoted to level 2, and the second parenthesis is the yield of the backward path $2 \rightarrow 1$. So, the left-hand side of eqn [19] is the new number of ions after a looping path $1 \rightarrow 2 \rightarrow 1$, which has to be higher than 1 for the avalanche to occur. If we consider a lot of successive loops, the origin of the exponential behavior is clear. The role of the first ion in level 1 (and the weak pumping rate in the ground state $I\sigma_0$) is limited to initialize the process. Note that the value of the first parenthesis in eqn [19] is less than 1, so the second parenthesis has to be higher than 1. This condition is equivalent to eqn [15].

Materials: The Energy Gap Law

As we can see from the above mechanisms, up conversion needs intermediate energy levels and is not efficient if these cannot accumulate populations due to a short lifetime. The spontaneous rate of de-excitation of an electronic level is the sum of a radiative part W^{rad} and of a nonradiative part W^{nrad}. The radiative part can be obtained through the absorption cross-section corresponding to the transition or from the Judd–Ofelt theory which also exploits the absorption spectrum. The nonradiative rate is then obtained by subtracting W^{rad} from the measured fluorescence decay rate of the level. Based on the measurements in many hosts for the different trivalent rare earth ions, at different temperatures, the nonradiative decay rate of a J-level towards the next lower J′-level was found to have the form:

$$W_{\mathrm{JJ'}}^{\mathrm{nrad}} = B\exp(-\beta\Delta E_{\mathrm{JJ'}})\left(1-\exp\left(-\frac{\omega_{\max}}{kT}\right)\right)^{-p} \quad [20]$$

where $\Delta E_{\mathrm{JJ'}}$ is the energy gap between the two levels, $p = \Delta E_{\mathrm{JJ'}}/\omega_{\max}$, $\omega_{\max}$ being the energy of an effective optical phonon of the host. The values of B, β and $\omega_{\max}$ are found by fitting with experimental data. An example of such a fit is represented in Figure 4.

Equation [20] is the well-known and familiar 'energy gap law'. We have represented it for several oxide and nonoxide hosts at $T = 300$ K in Figure 5. It is clear that chloride, bromide, fluoride will be favorable hosts for up conversion due to their low phonon energy ($LaBr_3$: $\omega_{\max} = 175\ \mathrm{cm}^{-1}$, $LiYF_4$: $\omega_{\max} = 400\ \mathrm{cm}^{-1}$, $Y_3Al_5O_{12}$: $\omega_{\max} = 700\ \mathrm{cm}^{-1}$, silicate glass: $\omega_{\max} = 1100\ \mathrm{cm}^{-1}$). Let us mention also a fluorozirconate glass, ZBLAN, widely used in up-conversion fiber lasers.

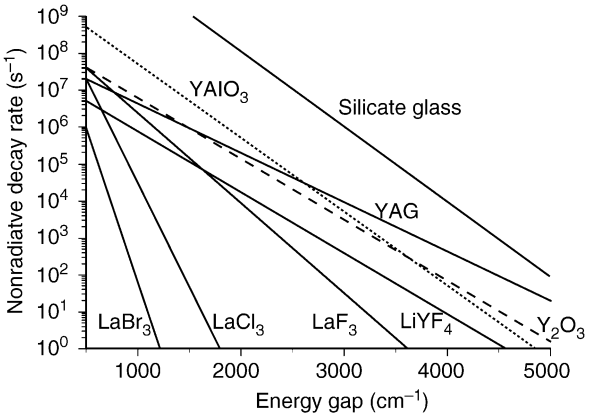

Figure 5 Energy-gap law for different hosts at 300 K.

Up-Conversion from Second-Order Optical Nonlinearity

The inter-atomic electric field acting on the electrons inside a medium has a magnitude of $\sim 10^8$ V/cm and derives from a potential that is anharmonic. The electric field **E** of an electromagnetic wave propagating through the medium drives the electrons beyond the quadratic region of the potential in the case of high **E**. So, the electron response and the associated polarization **P** take the form of a function of **E**:

$$\mathbf{P}(\mathbf{E}) = \varepsilon_0(\chi^{(1)}:\mathbf{E} + \chi^{(2)}:\mathbf{E}^2 + \chi^{(3)}:\mathbf{E}^3 + \cdots) \quad [21]$$

The different terms in eqn [21] are responsible for many optical phenomena because in Maxwell electromagnetic theory, the polarization is the source of the waves. We have selected in Table 1 the terms relevant for linear effects and for the purpose of frequency up conversions: second-harmonic generation (SHG) and sum-frequency mixing, due to second-order terms. It should be noticed that the latter have a nonzero value only in noncentrosymmetric materials.

Figure 6 visualizes the up conversion from SHG: two photons of the fundamental field at angular frequency ω_1 are annihilated while one photon at twice the angular frequency is created. A similar picture could be drawn for sum-frequency up conversion: SHG is the degenerate case where $\omega_1 = \omega_2$.

The second-order nonlinear processes have an efficiency given by an effective coefficient d_{eff} given hereafter:

$$d_{\mathrm{eff}} = \sum_{ijk} e_i(\omega_3)d_{ijk}e_j(\omega_1)e_k(\omega_2) \quad [22]$$

where $e_i(\omega_l)$ is the ith component of the unit vector of the electric field of the wave l at angular frequency ω_l and $d_{ijk} = (1/2)\chi_{ijk}$.

Table 1 Relevant terms for frequency up-conversion

Optical process	*Term*	*New wave*
Linear		
Refractive index, absorption, stimulated emission	$\chi^{(1)}(-\omega;\omega)$	
Second order nonlinear		
Second harmonic generation	$\chi^{(2)}(-\omega_3;\omega_1,\omega_1)$	$\omega_3 = 2\omega_1$
Sum-frequency mixing	$\chi^{(2)}(-\omega_3;\omega_1, \pm\omega_2)$	$\omega_3 = \omega_1 + \omega_2$

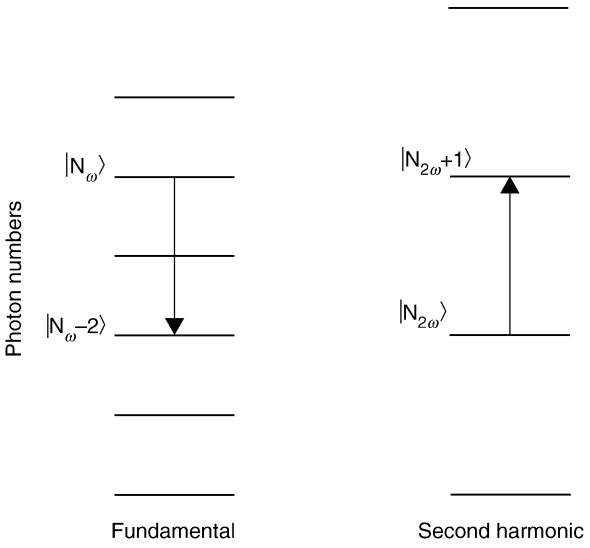

Figure 6 Up-conversion from second harmonic generation.

Moreover, the wave propagation equations in the slow varying envelope approximation, given hereafter for the E_3 electric field of the sum-frequency mixing wave:

$$\frac{dE_3}{dz} = \frac{i\omega_3 d_{eff}}{n_3 c} E_1 E_2 \quad \exp(i(k_1 + k_2 - k_3)z) \qquad [23]$$

$$(\text{with } k_j = \omega_j n_j / c)$$

impose that the frequency conversion is efficient in practice, only if the following phase matching condition is satisfied:

$$\omega_1 n_1 \uparrow (\theta, \varphi) + \omega_2 n_2 \uparrow (\theta, \varphi) = \omega_3 n_3 \downarrow (\theta, \varphi) \qquad [24]$$

where $n_i \uparrow$ and $n_i \downarrow$ are respectively the upper and lower refractive index in the direction of propagation (θ, φ) (n_i in eqn [23] are the same with a simplified notation). Equation [24] is restricted here for simplicity to collinear type I (waves 1 and 2 and the same polarization) and is the expression of photon momentum conservation. It is usually achieved from the birefringence of the crystals. When this is not possible, another technique can be used, namely quasi-phase matching, which involves reversing periodically the sign of the nonlinear optical coefficient.

In bifunctional crystals, the laser effect and the $\chi^{(2)}$ interaction occur simultaneously inside the same crystal. In the case of the self-frequency doubling laser, the angular frequency $\omega_1 = \omega_2$ in eqn [24] is that of the fundamental laser wave. In the case of the self-sum frequency mixing laser, ω_1 corresponds to the fundamental laser wave and ω_2 to the pump wave. As we can see from eqns [22]–[24], the polarization of the laser emission is crucial in order for the device to work. So, the laser stimulated emission cross-section σ for propagation in the phase matching direction (θ, ϕ) in the adequate polarization has to be evaluated. This can be performed with the formula:

$$\sigma(\theta, \varphi) = \frac{\sigma_X \sigma_Y \sigma_Z}{\sqrt{\sigma_Y^2 \sigma_Z^2 e_X^2 + \sigma_X^2 \sigma_Z^2 e_Y^2 + \sigma_X^2 \sigma_Y^2 e_Z^2}} \qquad [25]$$

where $\sigma_{X,Y,Z}$ are the emission cross-sections for X, Y, Z-polarizations and $e_{X,Y,Z}$ are the components of the unit vector or the electric field of the laser wave.

To summarize, the conditions necessary for a crystal to be a bi-functional material are: (i) it must be noncentrosymmetric; (ii) it must accept fluorescent doping (usually with Nd^{3+} or Yb^{3+}); and (iii) it must be phase matchable for its laser emission. In practice, only a few crystals satisfy these requirements and have been tried with some success. The main ones are $LiNbO_3$, $LaBGeO_5$, $Ba_2NaNb_5O_{15}$, β'-$Gd_2(MoO_4)_3$, $YAl_3(BO_3)_4$, $GdAl_3(BO_3)_4$, $CaY_4(BO_3)_3O$, and $CaGd_4(BO_3)_3O$.

Up-Conversion Lasers Based on Luminescence Mechanisms in Materials

Energy Transfers

Up-conversion lasers from energy transfers have the advantage of using a single pump laser. This latter populates firstly a long-lived intermediate level. A typical example, based on $LiYF_4$:Er^{3+} crystal, is provided by Figure 7.

The pump at 802 nm from a GaAlAs diode laser, or at 969 nm, populates efficiently at the 8 ms lifetime $^4I_{11/2}$ level. The green laser, at 551 nm, corresponds to the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition and it can be shown that energy transfer is an essential part of the mechanism by stopping abruptly the pump laser: green lasing continues to occur for several hundred microseconds because the $^4S_{3/2}$ level is still fed (an excited-state

absorption would stop immediately). The involved energy transfer is:

$$^4I_{11/2} + {}^4I_{11/2} \rightarrow {}^4F_{7/2} + {}^4I_{15/2} \qquad [26]$$

and leads to a 20 mW laser threshold and 2.3 mW green output power at 50 K temperature upon 95 mW of incident power.

By using mirrors with high transmission in the green range but having high reflectivity at blue wavelengths, blue laser emission at 470 nm can be sustained, corresponding to the $^2P_{3/2} \rightarrow {}^4I_{11/2}$ transition. It originates from a mechanism involving three up-conversion energy transfers:

$$^4I_{11/2} + {}^4I_{11/2} \rightarrow {}^4F_{7/2} + {}^4I_{15/2}$$
$$^4I_{11/2} + {}^4I_{13/2} \rightarrow {}^4F_{9/2} + {}^4I_{15/2} \qquad [27]$$
$$^4S_{3/2} + {}^4F_{9/2} \rightarrow {}^4I_{15/2} + {}^2K_{13/2}$$

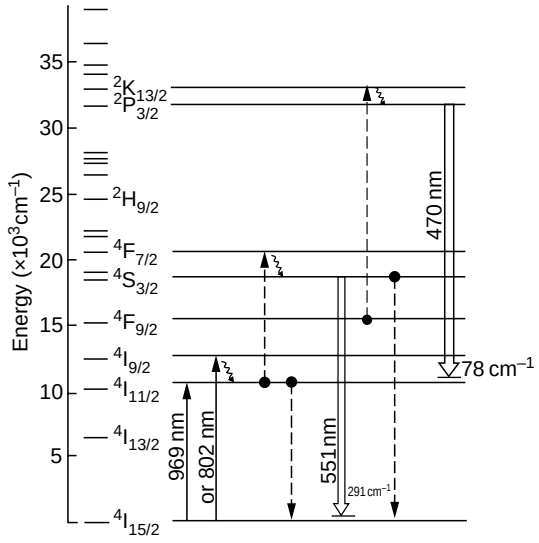

Figure 7 Energy level diagram of $LiYF_4:Er^{3+}$. The dashed lines indicate the energy transfers responsible for the green and blue up-conversion lasing. Reproduced with permission of American Institute of Physics from Macfarlane RM, Tong F, Silversmith AJ and Lenth W (1988) Violet CW neodymium upconversion lasers. *Applied Physics Letters* 52(16): 1300.

The illustration in Figure 7 shows up-conversion energy transfers between ions of the same chemical species, but co-doping the laser host with two ions of different chemical species provides the opportunity of separating their roles: one species is devoted to pump absorption (this is the sensitizer) and the other one is devoted to lasing (this is the activator). Due to the development of efficient semiconductor InGaAs diodes emitting near 980 nm, the most widely used sensitizer is Yb^{3+}. Table 2 provides a list of several up-conversion lasers based on energy transfer mechanisms, operating at room temperature. We can see that among the most efficient lasers, are those based on rare-earth ions doped glass fibers. The reason is that in fibers, the pump and laser waves remain confined inside a core (typically 5 μm diameter) and have high energy densities over a long length (tenths of cms), which is favorable for all up-conversion mechanisms.

Sequential Two-Photon Absorption

An example of an up-conversion laser pumped by a two-photon absorption mechanism is represented in Figure 8. The material is $LaF_3:Nd^{3+}$ and violet lasing at 380 nm corresponds to the $^4D_{3/2} \rightarrow {}^4I_{11/2}$ transition.

Transition from the ground state up to the $^4F_{5/2}$ level is firstly obtained from an infrared beam at 790 nm in order to feed the $^4F_{3/2}$ intermediate level after a fast nonradiative de-excitation. The $^4F_{3/2}$ level has a rather long lifetime: 700 μs, so it accumulates

enough population that a second yellow pumping at 591 nm (Figure 8a) can efficiently populate the $^4D_{3/2}$ initial laser level. With 110 mW of infrared pump and 300 mW of yellow pump, 12 mW of violet output were obtained at 20 K temperature.

A simpler device is obtained if a single-pump beam is used. This is the case in Figure 8b, where a yellow pump at 578 nm provides both ground state and excited state absorption. This doubly resonant scheme is less efficient in LaF_3:Nd^{3+} than the previous one but in Figure 9, we show another example: $LiYF_4$:Er^{3+}, working at room temperature. The lasing $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition at 551 nm delivers 20 mW upon 1600 mW pumping at 974 nm.

The simplified Er^{3+} level scheme of Figure 9 contains four main levels with population densities: $n_0 = [{}^4I_{15/2}]$, $n_1 = [{}^4I_{13/2}]$, $n_2 = [{}^4I_{11/2}]$, $n_3 = [{}^4S_{3/2}]$. The rate equations of populations of this system can

be written and solved because all the implied parameters (lifetimes, branching ratios, ground, and excited states absorption cross-sections) have been measured in this material. Predictive models of the up-conversion green laser are successful, matching experimental measurements, and confirm that the doubly resonant mechanism is realistic at low doping concentration.

Table 3 summarizes the performances of the main up-conversion lasers based on sequential photon absorption and working at room temperature.

Photon Avalanche

Photon avalanche up-conversion was observed mainly in Nd^{3+}, Tm^{3+}, Er^{3+}, and Pr^{3+} doped materials. As an illustration of this mechanism, let us consider the case of the continuous wave Pr^{3+}–Yb^{3+}-doped fluorozirconate fiber laser (3000 ppm Pr, 20 000 ppm Yb). With two Ti:sapphire pump lasers operating at 852 and 826 nm (Figure 10), an output power at 635 nm as high as 1.02 W was obtained with an incident pump power of 5.51 W (19% slope efficiency).

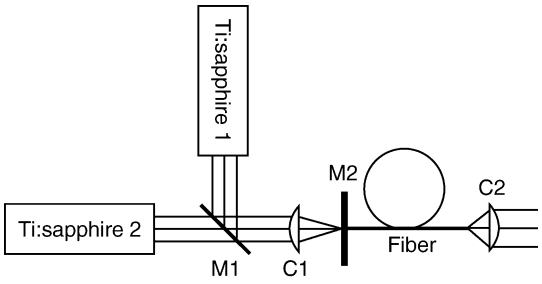

Figure 10 Experimental set-up for Yb–Pr-doped fiber up-conversion laser. M1: dichroic mirror, C1, C2: lenses, M2 dichroic input mirror. Reproduced with permission of Optical Society of America from Sandrock T, Scheife H, Heumann E and Huber G (1997) High power continuous wave up-conversion fiber laser at room temperature. *Optics Letters* 22(11): 809.

This remarkable result can be explained quantitatively by modeling the photon avalanche with a five-level diagram and restricted in Figure 11 to a single laser pump at 850 nm. The laser emission corresponds to the $^3P_0 \rightarrow {}^3F_2$ transition. The five relevant levels have the population densities: $n_0 = [{}^3H_4(Pr)]$, $n_1 = [{}^1G_4(Pr)]$, $n_2 = [{}^3P_0(Pr)]$, $n_3 = [{}^2F_{7/2}(Yb)]$, $n_4 = [{}^2F_{5/2}(Yb)]$.

The two components of the mechanism are:

(i) the excited state absorption of the pump by the spin allowed transition: $^1G_4 \rightarrow {}^1I_6$
(ii) the process leading to the doubling of the $^1G_4$ population, in this instance through two energy transfers:

$$\begin{aligned} {}^1I_6(Pr) + {}^2F_{7/2}(Yb) &\rightarrow {}^1G_4(Pr) + {}^2F_{5/2}(Yb) \\ {}^2F_{5/2}(Yb) + {}^3H_4(Pr) &\rightarrow {}^2F_{7/2}(Yb) + {}^1G_4(Pr) \end{aligned} \quad [28]$$

The rate equation analysis predicts that the avalanche threshold occurs at about 1 W pump and the long fluorescence rise time is somewhat shortened at higher pump power, as observed experimentally.

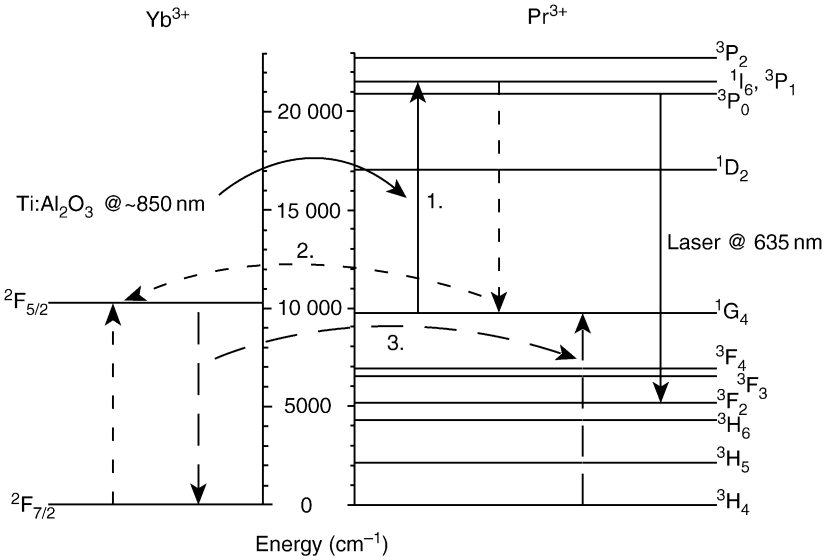

Figure 11 Energy level diagram of fluorozirconate: Yb^{3+}:Pr^{3+} fiber. The dashed lines indicate the energy transfers. Reproduced with permission of the Optical Society of America from Sandrock T, Scheife H, Heumann E and Huber G (1997) High power continuous wave up-conversion fiber laser at room temperature. *Optics Letters* 22(11): 809.

Table 4 Main room temperature up-conversion lasers operating from photon avalanche

Laser material	*Laser wavelength (nm)*	*Pump wavelength (nm)*	*Output power*
BaY_2F_8:Yb:Pr	607.5	822	55 mW
BaY_2F_8:Yb:Pr	638.7	841	26 mW
$LiY_{0.89}Yb_{0.1}Pr_{0.01}F_4$	720	830	1%
$LiY_{0.89}Yb_{0.1}Pr_{0.01}F_4$	639.5	830	
Fiber:Yb:Pr	635–637	780–880	300 mW
Fiber:Yb:Pr	605–622	780–880	44 mW
Fiber:Yb:Pr	517–540	780–820	20 mW
Fiber:Yb:Pr	491–493	780–880	4 mW
Fiber:Yb:Pr	635	850	1.02 W
Fiber:Yb:Pr	635	850	2.06 W
Fiber:Yb:Pr	520	850	0.3 W

Table 4 summarizes the performances of the main up-conversion lasers based on photon avalanche mechanisms.

Up-Conversion Lasers Based on Bi-Functional Crystals

The laser stimulated emission in a bi-functional crystal was first obtained in 1969 with Tm^{3+} in $LiNbO_3$ but the most used ion is, of course, Nd^{3+} working in the two channels:

$$^4F_{3/2} \rightarrow {}^4I_{11/2} \qquad [29]$$

$$^4F_{3/2} \rightarrow {}^4I_{13/2} \qquad [30]$$

and more recently Yb^{3+} working in the channel:

$$^2F_{5/2} \rightarrow {}^2F_{7/2} \qquad [31]$$

Channels in eqns [29] and [31] operate around 1060 nm wavelength and the channel in eqn [30] near 1338 nm.

The Self-Frequency Doubling Laser

A typical laser scheme is shown in Figure 12.

Table 5 Main results of Nd^{3+} and Yb^{3+} green self-frequency doubling lasers near 530 nm (eqns [29] and [31])

Crystal	*Input power (mW)*	*Output power (mW)*	*Pumping*
$LiNbO_3$:MgO:Nd	215	1	Dye laser
$YAl_3(BO_3)_4$:Nd	870	10	Laser diode
$YAl_3(BO_3)_4$:Nd	280	3	Laser diode
$YAl_3(BO_3)_4$:Nd	400	69	Laser diode
$YAl_3(BO_3)_4$:Nd	1380	51	Laser diode
$YAl_3(BO_3)_4$:Nd	369	35	Laser diode
$LiNbO_3$:MgO:Nd	850	18	Dye laser
$LiNbO_3$:Sc_2O_3:Nd	65	0.14	Ti:sapphire laser
$LiNbO_3$:MgO:Nd	100	0.2	Laser diode
$YAl_3(BO_3)_4$:Nd	1600	225	Laser diode
$YAl_3(BO_3)_4$:Nd	2200	450	Ti:sapphire laser
$(Y,Lu)Al_3(BO_3)_4$:Nd	880	24	Laser diode
$LiNbO_3$:ZnO:Nd	430	0.65	Ti:sapphire laser
$Ba_2NaNb_5O_{15}$:Nd	270	46	Ti:sapphire laser
$CaY_4(BO_3)_3O$:Nd	900	62	Laser diode
$CaGd_4(BO_3)_3O$:Nd	1600	192	Ti:sapphire laser
$CaGd_4(BO_3)_3O$:Nd	1250	115	Laser diode
$CaGd_4(BO_3)_3O$:Nd	1560	225	Ti:sapphire laser
$YAl_3(BO_3)_4$:Yb	11 000	1100	Laser diode
$GdAl_3(BO_3)_4$:Nd	2.8 mJ/pulse	0.12 mJ/pulse	Pulsed dye laser

The laser beam cannot escape from the cavity and dichroic mirrors are used. The input mirror has high transmission at the pump wavelength and is highly reflective at laser- and second-harmonic wavelengths. The output mirror is highly reflective at laser wavelength and has high transmission for second harmonic. Channels in eqns [29] and [31] generate green light near 530 nm and the channel in eqn [30] generates red light near 669 nm.

The most exploited bi-functional crystal is $YAl_3(BO_3)_4$:Nd^{3+}, well-known as NYAB. It is a negative uniaxial trigonal crystal (extraordinary index lower than the ordinary one) and its laser emission is easily observed in ordinary polarization with a high cross-section: 2×10^{-19} cm^2 at 1063 nm. Type I phase matching occurs at a polar angle $\theta = 30.7°$ and 26.8° for channels in eqns [29] and [30] respectively. The effective nonlinear optical coefficient d_{eff} is close to 1.4 pm V^{-1} at azimuthal angle $\phi = 0°$.

The Yb^{3+} ion has some advantages over the Nd^{3+} ion due to its very simple energy level scheme: there is no excited state absorption at the laser wavelength, no up-conversion losses, no concentration quenching, and no absorption in the green. The small Stokes shift between pump and laser emission reduces the thermal loading of the material during laser operation. A self-doubling laser based on $YAl_3(BO_3)_4$:Yb^{3+} of crystal has produced 1.1 W green power upon 11 W diode pumping.

The drawback of $YAl_3(BO_3)_4$ is that it is rather difficult to grow because it is not congruent. This difficulty was overcome by the discovery at Ecole Nationale Supérieure de Chimie de Paris of the rare-earth calcium oxoborate $CaGd_4(BO_3)_3O$ which can be grown to a large size by the Czokhralski method. It is a monoclinic biaxial crystal and doped with Nd^{3+}, it was firstly exploited (channel in eqn [29]) in the XY principal plane at $\theta = 90°$, $\phi = 46°$ with ($d_{eff} = 0.5$ pm V^{-1}). It was soon recognized that the optimum phase matching direction ($d_{eff} = 1.68$ pm × V^{-1}) occurred out of the principal planes, in the direction $\theta = 66.8°$, $\phi = 132.6°$, and high green power can be obtained: 225 mW under 1.56 W pump.

Table 5 summarizes the main self-frequency doubling results obtained with the channel in eqn [29].

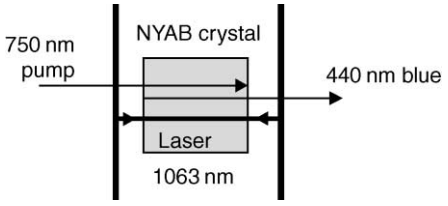

Figure 13 Scheme of a self-sum frequency mixing laser. Note that in reality the three beams are superimposed.

The Self-Sum Frequency Mixing Laser

The example in Figure 13 gives the main features of such a laser. The input mirror has high transmission at the pump wavelength and both mirrors are highly reflective at laser wavelength. The output mirror has high transmission at sum frequency mixing wavelength.

The laser wave at angular frequency ω_1 in Table 1 corresponds to the channel in eqns [29] or [30] in the case of Nd^{3+}. The wave at angular frequency ω_2 in Table 1 has two different roles: first it excites the Nd^{3+} laser center and secondly its nonabsorbed part is up converted by the second-order nonlinear process. ω_2 (corresponding to the wavelength λ_2) is then chosen to match the main Nd^{3+} absorption lines:

$$\begin{aligned} &{}^4I_{9/2} \rightarrow {}^4G_{5/2} - {}^2G_{7/2}\ (\lambda_2 = 590\ \text{nm}) \\ &{}^4I_{9/2} \rightarrow {}^4F_{7/2} - {}^4S_{3/2}\ (\lambda_2 = 750\ \text{nm}) \\ &{}^4I_{9/2} \rightarrow {}^4F_{5/2} - {}^2H_{9/2}\ (\lambda = 800\ \text{nm}) \\ &{}^4I_{9/2} \rightarrow {}^4F_{3/2}\ (\lambda_2 = 880\ \text{nm}) \end{aligned} \qquad [32]$$

The most efficient self-frequency mixing lasers based on channels in eqns [29]–[31] are gathered in Table 6.

LASER-INDUCED DAMAGE OF OPTICAL MATERIALS

A J Glass and A H Guenther, The University of New Mexico, Albuquerque, NM, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Shortly after the invention of the laser, in the early 1960s, it became apparent that laser performance was limited by the ability of optical materials to withstand high energy and power densities. Broadly speaking, laser damage arises from two causes: (i) thermal effects, which are associated with high average power; and (ii) dielectric breakdown, which is associated with high values of the local electric field. Early researchers quickly recognized that most of the observed damage effects arose from extrinsic causes, such as impurities and inclusions in the bulk material, or particles or defects on exposed optical surfaces. At that time, optical materials had not been developed for high-power use, and lacked the quality needed for laser applications. In fact, in many situations, the laser provided the inspection light source used to assess the properties of the materials, such as absorption, defects, scattering centers, surface topography, and dynamic behavior. Thus, the field of laser damage studies was broadened to include many aspects of material preparation and characterization. At high-power densities, nonlinear effects become important, often limiting performance without creating any irreversible change in the material's properties. The most general definition of laser-induced damage includes all effects arising in optical materials and components that limit or degrade the performance of laser systems.

The pursuit of improved performance at high values of power and energy densities was motivated by several factors and applications. In general, improved tolerance to high flux and fluence leads to smaller, lighter, and more efficient systems. These are particularly important for military and energy applications. Since the 1970s, the laser fusion program alone has produced an extensive body of research on laser-induced damage in high-power nanosecond-scale systems, which has enabled orders of magnitude improvement in the damage resistance and extraction efficiency of glass lasers. More recently, with the development of fiber laser systems producing and transporting a kilowatt of average power in a fiber of less than 100 μm diameter, laser damage phenomena on an entirely different spatial scale have become important.

Since the early 1970s, the literature of laser damage research has been collected in a series of annual publications of the Boulder Damage Symposium, initiated by the authors of this article, which was first held in 1969. Recently the papers presented at the Damage Symposium in the years 1969 to 1998 were collected and published in CD form by the SPIE. A CD containing the proceedings of the next five years (1999–2003) will be released by SPIE this year. Also in the late 1960s, in the Soviet Union, Academician Aleksei Bonch-Bruevich launched a comprehensive research project on the nonresonant interaction of laser radiation with matter, opening up a new branch of photonics research, known in the Soviet Union as power optics. In 1969, he founded the All-Union Conference on Interaction of Optical Radiation with Matter (AURICOM), which was held every two to three years until 1990. After 1990, the conference was renamed Nonresonant Laser-Matter Interaction (NLMI), and chaired by Professor Mikhail Libenson. NLMI was held in St Petersburg in 1996, 2000, and

2003. The proceedings of the 1996 AURICOM and subsequent NLMI conferences have been published by the SPIE. We are saddened to note that Professor Libenson died in February 2004.

The Boulder Damage Symposium grew out of a one-day Symposium convened in Boulder in 1969 under the auspices of the ASTM Subcommittee on Lasers, to establish standards for laser materials. In their summary of the first Symposium, the conference organizers remarked:

> The entire question of the nature of the standards remains to be addressed. Should they take the form of energy density at which catastrophic damage is likely to occur, or should they be specified in terms of a mean number of shots at a given level of energy density before certain degradation of performance is measured? The latter would seem to express the kind of information that the buyer of laser materials would find most useful. Once a standard is agreed upon, a meaningful test configuration must be established. It is likely that this will be a well-controlled oscillator amplifier chain with the test specimen an active element of the system, but this is not certain. Another point to be determined is that of the accuracy to which its specifications should be written. This depends in part on the kind of quality control the producers of laser glass believe is feasible.

The questions raised in this first Symposium remain at the core of laser damage studies today. How do we define damage, in terms of the physical effect on the material or in terms of the degradation of performance of the system? How do we measure damage thresholds or values? How do we specify the properties and preparation of the sample, including the relevant experimental and material variables? How can we ensure that damage values are reproducible, unless we make the measurements in a very well controlled and characterized system? With what precision should damage levels be stated, in order to be useful? Extensive research was required in order to answer these questions, and to elucidate the fundamental nature of damage mechanisms. Many of the results of this research are documented in the 35 year record of the Boulder Damage Symposium and the corresponding Russian-based conferences.

From the beginning of this area of research, investigators devoted a significant effort to establishing the 'first causes' of damage phenomena. However, they quickly realized that in most cases, damage occurred at surfaces and material interfaces, or was mediated by impurities or inclusions in bulk materials. As material fabrication processes improved, and higher-quality materials became available, observed damage thresholds approached the intrinsic limits of the pure material. This was particularly true of silicate glass, metal reflectors, and in some cases, polymers. In fact, silicate glass has become one of the purest noncrystalline materials available in bulk quantities. However, for practical purposes, most laser systems are limited by damage at surfaces, coatings, or impurities. Impurities aggregate at grain boundaries in crystalline materials, and coalesce into inclusions in glasses, resulting in absorption, scattering, and field enhancement.

The coherent nature of laser light makes any scattering phenomena potentially damaging, because the scattered light interferes constructively with the laser beam, leading to the formation of intensity hot spots. Every interface in an optical system is potentially a source of constructive interference between the reflected and incident waves. Multilayer dielectric coatings are particularly vulnerable to damage, due to the presence of residual stress as well as field enhancement from Fresnel reflection. This has led to attempts to mitigate the problem by use of specific designs, such as avoiding AR coatings by using Brewster-angle surfaces, or use of nonquarter wave layers to move the peak field away from the vicinity of boundaries where impurities tend to collect. Other damage-sensitive design considerations can be found in the literature. Multiple reflections are the basis of photonic crystal optics, and applications of these devices to high-power density systems will undoubtedly be limited by field-enhanced damage phenomena.

In CW operation, of course, thermal effects dominate. They may be irreversible, creating permanent damage sites in the medium, or reversible, such as color centers that can be bleached out. As laser pulse durations vary from nanosecond to picosecond and femtosecond durations, the nature of the dominant damage mechanisms changes as well. As a rule of thumb, the scaling of damage thresholds as $\tau^{1/2}$, where τ is the pulse duration, was established empirically, and was found to be valid over a wide range of pulse durations. This scaling implies the presence of diffusion effects, either of heat or of electrons, in the vicinity of a damage center. As might be expected, this scaling does not apply for very short pulses (femtoseconds or less), where the extremely high field values can lead to instantaneous breakdown of the material.

Whether the damage is due to field enhancement or is impurity-mediated, it is difficult to establish a reproducible value for a damage threshold, unless the sample is macroscopic in extent, and the sampling laser beam is reproducibly of high spatial and temporal quality, preferably truly single-mode. Damage measurements on microscopic areas are unlikely to be representative of the entire sample. Damage will occur first at a point where the field is strongest or the material is weakest, and a sufficient

area must be tested to ensure that it includes such sites. Also, unless the beam quality of the laser used for testing is well controlled and well characterized, it will not be possible to reproduce the test results. It is equally important to characterize the samples, including their method of preparation, cleaning, and test environment. For damage research, as opposed to simple threshold testing, postmortem examination is also required, to elucidate the mechanism of the observed damage effect. However, we now have several techniques, such as photothermal deflection, that can provide useful pre-catastrophic indicators of the onset of laser damage, and thus are appropriate for quality control.

Professor Roger Wood had published a series of reviews and textbooks on laser damage in optical materials, which provide an overview of the field, with appropriate emphasis on measurement techniques, characterization of the test setup and sample, and implications for system design. He has also edited a collection of seminal publications in the field, published by the SPIE in 1990.

It is gratifying to those working in this field to observe how much of the research carried out to elucidate and, if possible, avoid the deleterious effects of laser damage has been applied to the constructive purpose of laser-assisted material processing and manufacturing. The introduction of low-cost, reliable femtosecond lasers has stimulated activity in this field, since it enables the experimenter to control to exquisite precision the power and energy deposited on a material. With femtosecond pulses, one can ablate material from the surface of an object while minimizing any collateral damage to the interior material. Surface layers of dirt can be removed from priceless art works such as oil paintings, without concern for damage to the object itself. Objects with arbitrary shape can be built up from metal particles, using laser additive manufacturing techniques. Thin films and photonic crystal structures can be created using laser-assisted deposition. Laser irradiation provides a power tool for surface cleaning, conditioning, and annealing. Laser interaction with materials and laser-assisted manufacturing techniques comprise a vital area of research in the materials science community.

In both the US and Russia, study of the interaction of intense coherent light with optical materials began with a disarmingly simple objective; to understand the fundamental mechanisms of interaction. In the review and summary of the 1969 ASTM Symposium, the editors wrote:

> In view of the number of problems remaining to be resolved, it is suggested that another Symposium on laser damage be held in 1970. Hopefully, at that time a better understanding of the nature of damage in laser glass will have been obtained. Higher threshold values will have been reproducibly achieved, and some agreement can be arrived at regarding useful and realistic standards.

Thirty-five years later, damage levels in optical materials have been significantly improved, and realistic and useful standards have been developed under the auspices of the International Organization for Standardization (ISO), and are now accepted globally. However, as the operating regimes of lasers have moved to femtosecond temporal scale and micrometer dimensions, new phenomena have arisen that require further research. An entirely new technology of laser-enabled manufacturing and materials conditioning has developed, based on the same physics as laser damage. Combining the disciplines of materials science and applied optics, the interaction of intense light with materials remains a scientifically challenging and economically important field of research.

Introduction

Short Historic Overview

During the second half of the nineteenth century, electric lighting became possible. In 1879, Edison demonstrated his incandescent lamp, and although some electric arc lamps competed with the incandescent lamp bulb for a few years, the first 50 years of electrical lighting was dominated by the incandescent lamp. Gas discharge lamps (both low- and high-pressure lamps) became more widely distributed only by the end of the third decade of the twentieth century, and widespread distribution of the fluorescent lamp, that still dominates our offices and many other lighting applications today, was generally accepted only after the Second World War.

The early incandescent lamps had an efficacy of a few lm/W, but by 1920 this could be increased by up to 10–15 lm/W. Gas discharge lamps started with approximately 30 lm/W, but by 1960 their efficacy increased to about 70 lm/W. Fluorescent lamps still provide only 70 to 100 lm/W; high-pressure lamp efficacy could be increased above this value. The different lamp types can be used, however, in different applications, depending on the size and the unit power of the lamp type. Nonincandescent light generation in solid-state materials dates back to the 1920s: a faint glow of a SiC crystal was observed when current passed through it at a point contact. In the 1930s, electroluminescence of ZnS powder layers was detected (Destriaux effect). By the mid-1960s, it became clear that by using the then available technology, good luminous efficiency could be expected only in III–V compounds (GaAs, GaP, and their ternary and quaternary compounds using Al, In, and N in the compounds). Pure GaAs has a bandgap in the infrared (IR), thus one can build good IR-emitters using this material, but no visible light emitter. However, GaAs proved to be an excellent coherent light-emitting material and enabled the construction of IR-emitting semiconductor lasers.

First visible light-emitting diodes were fabricated using a GaAsP alloy. Figure 1 shows how the efficacy of III–V compound LEDs can be increased by introducing new compositions, and later, new technologies and better light extraction techniques. In the figure we also show the efficacy values of average incandescent, high-pressure Hg- and fluorescent lamps. The first LEDs emitted in the red part of the spectrum, and only by 1975 was the green LED invented. By 1985, practically any color between red and green became possible, and the efficacy of these lamps reached a level where for monochromatic light applications, their efficacy could compete favorably with filtered incandescent light. LEDs emit in a relatively narrow wavelength band (20 nm–30 nm bandwidth), and if one has to filter from the continuous spectrum of an incandescent lamp such a narrowband, the loss becomes considerable. LEDs needed only a few volts to function and it became general practice to build LEDs with approximately a 20 mA current load. These LEDs became very popular for interior signaling (on instruments, household appliances, and in similar applications). The goal was, however, to be able to produce white light, but the blue-emitting LED was still missing. Only after 1990 could the problem of producing p–n junctions from GaN, that had a bandgap large enough to emit blue light, be solved. Different ternary and quaternary compounds, as shown in Figure 1, enabled efficacies comparable to incandescent lamp efficacy, and the race for producing white light began.

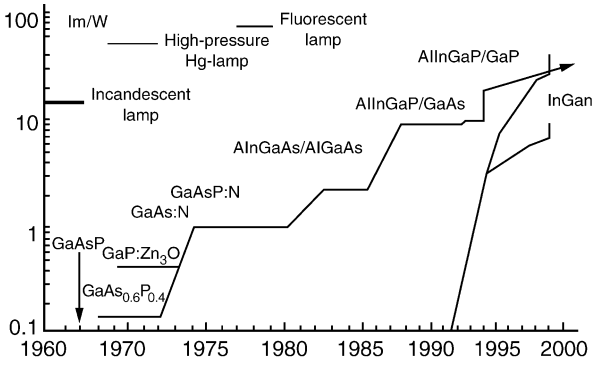

Figure 1 Increase of luminous efficacy of LEDs during the past 40 years. Courtesy of Lumileds Lighting.

Physical Fundamentals

Figure 2 shows a forward-biased p–n junction. As injected free electrons and holes are driven towards the junction, they can radiatively recombine, emitting a photon. The probability of photon emission versus nonradiative recombination will depend on the band

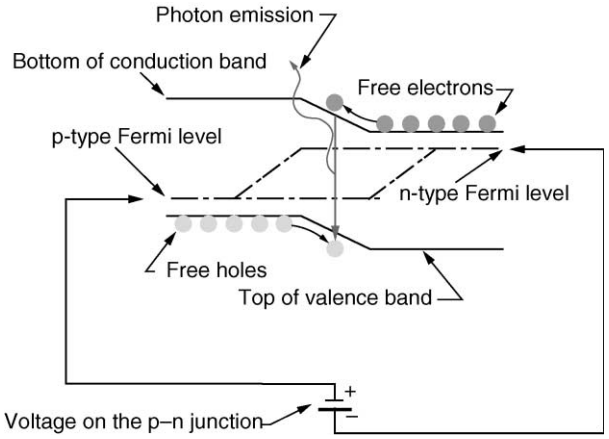

Figure 2 Forward biased p–n junction, light generation via recombination of free charge carriers.

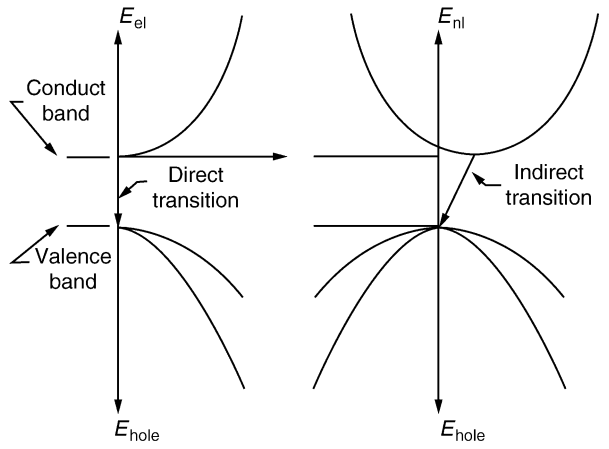

Figure 3 Band to band recombination in direct and indirect band semiconductor.

structure of the semiconductor. Figure 3 shows the two possibilities of a direct and an indirect bandgap semiconductor. GaAs is, for example, a direct bandgap material. In this material free electrons at the bottom of the conduction band can recombine with free holes at the top of the valence band, as the momentum of the two 'particles' is the same and a photon emission takes care of the principle of energy conservation. GaP is an indirect bandgap material where the momentum of the free electrons at the bottom of the conduction band differs from the momentum of the free holes at the top of the valence band, and thus the recombination needs not only the fulfilment of the conservation of energy, but also of momentum. Thus, besides photon emission, phonon emission or absorption has to take place. Thus, the probability of the transition will decrease and competing nonradiative processes will become important. Using N doping produces very shallow

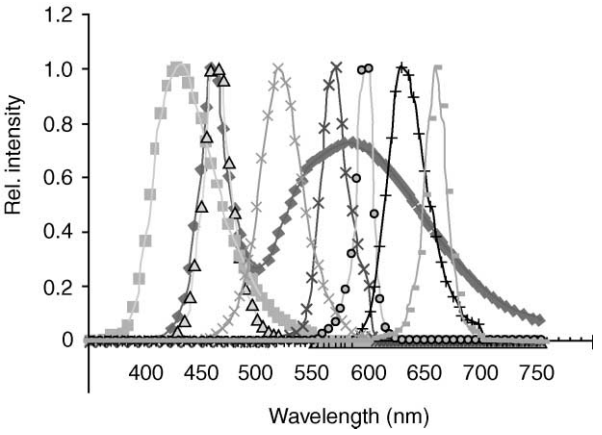

Figure 4 Relative spectral power distribution of some LED structures.

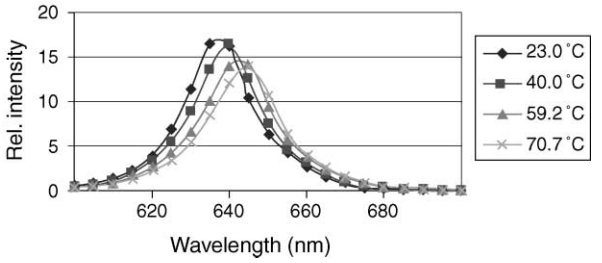

Figure 5 Spectral power distribution of a red LED at different temperatures.

donor states and from these an efficient recombination can take place. This enabled the production of early relatively efficient green-emitting LEDs.

GaN is ideal for producing LEDs, as it is a direct gap material and has a high bandgap. The technological difficulties are, however, enormous. Modern high-efficiency LEDs use (Al)InGaN-based materials for shorter wavelength LEDs, and AlInGaP-based materials for longer wavelength LEDs. Figure 4 shows a number of LED spectra of different wavelengths including a white LED. Its spectrum consists of a blue maximum produced by the LED emission and a yellow broader band produced by the luminescent material excited by the blue emission of the LED.

LEDs are semiconductor materials, and as with every semiconductor the LED characteristics are also temperature dependent. Not only the efficiency of the current carrier–photon emission process depends on the temperature, but the bandgap of the base material also depends on the temperature, and thus both the efficacy and the relative spectral distribution of the emission change with temperature. Figure 5 shows the spectral power distribution of a red LED at different temperatures.

Modern High Brightness LEDs

Besides the high quantum efficiency of the semiconductor junction, two further requirements to achieve high luminous efficacy are the efficient light extraction from the junction and keeping the temperature of the semiconductor chip low.

All semiconductors for producing LEDs have a high refractive index, thus light reflection at the semiconductor–air interface is relatively high, and for obliquely impinging rays the critical angle for total internal reflection is soon reached. Different manufacturers shaped the semiconductor chip in different forms to secure maximum light extraction. Figure 6 shows the cross-section of an LED, where the side planes have been cut obliquely to secure good light extraction.

The other problem that has to be solved is good heat conduction from the chip to a heat sink. At the time of writing, highest single chip power loads were in the order of 5 W. The structure of such a construction is seen in Figure 7. The GaN-based LED is grown on a visible light transparent sapphire (Al_2O_3) substrate. In modern LEDs the structure itself is quite complicated; in the vicinity of the p–n junction some nanometer thick layers are deposited forming quantum wells (QW(s)). The p-type original upper layer is metalized and soldered to the submount serving as heat-sink. The n-type layer gets a second soldered heat conducting current leading to the submount. As seen, the original structure grown on the sapphire substrate is inverted, and now the light can be extracted through the sapphire layer. The metalization on the p-type layer serves at the same time as a mirror. High brightness LEDs are now available in package sizes of over 100 lumen.

White LED Structures

The advantages of LEDs (low drive voltage, extreme long lifetime of 50000 to 100000 hours, robust shock-resistant construction) can open up a new era of lighting engineering, if white light emission can be obtained. The LED structure in itself is a narrowband emitter, thus – with inorganic LEDs – it is not possible to produce white light within one chip. Organic LEDs (OLEDs) promise the production of broadband and white light emission, but these are still in an experimental phase. At present they are used in smaller, portable displays, such as those used on portable phones, cam-coders, etc. To get further information, go to the Further Reading section at the end of this article.

At present three techniques to generate white light get thorough investigation: first, mixing the light of a red, a green, and a blue LED. This should theoretically give the highest efficiency; the problem is, however, that the three LEDs have different temperature dependence and aging characteristics, and thus it is difficult to keep the chromaticity of the mixed color constant (the three colored LEDs can be used in LED-based displays to produce full-color reproduction). At present the following technique is widely used. A blue LED excites a yellow phosphor, so that the mixture of the blue and yellow lights produce a white appearance. The color rendering of such white LEDs is not too good, and therefore alternative techniques using a green and a red phosphor are receiving increasing attention. The third method uses the same principle, but with an LED emitting in the near ultraviolet. This has the advantage that it provides a greater selection of phosphors, but as the energy difference between the UV photon and the photon emitted by the phosphor is larger than in the case of a blue-emitting LED, the theoretical efficiency is lower.

The phosphor layer is deposited on the chip surface, and for blue-emitting diodes special care has to be taken that the LED light and the phosphor

light are properly mixed so that the emitted light shows no directional color shift. Early white LEDs suffered much from the fact that the spectral distribution of the light changed considerably with viewing angle.

The problems with phosphor-coated white LEDs are how a suitable correlated color temperature and color rendering can be obtained. Early white LEDs had very bluish chromaticity, their correlated color temperature was very high, above 7000 K. Preferred white light has different chromaticity in different cultural regions, in the Far East 6000 K to 6500 K is preferred, in Europe and North America for general lighting a correlated color temperature of 4000 K is well accepted and for social and home lighting even lower correlated color temperatures, 2800 K to 3200 K are preferred. Recently, white LEDs based on blue chips and special phosphor blends have been produced that meet these requirements.

A further problem is the color rendering of the white LEDs. The Commission Internationale d'Eclairage (CIE), the International Commission on Illumination, provides standards, recommendations, and technical reports in the field of light and lighting, including vision, color, and image processing. Photometry and colorimetry are based on the standards and recommendations of the CIE.

The CIE established a method of calculating a color-rendering index in 1965 and updated it in 1974. Despite several attempts, the lighting community has been unable to agree on a revision of this outdated document since the 1970s. Thus, color-rendering indices are still calculated based on this method, although several investigations have shown that the calculated indices do not correspond with the visual observation. CIE, therefore, established a technical committee (TC) dealing only with the question of LED color rendering. It is hoped that this TC will be able to come up with some recommendations soon and, therefore, that LED manufacturers can tailor the emission spectra of their LEDs for optimal efficacy and color rendering. Until this happens, however, the published color rendering indices, especially the General Color Rendering Index (R_a) have to be handled carefully. The color appearance of objects under LED illumination might deviate considerably from what one expects based on the R_a index.

Application of LEDs

LEDs are the solution for practically every signaling application. Figure 8 shows an LED traffic light. Here it is also shown that, despite the fact that LEDs have extremely long life expectancy, the failure of the electronic circuitry can lead to unpleasant dark spots and rows in the display.

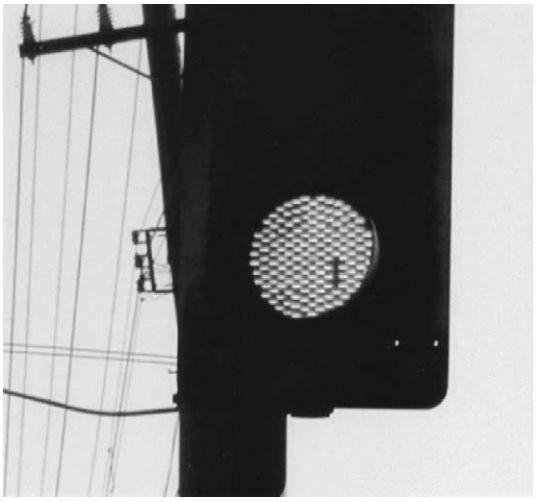

Figure 8 Green LED traffic light. Due to an electronic failure some LEDs stay dark.

LEDs are increasingly used in large active posters and displays. In such applications the highly saturated color of LED light is an advantage: LED displays can be very bright and emit saturated colors.

LEDs have an advantage in every situation where colored light has to be produced. Thus, they become the preferred automotive stoplights, dashboard lights, and are widely used in other signaling applications on the roads, at airfields, and in other traffic situations; much decorative lighting is now using LEDs.

Experiments are underway to find the best applications for white LEDs. Their drawback at the moment is still that their single unit power is below ten watts, as we often need ten to a hundred times larger units. For such applications, some LED clusters have been built, but these are still not competitive with other light sources. At places where the ruggedness of the LEDs is of an advantage, white LED lights are used – for example, in aircraft reading lights. One area where we will probably soon find higher-intensity white LEDs is car headlamps. Both the efficacy and the luminous flux output of the single LED units is increasing continuously. Applications, unbelievable only a few years ago, can now be realized efficiently with LEDs. Thus it is very difficult to foresee in which applications – beyond signaling – LEDs will first supersede other light sources, but it is certain that within the next decade we will see many new applications of LED sources.

List of Units and Nomenclature

Chromatic adaptation	Adaptation by stimuli in which the dominant effect is that of different relative spectral distributions.
Chromaticity	Partial description of the color stimulus, describing only chromatic aspects and not the 'intensity' (the luminance) of the stimulus. In light sources, chromaticity is an important descriptor, as the level of illumination can be changed by changing the distance between the source and the illuminated object. The luminance of the object will depend on the illumination and the reflection (transmission) characteristics of the object.
Color	In color science one distinguishes between color (perception), characteristic of visual perception that can be described by attributes of hue, brightness (or lightness) and colorfulness (or saturation or chroma), and color stimulus, a specification of the optical stimulus in terms of operationally defined values, such as three tristimulus values, or luminance, and chromaticity (or dominant wavelength and saturation).
Color rendering	Measure of the degree to which the psychophysical color of an object illuminated by the test illuminant conforms to that of the same object illuminated by the reference illuminant, suitable allowance having been made for the state of chromatic adaptation.
Correlated color temperature	The temperature of the Planckian radiator whose perceived color most closely resembles that of a given stimulus at the same brightness and under specified viewing conditions.
Efficacy (luminous efficacy of a source)	Quotient of the luminous flux emitted by the power consumed by the source.
Luminous efficiency	Ratio of radiant flux weighted according to $V(\lambda)$, the spectral luminous efficiency of the human eye, to the corresponding radiant flux.
Spectral luminous efficiency (of the human observer)	Ratio of the radiant flux at wavelength λ_m to that at wavelength λ, such that both radiations produce equally intense luminous sensations under specified photometric conditions and λ_m is chosen so that the maximum value of this ratio is equal to 1.

Introduction

A complete understanding of the band structure of a semiconductor close to the Fermi energy requires information on the fundamental energy gap, the effective masses and the effective g-factors of the valence and conduction band. Magneto-optical methods in principle allow one to determine all these quantities; they are particularly well suited to measure the spin splittings of the energy bands.

Faraday rotation is the rotation of the plane of polarization of linearly polarized light propagating through a sample parallel to an external magnetic field. The magneto-optical Kerr effect is the analog for reflection. Though in general it yields much smaller angles of rotation than the Faraday effect, it has to be applied in spectral ranges where the investigated sample is not transparent.

If a semiconductor is excited by circularly polarized light with photon energies not too high above the energy gap a spin polarization in the conduction band can be obtained (optical pumping). A small transverse magnetic field reduces the degree of this spin polarization (the Hanle effect). Owing to the spin polarization of the photo-excited conduction electrons the photoluminescence radiation is partly circularly polarized. Thus mounting the sample in a microwave resonator and applying a longitudinal magnetic field, electron spin resonance transitions can be detected optically by monitoring the degree of polarization of the photoluminescence (ODCESR: optically detected conduction electron spin resonance). Via a 'nuclear Hanle effect' mediated by the hyperfine interaction, nuclear magnetic resonance transitions can also be detected optically (ODNMR). ODCESR and ODNMR are summarized under ODMR (optically detected magnetic resonance).

In modern optics nonlinear optical effects have gained particular importance. Since electron spin resonances in semiconductors are Raman-active transitions, coherent Raman methods such as CARS (coherent anti-Stokes Raman scattering) or CSRS (coherent Stokes Raman scattering) are of great importance for the determination of spin splittings of energy bands and the investigation of magnetic structures in semiconductors.

In the present contribution the physical basis for these methods will be discussed and typical examples for their application will be presented.

For Faraday rotation and CARS the systems from which these examples will be taken are magnetic or dilute magnetic semiconductors. In these materials paramagnetic ions like Mn^{++} or Eu^{++} are incorporated. There are two types of exchange interactions: (i) between the magnetic ions which in most cases causes an antiferromagnetic coupling; and (ii) between the ions and free carriers which causes a

strong modification of the spin splittings of the energy bands with respect to nonmagnetic materials. Thus the Faraday effect or CARS are particularly well-suited methods for the investigation of such systems.

As examples of optical pumping and ODMR, results obtained with III–V semiconductors will be presented, which show the most important applications of these experimental methods.

Faraday Rotation and Magneto-optical Kerr Effect

Basic Principles

As already pointed out in the Introduction, the Faraday effect is the rotation of the plane of polarization of linearly polarized light traversing a sample parallel to a magnetic field. The angle of rotation Θ_{Far} is proportional to the length l of the sample and to the strength B of the magnetic field:

$$\Theta_{\mathrm{Far}} = VlB \qquad [1]$$

where V is called Verdet's constant.

For a phenomenological understanding of the effect one can consider plane polarized light as a superposition of right- and left-hand circularly polarized components. If the indices of refraction are different for both components, then at the end of the sample, when the two components are recombined, a phase shift occurs which manifests itself as a rotation of the polarization plane. The angle resulting from this consideration is

$$\Theta_{\mathrm{Far}} = \frac{l\omega}{2c}(n_- - n_+) \qquad [2]$$

where ω is the frequency, c the velocity of light, and n_- and n_+ are the refractive indices for left- and right-hand polarized light, respectively. If one neglects ellipticity of the light behind the sample only the real parts of the complex refractive indices $\tilde{n}_\pm$ are important,

$$\tilde{n}_\pm = n_\pm - \mathrm{i}\kappa_\pm \qquad [3]$$

The imaginary parts, however, are needed to understand the magneto-optical Kerr effect which occurs in the light reflected from the sample surface. According to Fresnel's formula for vertical incidence the field amplitude of the reflected beam is:

$$\tilde{E}^{\mathrm{r}}_\pm = \frac{1-\tilde{n}_\pm}{1+\tilde{n}_\pm}\tilde{E}^{\mathrm{i}}_\pm = \tilde{r}_\pm \tilde{E}^{\mathrm{i}}_\pm \qquad [4]$$

where the superscript 'r' refers to the reflected beam and 'i' to the incident beam. The complex reflection coefficient can be split into an amplitude and a phase factor:

$$\tilde{r}_\pm = r_\pm \exp(\mathrm{i}\psi_\pm) \qquad [5]$$

By comparing eqns [4] and [5] the phase shifts during reflection can be expressed in terms of the refractive index:

$$\psi_\pm = \arctan\frac{2\kappa_\pm}{1-n_\pm^2-\kappa_\pm^2} \qquad [6]$$

Finally the Kerr angle of rotation is obtained from the phase shifts in an analogous way to the Faraday rotation:

$$\Theta_{\mathrm{Kerr}} = \tfrac{1}{2}(\psi_- - \psi_+) \qquad [7]$$

It is seen that both effects can be understood in terms of the refractive index. In a simple oscillator model the refractive index has the form given in eqn [8]:

$$\tilde{n}^2_\pm = \tilde{\varepsilon}_\pm(\omega,B) = \varepsilon_\infty + \sum_{i,j}\frac{F^\pm_{i,j}}{\hbar\omega^\pm_{i,j} - \hbar\omega - \frac{1}{2}\mathrm{i}\Gamma^\pm_{i,j}} \qquad [8]$$

with $\hbar\omega^\pm_{i,j}$ representing the transition energies between the energy levels i and j in σ^+ and σ^- polarization, respectively, and $F^\pm_{i,j}$ and $\Gamma^\pm_{i,j}$ are the respective oscillator strength and linewidth parameter.

From eqn [8] it is seen that when tuning the frequency, ω, resonant enhancements of the rotation angles are expected whenever the frequency corresponds to an allowed electronic transition, e.g., an exciton in a wide-gap semiconductor. This is the reason why the Faraday and magneto-optical Kerr effect can yield information on interband transition energies. In the case of such a resonance, the refractive index will be dominated by the particular term in the sum, corresponding to that transition. By a Taylor expansion one can then show that the difference of the refractive indices for σ^+ and σ^- polarization and thus the angles of rotation (see eqns [2] and [7]) are proportional to the difference of the transition energies for right- and left-hand circularly polarized light, and this difference depends on the spin splittings of the valence and conduction band. So we understand why the most important information obtained from Faraday or magneto-optical Kerr effect studies is on the spin splittings of the energy bands.

A quantum mechanical description of the relation between the material properties and the magneto-optical effects beyond the simple oscillator model given here is published by Boswarva *et al.* and the reader is referred to this paper for

further studies. A matrix formalism to describe the effects for a multilayer system has been developed by Nies and Kessler.

Examples of Experimental Results

The straightforward method to measure Faraday rotation is to put the sample between polarizers and sweep the magnetic field. Then the transmitted intensity is proportional to a $\cos^2$ function. Subsequent maxima demonstrate a rotation by 180°. There have been numerous successful investigations done in this way, but the possibilities of detecting small angles of rotation are very limited in this method. Therefore differential methods have been developed either using a polarizing beam splitter, or a photo-elastic modulator which periodically switches the state of polarization. Rotation angles of the order of 10^{-4} rad can be detected in this way.

Figure 1 shows the Faraday rotation of an epitaxial film of $Pb_{0.933}Eu_{0.067}Te$ (thickness 11μm) for two temperatures. The plot demonstrates behavior typical for a diluted magnetic semiconductor in its paramagnetic phase. The spin splittings of the valence and conduction band and accordingly the Faraday rotation are proportional to the magnetization of the sample which behaves like a Brillouin function. (The lines without noise are fitted Brillouin functions.)

Examples of the application of the magneto-optical Kerr effect to the investigation of semiconductors, particularly multilayer systems, are published, e.g., by Pohlt *et al.* and Krenn *et al.*

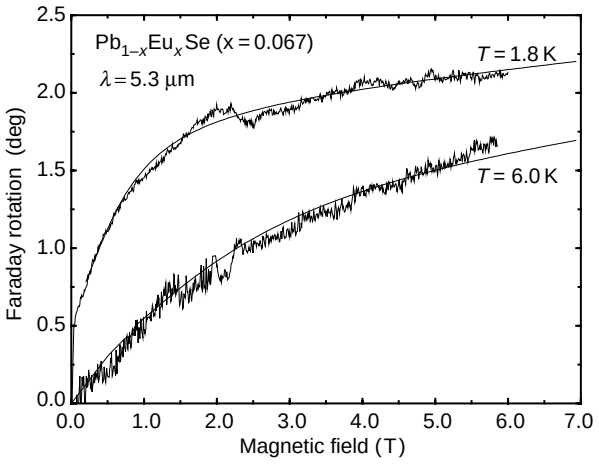

Figure 1 Faraday rotation as a function of magnetic field of a PbEuSe epitaxial film for two temperatures. Lines with noise: experimental recordings; lines without noise: fitted Brillouin functions.

Coherent Raman Scattering

Basic Principles

A more direct method for the determination of spin splittings of energy bands is provided by Raman scattering. There is a huge number of investigations of spin transitions in semiconductors using spontaneous Raman scattering (for a review of spontaneous Raman scattering in dilute magnetic semiconductors see the article by Ramdas and Rodriguez). However, there are several advantages in the spectroscopic application of the nonlinear Raman techniques compared to spontaneous Raman scattering:

(i) The scattered radiation is emitted as a collimated beam which is more easily detectable than the light spontaneously scattered into the entire solid angle. This advantage is particularly important for the investigation of narrow-gap semiconductors which have to be investigated by infrared light, a spectral range where the detectors are less sensitive than in the visible.
(ii) Fluorescence can be strongly suppressed by spatial filtering.
(iii) The spectral resolution is determined by lasers instead of a classical spectrometer.
(iv) Raman scattering cross-sections can be calculated from the intensity of a collimated beam without taking care of the aperture of the detecting system.

The coherent Raman techniques are special cases of optical four-wave mixing where two laser beams with frequencies ω_L and ω_S ($\omega_L > \omega_S$) are superimposed in the sample. Due to nonlinear interactions radiation with new frequencies is generated, among them:

$$\omega_{CARS} = 2\omega_L - \omega_S \qquad [9]$$

If one identifies ω_L with the frequency of the pump laser and ω_S with that of the scattered Stokes radiation of a spontaneous Raman experiment, then ω_{CARS} is the frequency of the anti-Stokes radiation. For the intensity of the radiation generated at ω_{CARS} one finds:

$$I_{CARS} = \frac{9}{16c_0^4\varepsilon_0^2}\frac{\omega_{CARS}^2}{n_{CARS}n_S n_L^2}\left|\chi^{(3)}\right|^2 l^2 I_S I_L^2 \times \left[\frac{\sin(\overrightarrow{\Delta k}\,\vec{l}/2)}{\overrightarrow{\Delta k}\,\vec{l}/2}\right]^2 \qquad [10]$$

where c_0 is the velocity of light, l is the length of the sample, I denotes the intensity, and n the refractive index at the respective frequency. $\chi^{(3)}_{kjkj}$ is the third-order nonlinear susceptibility of the scattering medium and

$$\overrightarrow{\Delta k} = 2\vec{k}_{\mathrm{L}} - \vec{k}_{\mathrm{S}} - \vec{k}_{\mathrm{CARS}} \qquad [11]$$

is the phase mismatch. $\overrightarrow{\Delta k} = 0$ can be achieved by noncollinear alignment of the laser beams. However, for very thin epitaxial layers with $l \ll \pi/\Delta k$ the phase factor in eqn [10] can be approximated by 1.

The information on the investigated material is contained in the nonlinear susceptibility. It can be calculated by time-dependent perturbation theory taking into account a ground state $|a>$ and intermediate states $|b>$, $|c>$ and $|d>$. It turns out that $\chi^{(3)}$ is proportional to a sum over all states of the system as intermediate states; in the sum 24 terms like the one given in eqn [12] have to be added:

$$\frac{\mu_{ijkl}}{(\omega_{ba} - \omega_{\mathrm{L}} - \mathrm{i}\Gamma_{ba})(\omega_{ca} - \omega_{\mathrm{L}} + \omega_{\mathrm{S}} - \mathrm{i}\Gamma_{ca})(\omega_{da} - \omega_{\mathrm{CARS}} - \mathrm{i}\Gamma_{da})} \qquad [12]$$

μ_{ijkl} is a product of four dipole matrix elements between states $|a>:|b>$; $|b>:|c>$; $|c>:|d>$ and $|d>:|a>$ with field polarizations as given by the indices. $\omega_{\alpha\beta} = (E_\alpha - E_\beta)/\hbar$ and $\Gamma_{\alpha\beta}$ is the linewidth of the respective transition. Resonances of the susceptibility are found by inspection of the denominators. $\chi^{(3)}$ exhibits Raman-like resonances whenever $\hbar(\omega_{\mathrm{L}} - \omega_{\mathrm{S}})$ is equal to the excitation energy of a Raman allowed transition (see the second factor in the denominator of eqn [12]). If in this case the laser beams are polarized according to the Raman selection rules then μ_{ijkl} is not zero. For spin transitions in a semiconductor in a magnetic field (free electron spin flip as well as transitions within the magnetic ions) this is the case if in the Voigt configuration ($\vec{k}_{\mathrm{L,S}} \perp \vec{B}$) the beams with frequencies ω_{L} and ω_{S} are polarized perpendicular to one another. In the case of a spin transition $\omega_{ca} = g^* \mu_{\mathrm{B}} B$ (g^* being the effective Landé-factor and μ_{B} the Bohr magneton). Thus holding the frequencies ω_{L} and ω_{S} fixed and tuning the magnetic field a resonance in I_{CARS} will be observed from the position of which the effective g-factor can be obtained. Using tunable dye lasers, of course, the laser frequencies can be tuned as well.

Close to the resonance the real part of the susceptibility becomes small and the imaginary part is not negligible. Furthermore, one-photon resonances may occur if the laser frequency ω_{L} corresponds to the energy of a real electronic transition, e.g., an allowed interband transition. If one-photon and Raman-like resonances occur simultaneously one talks about resonance CARS.

As discussed in the literature $\chi^{(3)}$ can be split into a resonant part χ_{r}, summing up all the resonant terms, and a nonresonant part χ_{nr}. In a semiconductor there are contributions to χ_{nr} due to free carriers and a background due to bound valence electrons. The background contribution in general is real. As can be seen from eqn [10],

$$I_{\mathrm{CARS}} \propto \left|\chi^{(3)}_{\mathrm{CARS}}\right|^2 = |\chi_{\mathrm{nr}}|^2 + |\chi'|^2 + |\chi''|^2 + 2 \cdot \chi_{\mathrm{nr}} \chi' \qquad [13]$$

χ' and χ'' being the real and imaginary parts of the resonant contribution. Depending on the relative strength of resonant and nonresonant contributions to $\chi^{(3)}$ the last term in eqn [13] may cause complicated lineshapes which make it difficult to find the correct transition energy in spectroscopic applications of CARS. If more than one resonance is not completely resolved the lineshape is even more complicated and a careful analysis has to be performed to get the correct resonance positions and linewidths of the transitions.

Examples of Experimental Results

Figure 2 shows a scheme of a CARS setup suitable to measure spin transitions in a semiconductor. The scheme is drawn for backscattering geometry; forward detection is accomplished by directing the incoming beams onto the sample from the opposite side to that plotted.

Two dye lasers (frequencies ω_{L} and ω_{S}) are pumped by a frequency-doubled Nd:YAG laser. A Glan–Thomson prism combines the two beams. The monochromator is set to $2\omega_{\mathrm{L}} - \omega_{\mathrm{S}}$. The iris and the polarizer PZ3 reduce stray light. The experiment is performed either at fixed magnetic field and tuning one of the dye lasers (with the monochromator swept accordingly) or by keeping the laser frequencies fixed and sweeping the magnetic field. The latter method is also applicable in the mid-infrared using step-tunable CO or CO_2 lasers.

As an example, in Figure 3 a spectrum obtained from a CdMnTe alloy crystal is reproduced. There are two peaks observed due to the paramagnetic resonance of the Mn 3d electrons and due to the spin resonance of photo-excited free electrons in the conduction band. The inset shows the paramagnetic resonance on an extended scale. The linewidth of 0.5 cm^{-1} is not limited by the experimental resolution, which in the present case is about a factor of 10 better.

Optical Pumping

The basic principles of optical pumping have been developed by Kastler. A material (gas or solid) is excited by absorption of circularly polarized light. Lampel was the first to demonstrate the possibility of optical spin orientation of free electrons in a semiconductor. The method has the most important applications in zincblende materials. Thus it is explained here with the example of GaAs.

Principles of Optical Spin Orientation

Most of the III–V and II–VI semiconductors have direct gaps at the center of the Brillouin zone. The conduction band (cb) is doubly degenerate with spin. The valence band consists of the heavy hole band (hh; $m_j = \pm 3/2$), the light hole band (lh; $m_j = \pm 1/2$) and the split-off band (so; $m_j = \pm 1/2$), each doubly degenerate. In bulk material hh and lh are degenerate at $k = 0$. The transition probabilities for interband transitions between hh and cb are three times larger than for transitions between lh and cb. Due to the selection rules, e.g., for the absorption of σ^+ circularly polarized light, transitions $-3/2 \rightarrow -1/2$ and $-1/2 \rightarrow +1/2$ are allowed, the first having three times higher probability. The electronic spin polarization P is defined as:

$$P = \frac{n_+ - n_-}{n_+ + n_-} \qquad [14]$$

where n_+ and n_- are the densities of electrons with the two spin orientations with respect to the direction of propagation of light. These considerations yield $P_\mathrm{i} = -0.5$ as the initial spin polarization under excitation with σ^+ circularly polarized light with a photon energy between the fundamental gap and the energy difference from the spin–orbit split valence band to the conduction band. Due to relaxation processes the actual electronic steady state polarization P is smaller than P_i:

$$P = P_\mathrm{i} \frac{T_1}{T_1 + \tau} \qquad [15]$$

with T_1 being the spin relaxation time, which in zero magnetic field is equal to the transverse relaxation time T_2, and τ is is the lifetime of conduction electrons.

The spin polarization of the electrons can be detected by analyzing the degree of circular polarization of the luminescence light which is defined as:

$$\Pi = \frac{I_+ - I_-}{I_+ + I_-} \qquad [16]$$

where I_+ and I_- are the intensities of σ^+ and σ^- polarized light, respectively. Since for emission due to free-electron/free-hole or free-exciton recombination the same transition probabilities as for absorption are obtained, one finds:

$$\Pi = 0.5\, P = 0.25 \frac{T_1}{T_1 + \tau} \qquad [17]$$

In the case of quantum wells, the lh-hh degeneracy is lifted due to different confinement energies. Then the maximum polarization of cb $\rightarrow$ hh as well as for cb $\rightarrow$ lh luminescence light is 0.5.

Of course these considerations are only true for intrinsic or p-type materials where the number of photo-excited electrons is high compared to the equilibrium number of electrons.

Hyperfine Interaction of Spin-Polarized Electrons and Atomic Nuclei

In GaAs three isotopes exist with spin 3/2, namely ^{69}Ga, ^{71}Ga and ^{75}As. Owing to the small energy separation of the nuclear spin levels in moderate magnetic fields, in thermal equilibrium no significant nuclear spin polarization exists even at a temperature of 2 K. However, the hyperfine interaction between electrons and nuclei allows so-called flip-flop processes, that is a simultaneous reversal of electronic and nuclear spins. This causes a considerable dynamic spin polarization of the nuclei if the electronic spin system is polarized due to optical pumping. Under most experimental conditions and when nuclear spin relaxation mechanisms other than via the hyperfine interaction are negligible, the mean nuclear spin is approximately:

$$\langle I \rangle = \frac{I(I+1)}{S(S+1)} \frac{P}{2} \qquad [18]$$

where I and S are the operators for nuclear and electron spin. These dynamically polarized nuclei act on the electrons and shift their spin resonance magnetic field by an effective nuclear field (the Overhauser shift). This shift is proportional to $\langle I \rangle$ and to the probability of finding the electrons at the nuclear sites, and is inversely proportional to g^*. In GaAs due to the small value of g^* this field can reach several tesla.

Effect of a Constant Transverse Magnetic Field – The Hanle Effect

In a transverse (with respect to the direction of propagation of light) magnetic field the spin-oriented electrons precess around the field with an

angular frequency $\Omega = g^*\mu_B B/\hbar$. If the spin lifetime T_S ($1/T_S = 1/T_2 + 1/\tau$) is long enough, this precession diminishes the average spin polarization and consequently the degree of circular polarization of the photoluminescence according to:

$$\Pi(B) = \Pi(0)\frac{1}{1+\Omega^2 T_S^2} \qquad [19]$$

This is a Lorentzian with a width at half height of $\Delta B = \hbar/(g^*\mu_B T_S)$.

It is seen that by measuring $\Pi(B)$ the spin lifetime can be determined if g^* is known. Together with eqn [17] the spin and interband lifetime can be determined in a steady-state experiment. If, on the other hand, T_S is known from a time-resolved experiment, g^* can be found from a Hanle effect measurement.

Optically Detected Conduction Electron Spin Resonance (ODCESR)

Optical spin orientation of conduction electrons is the presupposition for ODCESR. Suppose now, a longitudinal magnetic field $\mathbf{B}_0$ is applied on the sample ($\mathbf{B}_0$ parallel to $\mathbf{k}$, the direction of propagation of light, which is parallel to the direction of the optically oriented spins). If the field is not too high the considerations of optical spin orientation remain unchanged. In higher fields the spin polarization may be modified due to the energy splitting of the spin levels. In this case the spin polarization is enhanced or diminished, depending on the direction of the field parallel or antiparallel to $\mathbf{k}$. If now an additional transverse microwave field B_1 of frequency ω_0, which fulfills the resonance condition $\hbar\omega_0 = g^*\mu_B B_0$, is applied, transitions between the two spin levels will occur which resonantly decrease the spin polarization. This decrease manifests itself in a decrease of the degree of circular polarization of the photoluminescence.

The method has several advantages compared to conventional ESR. Microwave photons with frequency of about 10^{10} Hz change the state of polarization of optical photons with frequency of about 10^{14} Hz. Thus the sensitivity is that of the optical detection which is much higher than in conventional ESR. Even electrons in a single quantum well or heterostructure can be detected by the optical method. There is also the possibility to distinguish between electrons in different quantized levels in heterostructures due to the different spectral position of their photoluminescence. Another advantage is that the electrons are photo-excited; the sample does not need to be n-doped. High-purity samples can be investigated which exhibit narrower linewidths.

Optically Detected Nuclear Magnetic Resonance (ODNMR)

With the presuppositions provided in the preceeding sections the basic principle of ODNMR is easily understood. As in ODCESR we assume that an external magnetic field $\mathbf{B}_0$ is applied parallel to $\mathbf{k}$. Perpendicular to it a radio-frequency field $\mathbf{B}_2$ with frequency ω is applied. The NMR resonance frequency is $\omega_0 = \gamma_n \cdot B_0$ with γ_n being the gyromagnetic ratio of the nucleus under consideration. In the frame rotating with ω around the direction of $\mathbf{B}_0$ an effective field $\mathbf{B}_{\text{eff}} = \mathbf{B}_0 - \boldsymbol{\omega}/\gamma_n + \mathbf{B}_2$ acts on the nuclei. The nuclear magnetization is oriented parallel to $\mathbf{B}_{\text{eff}}$. It is seen that in resonance $\mathbf{B}_{\text{eff}}$ is parallel to $\mathbf{B}_2$, which means perpendicular to $\mathbf{k}$. Via the hyperfine interaction this nuclear field acts on the electrons, diminishing their spin polarization via the Hanle effect. So the nuclear magnetic resonance can be detected as a reduction of the degree of circular polarization of the photoluminescence.

The simplified model given above does not take into account several effects which influence the lineshape, position and intensity of the observed resonance lines.

Examples of Experimental Results for Optical Pumping and Optically Detected Magnetic Resonances

These experiments can be performed at liquid helium temperature in a standard photoluminescence setup. In addition one has to provide the possibility of applying transverse (Hanle effect) or longitudinal (ODCESR, ODNMR) magnetic fields. For ODCESR the sample is mounted in a microwave resonator with optical access; for ODNMR a radio-frequency coil is wound around the sample. The state of circular polarization of the exciting laser light has to be controlled. The measured quantity is the sign and degree of circular polarization of the luminescence light at a certain wavelength. The sensitivity can be enhanced by periodically σ^+/σ^--modulating either the exciting light or the detection. Which one of these possibilities is used depends on whether or not a high nuclear spin polarization is wanted.

As pointed out above the dynamically polarized nuclei, particularly in GaAs, strongly affect the

ODCESR resonant field. To get reliable values for the effective g-factor, the nuclear spin polarization must be completely suppressed. This can be achieved by σ^+/σ^--modulation of the exciting light with a modulation period much shorter than the nuclear spin relaxation time. But due to imperfections, e.g., if the intensities of σ^+ and σ^- light or their time intervals are not equal, residual optical fields may remain. To get precise values for g^* in addition the NMR has to be saturated by a suitable radio-frequency field. On the other hand, the strong Overhauser shift of the CESR can be useful for the determination of nuclear spin relaxation times. To perform such experiments the nuclei are first polarized by optical pumping with fixed circular polarization and afterwards, for the detection, σ^+/σ^--modulation is switched on.

For the optical detection of NMR a high nuclear spin polarization is favorable. Thus for those experiments one uses fixed polarization of the exciting beam and modulates the detected light.

Figure 4 shows examples of results obtained with a p-channel AlGaAs/GaAs single heterostructure. In this sample due to the doping profile a triangular potential well at the interface in the valence band of the GaAs layer is built, in which quantized hole levels exist. The luminescence band shown in Figure 4a between 821 nm and 825 nm is due to recombination of electrons with holes in these quantized states. For the experiments shown in the other panels of the figure the spectrometer is set at a position within this band. The other lines are due to excitons and impurities and are not interesting for what follows.

In Figure 4b the results of a Hanle experiment are reproduced. The line without noise is the fitted Lorentzian. The fit yielded $\tau = 8.1$ ns and $T_1 = 4.7$ ns.

In Figure 4c a typical ODNMR spectrum of the same sample is plotted. One observes resonances due to ^{75}As at 1.36 MHz, ^{69}Ga at 1.9 MHz and ^{71}Ga at 2.4 MHz. In the inset the ^{75}As resonance is plotted in an extended scale. A quadrupole splitting into three components is clearly resolved. This result demonstrates that the tetrahedral symmetry at the nuclear site is broken either due to local defects or due to the (rather small) lattice mismatch close to the AlGaAs/GaAs interface.

Finally Figure 4d shows the ODCESR spectrum. For the experiment the exciting beam was σ^+/σ^--modulated and in addition during the sweep the NMR of all three nuclei was permanently saturated to make sure that no Overhauser shift

affects the result. The g-factor calculated from this plot is $|g^*| = 0.468$, which is larger than that found for bulk GaAs. This value was also used for fitting the Hanle curve.

Introduction

The addition of a magnetic field to an optical study of a semiconductor generally improves the specificity of the experiment, but in particular affects primarily the electrons rather than the lattice so that the magneto-optical properties are determined to a large degree by the electrons alone. The major interest has been in the determination of the electronic energy band structure of semiconductors, both in their bulk and low-dimensional (two-, one-, and zero-dimensional) quantum forms. The magneto-optical experiments fall mainly into two categories according to whether the effects are associated with intraband (within a single conduction or valence band) or interband (valence to conduction band) transitions; there are also hybrid (i.e., higher-order) effects such as spin-flip Raman scattering or two-photon absorption where both inter- and intraband transitions are involved in a two-stage process. Interband transitions occur typically in the visible to mid-infrared (MIR) region, and intraband transitions in the MIR to far-infrared (FIR) region.

Theoretical Background

The most common band structure involved in semiconductor magneto-optics is the so-called quasi-Ge model, which gives an accurate description of group IV, and zincblende (III–V and II–VI) semiconductors, so it is convenient to describe the theory in terms of this model. In this model the small terms associated with inversion asymmetry are neglected to a first approximation. At the Brillouin zone center (i.e., at $k = 0$) the conduction band has s-like symmetry and the triply degenerate valence band p-like symmetry. In the presence of strong spin–orbit coupling, part of this degeneracy is raised resulting in the doubly degenerate (at $k = 0$) heavy and light mass valence bands and a so-called spin–orbit split-off band. The reader should go to the general reviews quoted under 'Further Reading' for the equivalent coverage of other common systems such as the wurzite II–VI and the lead salt systems.

The dynamics of a free electron subject to an external magnetic field have been given by a variety of authors, but the most universally used treatment is that of Landau. For the motion of an electron in a semiconductor we treat first the case of a simple parabolic energy band. For the case of the magnetic field, B, along the z-direction, k_z remains a good quantum number, but k_x and k_y are subsumed into the new magnetic orbital (Landau) quantum number, n. The original three-dimensional energy band, $E = \hbar k^2/2m^*$, is coelesced into a series of one-dimensional Landau sub-bands in the k_z-direction (where the motion along k_z remains unchanged):

$$E_n^{\pm}(k_z) = (n + 1/2)\,\hbar\omega_c + \frac{\hbar k_z^2}{2m^*} \qquad [1]$$

The cyclotron frequency is $\omega_c = eB/m^*$ and μ_B is the Bohr magneton. The resulting electron energy eigenvalues at $k_z = 0$ in an external magnetic field (i.e., Landau sub-band extrema) are referred to as Landau levels, LLs. In practice each state is doubly degenerate with spin which results in an additional term $\pm g^*\mu_B B$ on the right-hand side, where g^* is the effective g-factor. (Note that in the presence of strong spin–orbit coupling and small m^*, there is a corresponding g^* which becomes negative and substantially different from the free-electron g-factor; the largest value for a binary elemental compound is that for InSb, where $g^* \approx -50$.) The situation for a simple parabolic conduction band near $k = 0$ is shown in Figure 1a,b. Intraband optical absorption associated with direct transitions between successive Landau sub-bands is referred to as cyclotron resonance (CR) absorption. There are corresponding Landau sub-bands in the valence band, and direct transitions between valence and conduction sub-bands give rise to the so-called interband magneto-optical (IMO) effects.

Expressions for the density of states (DOS) in three, two, and one dimensions in the absence of a magnetic field are given elsewhere ('semiconductor basics' – Pidgeon). In the presence of a magnetic field the three-dimensional energy band is reduced to one-dimensional sub-bands so that the energy dependence of the DOS has the one-dimensional form with the energy given by eqn [1]. Performing this substitution and multiplying by a term for the degeneracy of the Landau levels (LLs) gives the following expression for the total DOS per unit volume:

$$g(E) = \frac{(2m^*)^{1/2}}{4\pi^2\hbar}\,\frac{eB}{\hbar}\sum_n \left[E - (n + 1/2)\,\hbar\omega_c\right]^{-1/2} \qquad [2]$$

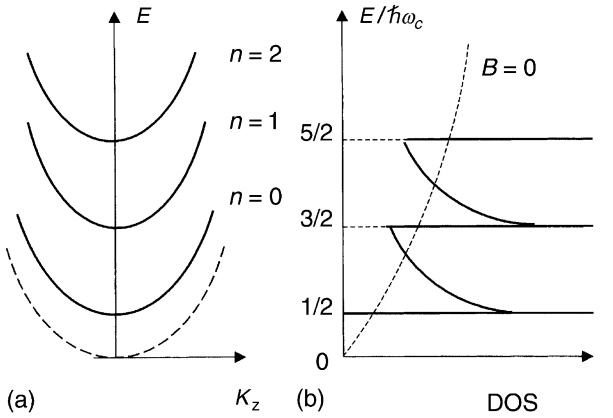

Figure 1 (a) Landau sub-bands according to eqn [1] with the magnetic field applied in the *z*-direction. The dashed line shows the parabolic conduction band for k along k_z and $B = 0$. (b) Schematic outline of the density of states (DOS) for free electrons in a magnetic field. It comprises the sum of identical contributions from each Landau sub-band. The density of states with $B = 0$ is shown dashed.

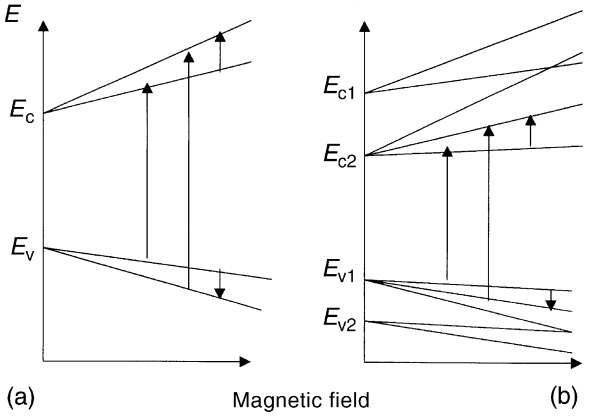

Figure 2 Fan plots of the conduction and valence band Landau levels versus magnetic field for simple parabolic bands: (a) a three-dimensional semiconductor; (b) quasi-two-dimensional systems. Some CR and interband magneto-optical transitions are shown by vertical arrows.

Thus, the DOS for Landau sub-bands is quite different from the zero-field DOS, and is a series of square-root singularities with divergences at the energies $(n + 1/2)\hbar\omega_c$. The two cases are illustrated schematically in Figure 1b. Since the optical absorption strength for both interband and intra-band transitions is proportional to the joint density of states for the initial and final states, this result shows the important advantage of the use of a magnetic field in semiconductor spectroscopy because it means that the absorption lines for CR or IMO transitions are strongly peaked at the sub-band extrema (i.e., at $k_z = 0$). This allows accurate measurement of LL energy differences for transitions observed in a single experiment, and hence, by comparison to theoretical models, leads to the best determination of fundamental energy-band parameters. The basic LL selection rule can be shown straightforwardly from time-dependent perturbation theory to be $\Delta n = 0$, $\Delta m_s = 0$ for IMO transitions and $\Delta n = 1$, $\Delta m_s = 0$ for CR absorption, where m_s is the spin quantum number (i.e., $\pm\frac{1}{2}$, for spin up and spin down). The cyclotron resonance absorption occurs only for one sense of circularly polarized light, but the IMO effect can occur for all polarizations. The choice then of magnetic field direction, crystal orientation, and polarization of the optical radiation allows extremely detailed determination of the energy band parameters for particular crystal symmetries.

The data are often summarized in a so-called fan diagram of the energy levels, or transition energies, versus magnetic field. Such a plot is shown for hypothetical conduction and valence band LLs in Figure 2a, together with interband and CR transitions. The states are labeled by the Landau quantum number, with selection rules $\Delta n = 0$ and $\Delta n = 1$ for interband and CR absorption transitions, respectively (or $\Delta n = -1$ for CR emission). If the energies of the transitions themselves are plotted versus the magnetic field, then the intercept of the fan plots at $B = 0$ gives the zero-field energy gap. Note that in the presence of excitonic effects (see below) the intercept will give the energy gap plus the exciton binding energy.

For a strictly two-dimensional system the DOS per unit area is independent of energy: $g(E) = m^*/\pi\hbar^2$. In the case of quasi two-dimensional confinement in the *z*-direction the motion in the *z*-direction is quantized, and the total energy becomes (*see* **Semiconductor Physics:** Quantum Wells and GaAs-Based Structures):

$$E = E_i + \frac{\hbar^2}{2m^*}(k_x^2 + k_y^2) \qquad [3]$$

Equation [3] describes a set of confinement sub-bands (parabolas induced by geometric, as opposed to magnetic, confinement), the bottoms of which are at the energies E_i, where i is the sub-band index. The energies, E_i, depend on the shape of the confining potential. The DOS per unit area is in this case a series of step functions of height $m^*/\pi\hbar^2$. From the point of view of magneto-optics, the main effect of the quantum confinement is to suppress the k_z motion, so that in the presence of an external magnetic field along the *z*-direction, the motion is completely quantized. The energy eigenvalues are given by:

$$E_{n,i} = E_i + (n + 1/2)\,\hbar\omega_c \qquad [4]$$

The total DOS becomes:

$$g(E) = \frac{m^* \omega_c}{\pi \hbar} \delta[E - (n + 1/2)\,\hbar\omega_c] \qquad [5]$$

a series of delta-functions located at the energy positions of the LLs. The DOS is obviously more singular in two dimensions than in three dimensions, and leads to substantially sharper magneto-optical and magneto-transport effects. For confined structures the selection rules for interband and intersub-band transitions are identical to the bulk case for the electromagnetic (em) radiation polarized in the xy plane provided that the external magnetic field is along the confinement (z-) direction. The only difference is that the conservation of momentum in the z-direction ($\Delta k_z = 0$) is replaced by a selection rule on the sub-band index, $\Delta i = 0$. A fan plot for this configuration is shown schematically in Figure 2b. For each confinement sub-band transition there is a set of LL transitions. When the energy positions are plotted against B, this leads to a set of Landau 'fans', each of which extrapolates to the sum of a valence plus conduction confinement sub-band energy at $B = 0$. Allowed transitions are shown for the lowest two confinement sub-bands in Figure 2b. Again this picture may be complicated in the presence of excitonic effects at low temperature.

Turning again to the bulk semiconductor picture, eqns [1]–[5] apply for a single parabolic energy band and are valid for the conduction band in the quasi-Ge model. In actual semiconductors further complications arise. Most importantly the triply degenerate p-like valence band (heavy hole, light hole, and split-off band) must be treated by so-called degenerate perturbation theory. In the quasi-Ge model the conduction and three valence bands are treated together as one coupled band system using the so-called $\mathbf{k} \cdot \mathbf{p}$ method (described elsewhere by Zawdzki). With spin this results in an 8×8 matrix equation which has to be diagonalized for the eigenvalues and eigenvectors of the system. The spin–orbit coupling results in so-called complex, mixed-spin valence bands and anomalously spaced low quantum number LLs (the so-called quantum effects). The overall energy band scheme for InSb, near the fundamental direct gap in the center of the Brillouin zone for conduction and (heavy and light mass) valence bands is shown schematically in Figure 3, for no magnetic field and for an applied magnetic field. Each LL is doubly degenerate with spin, the a-set representing the so-called spin-up and the b-set the spin-down states.

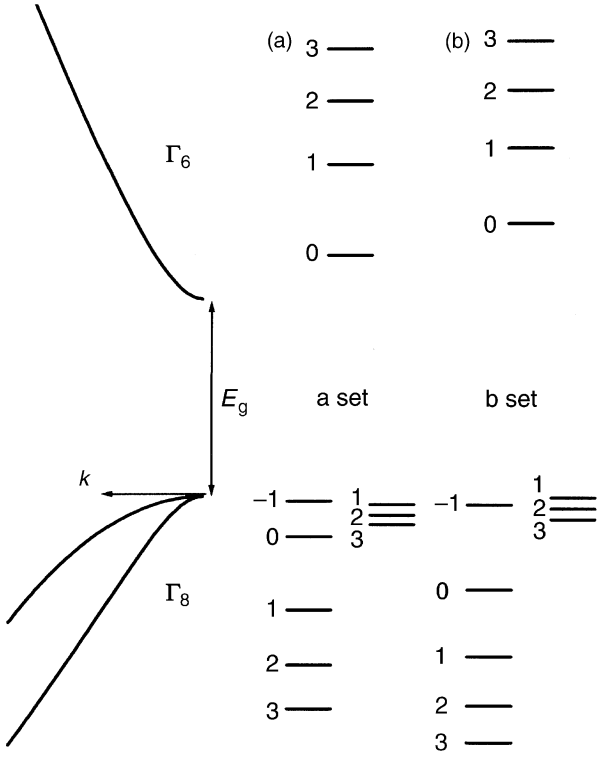

Figure 3 (a) Schematic diagram of the conduction and valence bands for InSb (symmetry labels Γ_6 and Γ_8 respectively) at $B = 0$. (b) Computed Landau levels for the conduction and valence bands of InSb at 4 K ($E_g = 0.23$ eV) with $B = 5$ T along the [100] direction, grouped according to the so-called a- and b-spin sets (see text).

Experimental

The first serious use of magneto-optics to study effective mass and energy band structure of semiconductors was in the microwave cyclotron resonance (i.e., intraband) investigations of Ge and Si in the early 1950s. Classically it can be shown that the ratio of the radiation power absorbed, P, to power absorbed in zero magnetic field, P_0, is given by:

$$\frac{P}{P_0} = \frac{1 + (\omega^2 + \omega_c^2)\tau^2}{[1 + (\omega_c^2 - \omega^2)\tau^2]^2 + 4\omega^2\tau^2} \qquad [6]$$

where τ is the collision time of the carriers. This expression for P/P_0 describes cyclotron resonance absorption and is plotted as a function of frequency in Figure 4 for different values of the parameter $\omega_c\tau$. Clearly the peak absorption occurs at $\omega = \omega_c$, namely at cyclotron resonance. Also evident is the very important requirement for observation of a clear resonance that $\omega_c\tau > 1$; this condition corresponds physically to a travel time between collisions of the particle of at least $1/2\pi$ of a revolution so that the particle can interact for a sufficiently long time

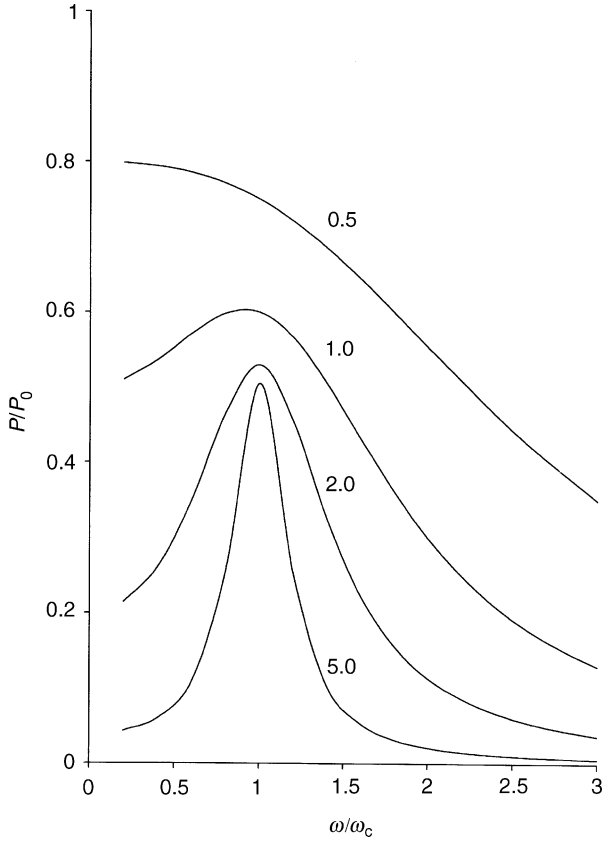

Figure 4 Ratio of the radiation power absorbed to the power absorbed at zero magnetic field, P/P_0, plotted as a function of ω/ω_c according to eqn [6], for different values of $\omega_c\tau$ from 0.5 to 5.0.

with the electromagnetic wave to absorb energy. For pure materials and low temperatures (where the condition $\omega_c\tau > 1$ is achievable) this is the best technique for obtaining the details of the electron and hole band parameters of a semiconductor near $k = 0$. The most thorough and successful studies of this type have been achieved in pure Si, Ge, and InSb where (with the aid of optical excitation to populate the levels shown in Figure 3) all possible electron, light and heavy hole cyclotron resonances have been resolved. In this way the valence band quantum effects, described above, have been observed in detail. The technique is equally applicable in low-dimensional systems where CR of both electrons and holes has been resolved in a large number of n- and p-type semiconductor heterostructures and quantum wells.

In interband – either absorption or photoluminescence (PL) – spectroscopy at low temperatures, the photo-excited electrons and holes interact and form excitons (*see* **Semiconductor Physics:** Excitons). In many cases the excitonic state may be described in the so-called envelope function approximation as a hydrogenic system, in which the electron and hole are bound by their mutual Coulomb attraction. The energy spectrum of such a hydrogenic exciton is given by

$$E_n = \frac{\mu e^4}{2\hbar^2\varepsilon^2 n^2} \qquad [7]$$

where n is the principal quantum number ($n = 1, 2, 3, \ldots$, but note that the symbol n is also used for the Landau quantum number above), μ is the electron–hole reduced effective mass, and ε is the background dielectric constant. In low-dimensional (i.e., confined) semiconductor systems of the type described above the degeneracy of the valence bands at $k = 0$ is removed, and two types of excitons are observed; these are referred to as 'heavy' and 'light' hole excitons in the literature, where heavy and light refer to the effective masses along the confinement direction. These excitons can move freely (in the remaining two unconfined directions) or be bound to an impurity or defect. In these systems exciton absorption may be observed involving not only the ground-state excitons, but also excitons associated with higher confinement sub-bands. This is shown for the so-called asymmetric quantum well system $Al_yGa_{1-y}As/In_xGa_{1-x}As/GaAs$ in Figure 5a. The data are taken both by the direct PL method (where the exciting beam has an energy much larger than the bandgap and the electrons and holes de-excite instantaneously to the bottom of the bands before recombining as exiton recombination radiation), and so-called PL excitation spectroscopy (where the exciting beam is a tunable laser, tuned into resonance with the successive exciton resonances).

The interband Landau transitions can be observed either in PL or as excitations in a magneto-absorption or magnetoreflection experiment. Excitons are affected differently by the application of an external magnetic field depending whether the ratio $\gamma = \hbar\omega_c/2E_B$ (where E_B is the exciton binding energy with $n = 1$ above) is less than or greater than one. In the so-called magnetic limit where $\gamma \gg 1$, the excitonic ground state moves approximately as $\frac{1}{2}\hbar\omega_c$, i.e., linearly with B. In this regime the magnetic field energy is the dominant term in the exciton Hamiltonian. The various states of the exciton (ground and excited states) become associated with the interband LL transition, and exhibit an energy dependence that is nearly identical to the free carrier LL transitions. The energies of the various excitonic transitions are shifted down with respect to the corresponding LL transitions by an amount equal to the binding energy of the excitonic state to that LL. Typical PL and PLE (photoluminescence excitation)

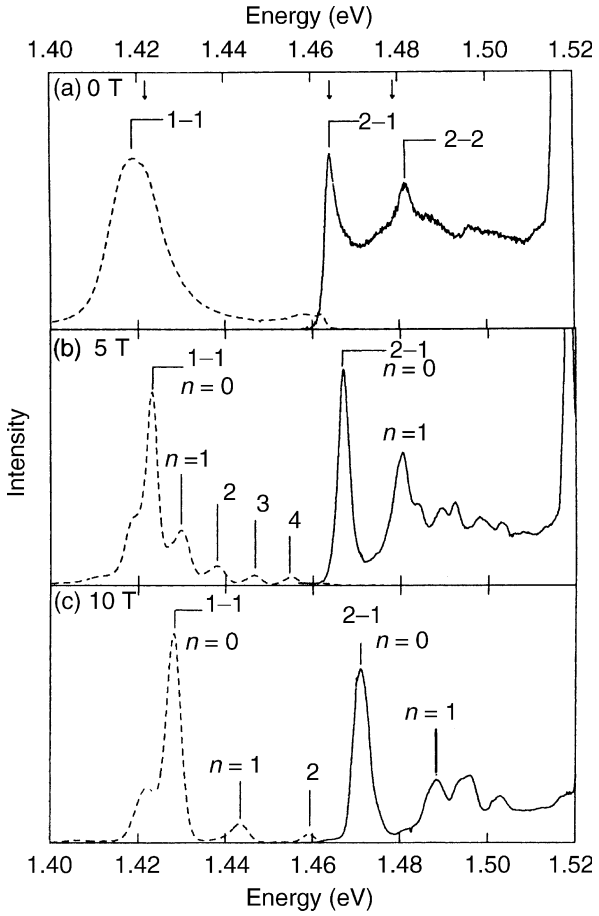

Figure 5 Interband transition data obtained in zero magnetic field (a) and fields of 5 T (b) and 10 T (c) from asymmetric quantum wells. The dashed lines indicate data obtained from PL and the solid lines data from PLE. The arrows in (a) indicate the calculated interband transition energies $1 \rightarrow 1$, $2 \rightarrow 1$, and $2 \rightarrow 2$, the latter being clearly resolved in PLE (the asymmetric wells mean that transitions with $\Delta i \neq 0$ are allowed). In (b) and (c) the development of the spectra into LL transitions is clearly seen, although beyond 1.48 eV the analysis is obviously extremely complicated by the overlap of LL transitions associated with all three of the above sub-bands.

spectra for interband magneto-optical transitions are shown in Figure 5b,c for a fixed applied magnetic field in the asymmetric quantum well system $Al_yGa_{1-y}As/In_xGa_{1-x}As/GaAs$.

Spin Flip Raman Scattering

In addition to the interband transitions discussed above, Raman scattering of intersub-band transitions between conduction or valence band LLs can also be studied. It provides a versatile means of probing band edge parameters of electrons and holes in semiconductors since the excitation (normally a laser pump) is not confined to the resonance frequencies under investigation, i.e., any pumping energy below the band edge will do. Electronic Raman scattering is then allowed between LLs via virtual interband transitions. In the presence of spin–orbit coupling strong spin-flip processes via electric dipole transitions become allowed giving rise to the so-called spin-flip Raman (SFR) cross-section. This is a single-particle process in which electrons or holes interacting with the radiation change their spin state. This process can be made to go stimulated particularly easily when the pump radiation is resonant with the bandgap of the semiconductor, forming the spin-flip Raman laser. The most important practical case has probably been that of InSb, resonantly pumped near 5 μm with the CO laser. In this case the small effective mass of a narrow-gap semiconductor in the presence of substantial spin–orbit coupling leads to both an extremely large anomalous effective g-factor ($g^* \sim -50$) – giving a large tuning range, $\Delta E = \hbar\omega_{SF} = g^*\beta B$ – and a strong cross-section which is larger than that of the free electron by a factor $(m_0/m^*)^2$. Efficient cw operation is possible with threshold powers less than 50 mW.

SFR scattering has enabled the observation of a great variety of excitations in nonmagnetic and dilute magnetic semiconductors, including: free electrons and holes, electrons bound to donors and holes bound to acceptors, scattering from bound magnetic polarons, and scattering due to SF transitions within the Zeeman multiplets of paramagnetic ions. In addition to pure SF transitions, combined resonances with combinations such as $\omega_{CR} \pm \omega_{SF}$ have also been detected. The process has also been used in a similar manner to electron spin resonance to study coherent processes, including Raman photon echo spectroscopy in semiconductors.

Introduction

Techniques used to measure second-order susceptibility $\chi^{(2)}$ or nonlinear optical coefficients are described in this article, and some measured values are quoted. These are the parameters that describe the property of a material that is responsible for second-harmonic generation and other three-wave nonlinear optical interactions. These other interactions include sum- and difference-frequency generation in which two waves combine to generate a third wave of a frequency that is the sum or difference of the first two waves. Also included are optical parametric generation and optical parametric oscillation, in which a single pump wave generates two resulting waves with frequencies that sum to the frequency of the pump wave. The measurement techniques involve measuring the efficiency of nonlinear frequency conversion by these processes.

The measurements require a great deal of care and precision, and it is advisable to perform a comparison with previous measurements and obtain correlation with accepted standards whenever possible. A great deal of effort continues to be expended by researchers to establish correlations between measurements and provide additional values that are accepted as standards. A number of techniques have been used for these measurements sometimes yielding results that disagree. There are, however, values derived from early measurements that have proven accurate. In these measurements it is necessary to accurately control and characterize the polarization, power, spectral distribution, and spatial and temporal intensity distribution of the incident radiation and accurately measure the frequency-converted light, which can be many orders of magnitude smaller.

The development and availability of single-longitudinal-mode and nearly diffraction-limited lasers has greatly reduced the ambiguity and simplified increased accuracy of measurements of second-order nonlinear optical coefficients. The improved optical quality of nonlinear-optical crystals has also been an important component of the increased accuracy of measurement. Measurement techniques have also improved, providing absolute measurements of optical intensity over wide dynamic ranges at different wavelengths. Until the early 1990s, there was a range of measured values for nonlinear optical coefficients of common nonlinear materials, and numerous definitions were in use. Caution is required when consulting early publications on this topic, and some of this ambiguity is carried over to present time. Different definitions vary by factors of 2 and the permittivity of free space, $\varepsilon_0 \cong 8.854 \times 10^{-12}$ C/N $\times$ m^2. It is important that the definition of a nonlinear optical coefficient is clear before a value is used. This can be done through a statement of the nonlinear electric polarization or the coupled equations for nonlinear frequency conversion.

The standard techniques that have been used to measure nonlinear optical coefficients are covered in detail in publications listed in the Further Reading at the end of this article. Brief descriptions of some of these techniques, such as Maker-fringe and wedge,

optical parametric fluorescence, and phase-matched second-harmonic generation, will be presented in this article. Each of these techniques has a unique set of advantages and disadvantages. There was some lively controversy over the technique that provided the most accurate measurements and those measurements that should be dismissed. Measurements based on phase-matched second-harmonic generation had the advantage of being most similar to practical application of nonlinear optical frequency conversion. However, the large divergence and multiple-longitudinal-mode operation of early lasers made this method unreliable. Even relative comparisons of nonlinear optical coefficients between different materials were inaccurate because highly structured laser pulses had different conversion characteristics due to differences in bandwidth acceptance, group velocity walkoff, and birefringent walkoff in different materials.

Nonlinear optical coefficients of improved accuracy were required for analysis of optical harmonic conversion in the large, well-characterized laser systems used in inertial-confinement fusion research. The development of these systems provided a standardization on the value of $d_{36} = 0.39\ \text{pm V}^{-1}$ ($1\ \text{pm} = 10^{-12}\ \text{m}$) for second-harmonic generation of neodymium laser radiation in the material potassium dihydrogen phosphate (KH_2PO_4 or KDP). The development of injection-seeded Q-switched lasers provided single-longitudinal-mode laser output that allowed the phase-matched second-harmonic techniques to be extended to provide more accurate absolute measurements and relative comparisons on KDP and a number of other materials. Correlation was achieved on a larger number of relative and absolute measurements of nonlinear optical coefficients to provide some systematic agreement. It is not well understood why the earlier measurements referenced to optical parametric fluorescence produced values that were higher by about 60%. Measurement techniques have been further refined, and more exacting measurements are leading agreement, using different methods of measurement on an increasing number of nonlinear optical materials.

Definitions

The definition of the nonlinear optical coefficient can be specified in a number of ways. Examples given here are how the coefficient relates to the nonlinear electric polarization in a material, the coupled equations for nonlinear frequency conversion, and expressions describing second-harmonic generation with a monochromatic plane-wave fundamental.

The second-order optical nonlinearity is reported as both the second-order susceptibility $\chi^{(2)}$ and the second-order nonlinear optical coefficient d, which usually differ in definition by a factor of two. These are third-rank tensors that relate products of components of the electric field vector E_j and E_k to the vector components of the nonlinear polarization P_i^{NL}. The second-order susceptibility typically is used to express instantaneous values:

$$P_i^{NL}(t) = \varepsilon_0 \sum_{j,k} \chi_{ijk}^{(2)} E_j(t) E_k(t) \qquad [1]$$

whereas the nonlinear optical coefficient more often is used to relate the vector amplitudes of frequency components of these quantities. The electric field at the fundamental angular frequency ω can be expressed as

$$E_j(\omega, \mathbf{r}, t) = \frac{1}{2}\{E_j(\omega) \exp i(\mathbf{k}_\omega \cdot \mathbf{r} - \omega t) + c.c.\} \qquad [2]$$

and the nonlinear polarization at the harmonic frequency 2ω can be expressed as

$$P_i^{NL}(2\omega, \mathbf{r}, t) = \frac{1}{2}\left\{P_i^{NL}(2\omega) \exp i(2\mathbf{k}_\omega \cdot \mathbf{r} - 2\omega t) + c.c.\right\} \qquad [3]$$

The intensity is given by $I = (nc\varepsilon_0/2)|E|^2$. The relationship between the complex amplitudes expressed in terms on the nonlinear optical coefficient tensor is

$$P_i^{NL}(2\omega) = \varepsilon_0 \sum_{j,k} d_{ijk}(-2\omega; \omega, \omega) E_j(\omega) E_k(\omega) \qquad [4]$$

When waves of three different frequencies are involved, the expression becomes

$$P_i^{NL}(\omega_3) = 2\varepsilon_0 \sum_{j,k} d_{ijk}(-\omega_3; \omega_2, \omega_1) E_j(\omega_2) E_k(\omega_1) \qquad [5]$$

Expressing the coefficient as $d_{ijk}(-\omega_3; \omega_1, \omega_2)$ allows for dispersion and indicates that fields at frequencies ω_1 and ω_2 interact to produce a nonlinear polarization at frequency ω_3, the sum of the first two frequencies. The relationship between the second-order electrical susceptibility and the second-order nonlinear optical coefficient is

$$\chi_{ijk}^{(2)} = 2 d_{ijk} \qquad [6]$$

The dispersion of nonlinear optical coefficients is approximated by the use of Miller's delta:

$$\delta_{ijk} = \frac{d_{ijk}(-\omega_3; \omega_2, \omega_1)}{(n_i^2(\omega_3) - 1)(n_j^2(\omega_2) - 1)(n_k^2(\omega_1) - 1)} \qquad [7]$$

The indices of refraction in the direction of the electric field components $E_m(\omega_n)$ are $n_m(\omega_n)$ for $m=i,j,k$ and $n=1,2,3$. There is some theoretical and experimental justification for treating the components of Miller's delta as constants. Earlier definitions of Miller's delta included multiplication by ε_0, the permittivity of free space.

The nonlinear optical coefficient is usually reduced to a scalar quantity, the effective nonlinear coefficient or d_{eff}, that relates only the specific vector components of the fields involved in the interaction. The effective nonlinear optical coefficient will be discussed in more detail later. The coupled equations for second-harmonic generation using d_{eff} are

$$\frac{\mathrm{d}E_{2\omega}(z)}{\mathrm{d}z} = \mathrm{i}\frac{\omega d_{\text{eff}}}{n_{2\omega}c}E_{\omega}(z)E_{\omega}(z)\exp(-\mathrm{i}\,\Delta k z) \quad [8]$$

$$\frac{\mathrm{d}E_{\omega}(z)}{\mathrm{d}z} = \mathrm{i}\frac{\omega d_{\text{eff}}}{n_{\omega}c}E_{\omega}(z)E^{*}_{\omega}(z)\exp(\mathrm{i}\,\Delta k z) \quad [9]$$

Here ω is the angular frequency of the fundamental wave; z is distance in the direction of propagation, $n_{2\omega}$ and n_{ω} are the refractive indices of the harmonic and fundamental respectively; and c is the speed of light in free space. The complex electric field amplitudes of the harmonic and fundamental, $E_{2\omega}(z)$ and $E_{\omega}(z)$, respectively, are assumed to be slowly varying functions of position compared with the oscillation of the carrier waves $\exp \mathrm{i}(\mathbf{k}_{2\omega}\cdot\mathbf{r} - 2\omega t)$ and $\exp \mathrm{i}(\mathbf{k}_{\omega}\cdot\mathbf{r} - \omega t)$, with $\mathbf{k}_{2\omega}$ and $\mathbf{k}_{\omega}$ the wavevectors of harmonic and fundamental; the asterisk indicates complex conjugate. The quantity Δk is the wavevector mismatch and is given by $\Delta k = k_{2\omega} - 2k_{\omega}$. These are simplified expressions that apply to nearly monochromatic plane waves. Two solutions to the coupled equations are

$$I_{2\omega}(z) = \frac{2\omega^2 d_{\text{eff}}^2 l^2 I_{\omega}^2(0)}{n_{2\omega}n_{\omega}^2c^3\varepsilon_0}\frac{\sin^2(\Delta k z/2)}{(\Delta k z/2)^2} \quad [10]$$

for insignificant depletion of the fundamental amplitude and

$$I_{2\omega}(z) = I_{\omega}(0)\tanh^2\sqrt{\frac{2\omega^2 d_{\text{eff}}^2 z^2 I_{\omega}(0)}{n_{2\omega}n_{\omega}^2c^3\varepsilon_0}} \quad [11]$$

for the case of perfect phase matching $\Delta k = 0$ and allowing depletion of the fundamental. The quantity $I_{2\omega}(z)$ is the harmonic intensity after propagating a distance z in the nonlinear material, and $I_{\omega}(0)$ is the fundamental intensity at the input surface of the nonlinear material where $I_{2\omega}(0) = 0$.

The above relationships for nonlinear polarization, the coupled equations for second-harmonic generation, or harmonic conversion of a monochromatic plane wave, each determine the definition of the second-order nonlinear optical coefficient.

Symmetry

Symmetry has an important role in the measurement of nonlinear optical coefficients. Indeed the second-order nonlinear optical coefficient must be identically zero if the material has inversion symmetry. This restricts materials to noncentrosymmetric crystals or isotropic materials in which inversion symmetry is removed by such techniques as application of an electric field or polymeric materials in which alignment of molecules is achieved by some poling process. The discussion here is limited to noncentrosymmetric crystals.

The nonlinear optical coefficient is a tensor of rank 3. Representation of the tensor in a rotated coordinate system is described by

$$d'_{ijk} = \sum_{l,m,n} R_{il}R_{jm}R_{kn}d_{lmn} \quad [12]$$

where R_{il} is the matrix that describes rotation of the initial coordinate system xyz to the new coordinate system $x'y'z'$. The representation of a vector r_l in the original coordinate system becomes $r'_{\mathrm{i}} = \sum_l R_{il}r_l$ in the new coordinate system. A required symmetry property of the nonlinear optical tensor, that exchange of the second two indices of a component does not change the value of the component $d_{ijk} = d_{ikj}$, allows the third-rank tensor to be written as a 3 by 6 matrix:

$$\begin{pmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} & d_{16} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} & d_{26} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} & d_{36} \end{pmatrix} \quad [13]$$

with the components of the matrix related to the tensor components by

$$\begin{aligned} &d_{i1} = d_{i11} \quad d_{i4} = d_{i23} = d_{i32} \\ &d_{i2} = d_{i22} \quad d_{i5} = d_{i13} = d_{i31}, \; i = 1,2,3 \\ &d_{i3} = d_{i33} \quad d_{i6} = d_{i12} = d_{i21} \end{aligned} \quad [14]$$

A further property, tensor components with any permutation of the indices are equal $d_{ijk} = d_{kij}$, called Kleinman symmetry or Kleinman's conjecture, is often applied if there is no absorption at any of the wavelengths involved. Kleinman symmetry assures that the amount of energy depleted from the

fundamental is equal to the amount of energy gained by the second harmonic. This reduces the number of independent components of the nonlinear optical matrix to 10: d_{11}; $d_{12} = d_{26}$; $d_{13} = d_{35}$; $d_{14} = d_{25} = d_{36}$; $d_{15} = d_{31}$; $d_{16} = d_{21}$; d_{22}; $d_{23} = d_{34}$; $d_{24} = d_{32}$; and d_{33}. Sometimes components equal, according to Kleinman symmetry, are measured individually, either as a check of the measurement or to check the validity of the conjecture.

Crystal symmetry places additional constraints on the components of the nonlinear optical matrix. These constraints determine the components that must be zero and determine additional relationships between the nonzero components. Matrices for selected crystal point groups are given in Table 1. Effective nonlinear optical coefficients can be found by a coordinate frame transformation in which the rotated axes align with the direction of propagation and the eigen polarizations. Effective nonlinear coefficients for a few crystal point groups are given in Table 2. More complete listings of both the reduced matrices and effective nonlinear optical coefficients are given elsewhere.

Measurements

Usually the symmetry of a nonlinear crystal is determined by techniques such as X-ray diffraction or surface morphology. Crystal symmetry determines the nonzero components of the second-order nonlinear optical tensor. Nonphase-matched second-harmonic-generation techniques, such as Maker-fringe and wedge measurements, allow selection of polarizations and propagation directions relative to the crystal lattice that isolates individual components of the tensor. Phase-matched measurement techniques usually require propagation in a direction for which an effective nonlinear optical coefficient applies and can involve more than one tensor component. Parametric fluorescence and sum- and difference-frequency-generation measurements are phase-matched processes that involve three wavelengths. All of the measurement techniques have been used with pulsed and continuous-wave laser output. In all of these methods, except parametric fluorescence, it is necessary to accurately characterize the incident radiation. Measurements relative to a standard material avoid some of the concerns of characterization of the fundamental radiation. Relative measurements are important in that they allow correlation between different sets of measurements. Measurement sets, that include both relative and absolute measurements on a number of materials, are useful in developing correlations that achieve more accurate compilations of values.

It is desirable to have an incident beam with a Gaussian-like transverse intensity distribution and close to diffraction limited propagation. Gaussian beams have advantages that they are most easily characterized and their propagation is described with relatively simple analytical methods. Accurate temporal characterization of the incident light is also essential. Here it is desirable to have stable single-mode laser operation to produce narrow bandwidth light that is well within phase-matching acceptance bandwidths and that has temporal structure slow enough to be easily characterized and slow enough

that group-velocity mismatch will be of no concern. Generating such laser output usually requires special techniques, such as injection-seeded pulse operation or stabilized single-frequency cw operation. Often spatial filters are required to improve the beam quality on the laser output. Even though these topics are only mentioned here, the techniques are important and demand much effort.

The analysis of measurements can also be complicated. Consider the Maker-fringe measurement technique (Figure 1). In this method a focused fundamental beam is incident on a thin slab of oriented nonlinear optical material for nonphase-matched second-harmonic generation. The thickness of the slab is large enough that the function $\sin(\Delta kz/2)$ has gone through many cycles. As the crystal is rotated both the path length in the material l and the wave vector mismatch Δk change, and $\sin^2(\Delta k \cdot l/2)$ oscillates between maxima and minima (Figure 2). The coherence length $L_c = \pi/\Delta k$ is normally small enough that conversion remains in the region of small depletion of the fundamental. Knowledge of the material dispersion and birefringence, required to calculate Δk, or L_c, can be obtained from the fringe spacing. Ideally, the incident fundamental beam will be focused to a spot size w_0, small enough to provide measurable harmonic conversion but large enough that the near-field approximation, in which diffraction is not significant, can be used for analysis of harmonic generation. In this case integration over the incident fundamental intensity distribution $I_\omega(r, z = 0) = I_{\omega,0} \exp(-2r^2/w_0^2)$ yields an expression for the harmonic power:

$$W_{2\omega}(\alpha) = \frac{8\omega^2 d_{\text{eff}}^2(\alpha) W_\omega^2 L_c^2(\alpha)}{\pi^3 w_0^2 n^3 c^3 \varepsilon_0} \sin^2\left(\frac{\pi l(\alpha)}{2L_c(\alpha)}\right) \times \text{correction factors} \quad [15]$$

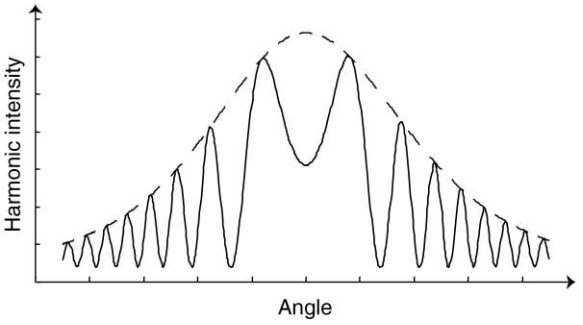

Figure 2 The envelope and spacing of the fringes allow determination of the second-order nonlinear optical coefficient and the coherence length.

where α is the angle of incidence of the fundamental radiation, $W_{2\omega}(\alpha)$ is the second harmonic power, and W_ω is the incident fundamental power. This equation applies to cw radiation. It is necessary to integrate over the temporal distributions for pulsed fundamental light. The effective nonlinear coefficient $d_{\text{eff}}(\alpha)$, the path length in the crystal $l(\alpha)$, and the coherence length $L_c(\alpha)$ change with the angle of incidence α. The correction factors include Fresnel losses at the crystal surfaces, harmonic generation at the surfaces, multiple reflections between the surfaces, absorption at either fundamental or harmonic wavelengths, and walkoff due to non-normal incidence and birefringence.

The wedge technique (Figures 3 and 4) also uses nonphase-matched second-harmonic generation. A wedged sample is translated through a focused fundamental beam, and the above equation applies with the angle α constant. The crystal length l varies with transverse position. It is important that the wedge angle and the fundamental beam spot size are chosen so that the entire beam fits well within a maximum of conversion and the beam is large enough to avoid divergence due to diffraction. Both the Maker-fringe

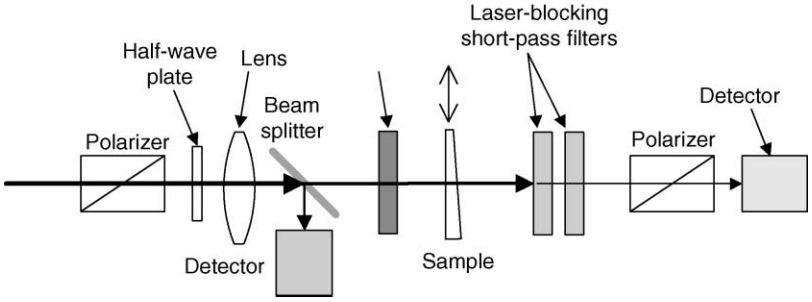

Figure 3 The setup for wedge measurements is similar to that used for Maker-fringe measurements but with a wedged sample translated in the fundamental beam to change path length.

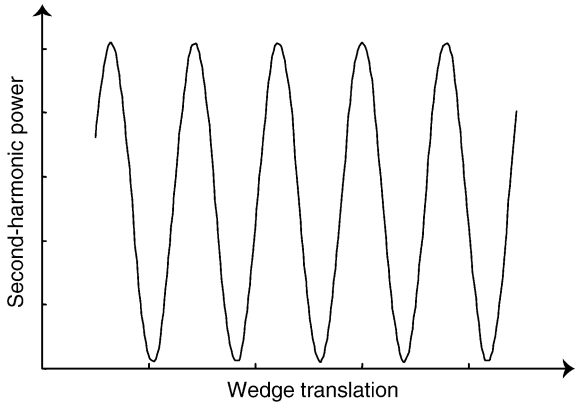

Figure 4 The harmonic intensity cycles between a minimum and maximum when the path is changed by one coherence length.

and wedge measurements have the advantage of being able to isolate individual components of the nonlinear optical tensor. Harmonic power can be low with cw beams requiring chopped, lock-in detection methods or even photon-counting techniques. Even with pulsed fundamental radiation, peak harmonic power may only be at the level of milliwatts. It is necessary to isolate the harmonic radiation from the fundamental radiation that could have peak power in the range of 10^5 W for a Q-switch laser.

Phase-matched second harmonic generation (Figure 5) offers a measurement technique that is similar to practical applications. Harmonic signals are large, thus simplifying detection. However, it is helpful to keep conversion levels below a few percent to allow the use of small depletion approximations in data analysis. Good optical quality of the nonlinear optical material and good quality and accurate characterization of the fundamental radiation are important in this measurement technique. The analysis is simplified for low levels of conversion, spectral distribution well within the phase-matching bandwidth, no absorption or other losses, and no significant diffraction or walkoff. If the fundamental intensity is a pulse with distribution of $I_\omega(r,t) = I_{\omega,0} \exp(-t^2/\tau^2) \exp(-2r^2/w_0^2)$, integration yields second-harmonic energy:

$$U_{2\omega} = \int_{-\infty}^{\infty} \mathrm{d}t \int_0^{\infty} 2\pi r \, \mathrm{d}r I_{2\omega}(r, z = l)$$

$$\approx \frac{2\sqrt{2}\omega^2 d_{\mathrm{eff}}^2 l^2 U_\omega^2}{n^3 c^3 \varepsilon_0 \pi^{3/2} \tau w_0^2} \frac{\sin^2(\Delta k l/2)}{(\Delta k l/2)^2} \qquad [16]$$

where $U_{2\omega}$ is the second harmonic energy and U_ω is the fundamental energy, r is the radial coordinate, t is time, and l is the length of the material. Harmonic conversion can be measured as Δk and varied, either by crystal rotation or temperature change, to confirm that optical quality of the nonlinear material and incident fundamental radiation are a level of tuning that is accurately predicted by theory (Figure 6). Even this simplified equation shows the importance of accurate characterization of the fundamental radiation and second-harmonic conversion in obtaining values of the nonlinear optical coefficient. Conversion efficiency is calculated more accurately with detailed analytical techniques or numerical methods, provided accurate and complete characterization of the fundamental radiation is available.

Parametric fluorescence, in principle, offers an experimental simplification over second-harmonic generation techniques. Parametric fluorescence (Figure 7) is a phase-matched technique in which a pump beam of angular frequency ω_p produces a signal beam and an idler beam of angular frequencies $\omega_\mathrm{s} + \omega_\mathrm{i} = \omega_\mathrm{p}$ by the process of spontaneous parametric generation. It is only necessary to measure the ratio of the generated signal power W_s and the incident pump power W_p. The signal power is given by

$$W_\mathrm{s} = \frac{2(h/2\pi)\omega_\mathrm{s}^4 \omega_\mathrm{i} d_{\mathrm{eff}}^2 n_\mathrm{s} l W_\mathrm{p} \Omega}{(2\pi)^2 \varepsilon_0 c^5 n_\mathrm{i} n_\mathrm{p} |\partial \Delta k / \partial \omega_\mathrm{s}|_{\omega p}} \qquad [17]$$

where h is Planck's constant, Ω is the solid angle of detection (inside the crystal), and n_s, n_i, and n_p are

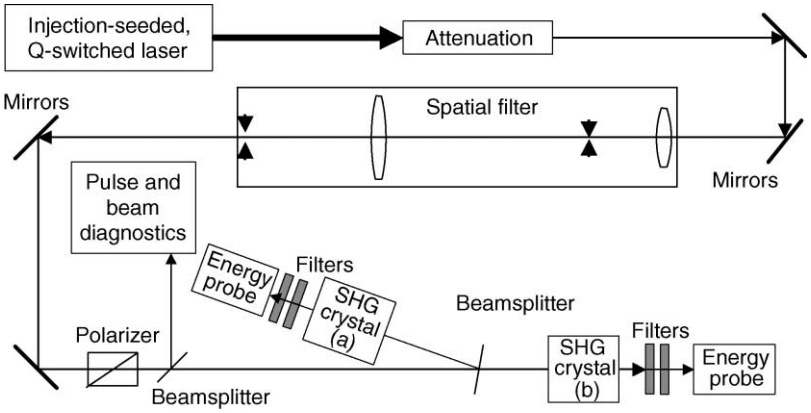

Figure 5 A setup for a relative measurement of second-order nonlinear optical coefficient based on phase-matched second-harmonic generation is shown.

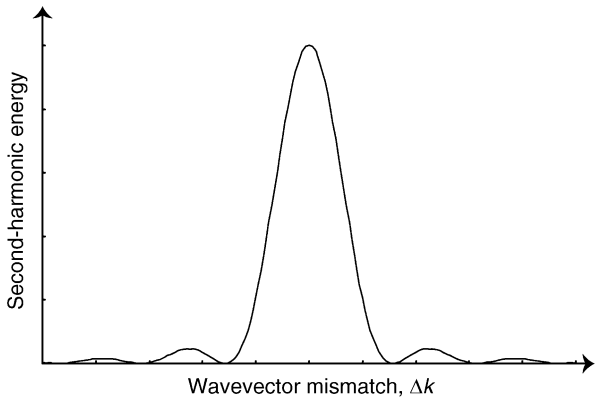

Figure 6 Observation of a theoretically predicted phase-matching tuning curve confirms required optical quality.

the indices of refraction of the signal, idler, and pump respectively. The absolute value of the partial derivative of $\Delta k = k_p - k_s - k_i$, with respect to signal frequency with the pump frequency held constant, is

$$|\partial \Delta k/\partial \omega_s|_{\omega p} = \frac{1}{c}\left| n_s - n_i + \omega_s \frac{dn_s}{d\omega_s} - \omega_i \frac{dn_i}{d\omega_i} \right| \quad [18]$$

It is still not well understood why the carefully performed earlier measurements by this method produced nonlinear optical coefficient values larger than those obtained by other techniques.

Tabulations of measurements of nonlinear optical coefficients are included in handbooks. The Internet posting 'SNLO' listed in the Further Reading is a good source of up-to-date values. Table 3 lists some nonlinear optical coefficients obtained from several sources. Signs of these coefficients are not always well determined, and they are reproduced where given and may only indicate relative polarity. Point group symmetry is given with some comments about axis assignments for the *mm*2 point group. The fundamental wavelength is given for second-harmonic measurements and twice the shortest wavelength is given for three-wave processes. Many of the values obtained by Shoji *et al.* are based on carefully performed wedge measurements with single frequency cw lasers and taking detailed account of multiple reflections in the analysis. Their measurements for congruent $LiNbO_3$ reported agreement between Maker-fringe and wedge measurements, and phase-matched difference-frequency generation measurements, and finally agreement with parametric fluorescence. The measurements of Alford and Smith combined optical-parametric amplification and second-harmonic generation at a number of different wavelengths and correlation with values previously reported in the literature to examine the validity of using a constant Miller's delta, and reported best-fit values for the second-order nonlinear coefficient. Constant Miller's delta provided reasonably accurate wavelength scaling, with good agreement for most materials in recent measurements.

The measurements of the nonlinear optical coefficients of $KNbO_3$, listed in Table 3 are of particular interest. These measurements were performed by the separated-beam wedge technique (Figure 8). With this technique, a large wedge angle is used in a relatively long crystal and with a larger fundamental beam than in the conventional wedge technique. The beam is large enough that many fringes are present in the second-harmonic at the exit surface. The fringe structure causes focused harmonic radiation to diffract into two clearly resolved spots. Integration of an earlier equation, with constant fundamental field amplitude $E_\omega(0)$, provides a simplified expression of the second-harmonic field $E_{2\omega}(z,t)$ in terms of a free wave with propagation constant

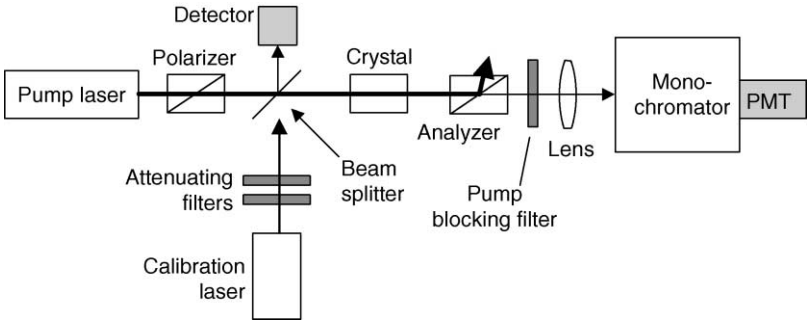

Figure 7 Spontaneous optical parametric fluorescence requires measurement of the ratio of the power of the signal fluorescent to the power of the pump radiation. The calibration laser is used to measure the signal transmission of the filtering system used to block the pump radiation from reaching the photomultiplier tube (PMT).

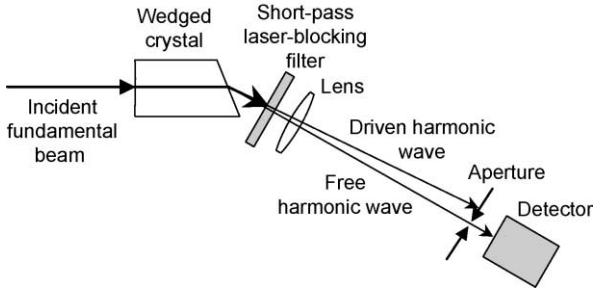

Figure 8 In the separated-beam wedge measurement technique, a fundamental beam of large transverse size generates harmonic radiation that is separated into a free harmonic wave and a driven harmonic wave after exiting the crystal.

$k_{2\omega}$ and a driven wave with propagation constant $2k_\omega$:

$$E_{2\omega}(z,t) = \frac{\omega d_{\text{eff}} E_\omega^2(0)}{n_{2\omega} c} \frac{1}{\Delta k} \{\exp i(k_{2\omega} z - 2\omega t) + c.c.\} - \frac{\omega d_{\text{eff}} E_\omega^2(0)}{n_{2\omega} c} \frac{1}{\Delta k} \{\exp i(2k_\omega z - 2\omega t) + c.c.\} \quad [19]$$

The two beams with different propagation constants are refracted at different angles at the wedged exit surface. The detailed analysis must include losses due to absorption and reflections at the surfaces and also nonlinear effects at the surfaces. Precision again is required in characterizing the fundamental beam and incident and generated intensities or energies as well as the geometry of the measurement. The large wedge eliminates problems of multiple reflections, and it is no longer necessary to carefully choose the beam spot size to fit within one fringe maximum, yet be large enough to allow use of the near field approximation. The accuracy of this measurement is demonstrated when the coefficients are expressed as Miller-delta values: $\delta_{24} = 0.153\,\text{pm V}^{-1}$, $\delta_{32} = 0.150\,\text{pm V}^{-1}$, $\delta_{15} = 0.195\,\text{pm V}^{-1}$, and $\delta_{31} = 0.192\,\text{pm V}^{-1}$. These values satisfy Kleinman symmetry, $\delta_{24} = \delta_{32}$ and $\delta_{15} = \delta_{31}$, well within the reproducibility of the measurement, which was about ± 3%.

The nonlinear optical coefficients of BBO $d_{22}(1064\text{ nm}) = 2.3\text{ pm V}^{-1}$ and KDP $d_{36}(1064\text{ nm}) = 0.39\text{ pm V}^{-1}$ are gaining agreement from a number of independent measurements. The apparent disparity in the values for GaAs $d_{36}(10.6\,\mu\text{m}) = 83\text{ pm V}^{-1}$ and $d_{36}(1064\text{ nm}) = 170\text{ pm V}^{-1}$, is resolved when the coefficients are converted to Miller's delta values: $\delta_{36} = 0.089\text{ pm V}^{-1}$ and $\delta_{36} = 0.086\text{ pm V}^{-1}$, respectively. The same thing can be done for GaP, for which $d_{36}(10.6\,\mu\text{m}) = 37\text{ pm V}^{-1}$ and $d_{36}(1064\text{ nm}) = 70.6\text{ pm V}^{-1}$ convert to $\delta_{36} = 0.085\text{ pm V}^{-1}$ and $\delta_{36} = 0.077\text{ pm V}^{-1}$, respectively. However, the older and newer values for other materials such as CdTe and CdS do not achieve this agreement. Other materials such as CLBO and LBO need additional investigation to resolve differences. The measurement of nonlinear optical coefficients is a continuing process.

Other techniques for measurement involving different nonlinear-optical processes are possible. Parametric amplification was mentioned above. Generally more complicated processes are less well suited for measurement of fundamental properties. Integrated-optical devices such as waveguides are even more complex. Often nonlinearity is measured in fractional conversion per unit of pump power to characterize overall device performance. There are survey techniques for evaluating materials such as grinding the material to a powder, illuminating with intense laser radiation, and looking for harmonic conversion. A surprising amount of information, such as a rough estimate of nonlinearity and the possibility of birefringent phase matching, can be gleaned by sorting the power and measuring the scattered harmonic radiation. Second-harmonic reflections from surfaces and thin film can be used in some instances. Electric fields can be use to orient molecules in polymers and solute molecules in solution to measure the hyperpolarizability of individual molecules.

Reporting Frames

Standardized axis specifications avoid confusion, but nonstandard axes can prove convenient in some applications provided care is used. The crystal $KNbO_3$ has *mm*2 point group; it could also be *m*2*m* or 2*mm* depending on the choice of axes to describe the crystal properties. The axis assignment for the orthorhombic class *mm*2, as it is used in Table 3, follows the IEEE/ANSI Std. 176-1987: Z is the polar axis, X is parallel to the shorter of the remaining unit cell dimensions, and Y is chosen to complete a right-handed coordinate frame. Polarity of the axes can be assigned by pyroelectric properties and piezoelectric properties of the crystal. The common assignments of the axes in the literature are given by X_L, Y_L, Z_L in the table. Reference to the biaxial indices of refraction are given by the lower case x, y, z with $n_x < n_y < n_z$. Finally the axes are identified by the unit cell dimensions $s < m < l$. Either a plus or minus rotation about the Y axis will bring the crystal into an *xyz* frame. However, a $+90$ degree rotation will give coefficients that are opposite in sign from a -90 degree rotation. The signs of the nonlinear optical coefficients are often not well determined because sign is not obtained from conversion efficiency in a single crystal. However, coefficient signs can be compared in the same crystal or between two crystals to determine if they are the same or opposite.

The crystals KTP or KTA are used here as an example. A 90° rotation about the Z-axis gives a new coordinate system $X'Y'Z'$ aligned with the *xyz* frame determined by the indices of refraction. In the new frame, the component of the nonlinear optical tensor, in terms of the standard frame, are $d_{zxx} = d_{32}$ and $d_{zyy} = d_{31}$. All that is needed here is to exchange d_{32} and d_{31} to change the standard frame to the one commonly used in the literature, X_L, Y_L, Z_L. When the largest index of refraction is not aligned with the polar axis, as is the case for LBO and $KNbO_3$, the specification of tensor components can become confusing if a standard frame is not used.

Often crystallographers and crystal manufacturers can identify axes by surface morphology or by poling processes of ferroelectric crystals. With other crystal symmetries a change in the reporting frame that does not change linear optical properties may change the sign of some of the nonlinear optical tensor components while leaving others unchanged. For a crystal of *3m* point group, a 180° rotation about Z will change the sign of d_{22}, d_{21}, and d_{16} and leave the other coefficients unchanged. The *xyz* frame with $n_x < n_y < n_z$ is convenient for calculations of optical propagation, and the standard XYZ frame is unambiguous for reporting of tensor properties.

Conclusion

There is still a range of values for nonlinear optical coefficients of many materials. Standardization is evolving on more commonly used materials. Greater precision in measurement and extension of measurement techniques are providing better accuracy. However, caution is still required when accessing values. It is necessary to scrutinize the sources of values to obtain the highest accuracy. Accurate measurements need to be extended to difficult spectral ranges of the ultraviolet and infrared. The ambiguity of the sign of tensor components needs to be resolved. In recent measurements, carefully executed wedge measurements are producing more reliable results. The separated beam wedge technique appears to be particularly promising. Phase-matched second-harmonic generation and other practical applications of nonlinear optical materials will continue to serve as techniques to verify accuracy. Current analytical and numerical techniques provide a method for precise modeling of nonlinear optical processes and the need for more accurate material characterization.

Introduction

Over the past 30 years, several methods have been used to measure and characterize optical nonlinearities. With increasing interest in nonlinear optics beyond the traditional harmonic generation, third-order nonlinear processes have been shown to be responsible for self-focusing and defocusing of optical beams, phase conjugation, optical bistability, etc. Third-order nonlinear processes in Kerr materials arise from the cubic dependence of the polarization $P = P^{L} + P^{NL}$, $P^{NL} = \chi^{(3)}{:}E{\cdot}E{\cdot}E$ in a material on the optical field E, through the nonlinear susceptibility tensor $\chi^{(3)}$. The cubic nonlinearity in turn results in a nonlinear refractive index coefficient n_2 defined through:

$$n = n_0 + n_2|E_p^{\omega_0}|^2 \qquad [1]$$

where $E_p^{\omega_0}$ is the phasor part of E : $E = Re[E_p^{\omega_0}\exp \times j\omega_0 t]$. The relation between $\chi^{(3)}$ and n_2 can be expressed as:

$$n_2 = (3/8n_0)\chi^{(3)}_{1111}(-\omega_0; \omega_0, \omega_0, -\omega_0) \qquad [2]$$

In some materials, an effective $\chi^{(3)}$ or an effective n_2 can be defined as well. For instance, in a second-order nonlinear material, an effective $\chi^{(3)}$ is established through cascading of $\chi^{(2)}$s, and in the presence of phase mismatch between the fundamental and the second harmonic. In other materials, such as liquid crystals, an effective n_2 can be defined due to the nonlinear dependence of the reorientation of the director axis on the optical field. In photorefractive materials, the induced nonlinearity stems from the nonlinear dependence of the induced space charge distribution in the material on the optical field. Some of the techniques used to measure the third-order nonlinearity in materials include degenerate four-wave mixing (DFWM) or phase conjugation, interferometry, ellipse rotation, and beam self-refraction and/or distortion and bending.

For instance, in DFWM, two contradirectional propagating pumps and the probe beam having the same frequency ω_0 interact to give rise to the conjugate, whose amplitude depends on the magnitude of the cubic nonlinearity coefficient. The conservation of energy and momentum describes a parametric interaction of the form $\omega_0 + \omega_0 - \omega_0 \rightarrow \omega_0$ (in frequency space) and, $\mathbf{k}_{probe} + \mathbf{k}_{pump1} - \mathbf{k}_{pump2} \rightarrow \mathbf{k}_{conj}$ (in $\mathbf{k}$-space). The conjugate beam is clearly distinguishable by its spatial separation from the other interacting waves. However, alignment of the three waves is critical to obtain a good phase conjugate; furthermore, the sign of the nonlinearity cannot be determined.

In the interferometric method, a laser beam is split into two parts, one serving as the reference, and the other being incident on the nonlinear sample. As in the case of interferometers, if the two beams are then recombined and introduced through a lens, an

interference pattern forms at the focal plane of the lens. While the information about the magnitude of the nonlinearity can be found from the fringes and their change when the incident power is varied, information of the sign of the nonlinearity is still not readily inferable.

In this article, we will concentrate on self-refraction, particularly in light of the fact that it results in a sensitive and at the same time simple method called the *z*-scan©, requiring the propagation of a single beam through the nonlinear sample. We comment that self-diffraction does also cause self-bending of an asymmetric beam due to the asymmetric phase change induced through the cubic nonlinearity; however, extracting the information of the sign and magnitude of the nonlinearity can be effectively done only if the sample is thin, implying that there is negligible linear diffraction of the beam as it passes through the sample. In the rest of the article, we will therefore concentrate on the *z*-scan method, since it is an elegant and simple single (symmetrical) beam technique that yields information on the magnitude and sign of the cubic nonlinearity, as well as its real and imaginary parts. We will describe in detail how the *z*-scan can measure the real part of the cubic nonlinearity, for both thin and thick samples, as well as showing its application in determining the reorientational nonlinearity of liquid crystals and the nonlinearity of photorefractive materials, where photovoltaic effect and diffusion of charge carriers contribute to the effective nonlinearity.

Since the mid-1990s *z*-scan has evolved as a standard method for determining effective nonlinear refractive index coefficients of nonlinear materials. The name *z*-scan is derived from the fact that the nonlinear test sample is scanned along the direction of propagation (z) of a beam about the back focal plane of an external lens illuminated by an incident Gaussian beam from a laser. The far-field diffraction pattern yields information about the nonlinearity of the test material. The *z*-scan technique has been used to measure and characterize the nonlinear refractive index coefficient and nonlinear absorption coefficient in materials such as CS_2, ZnSe, Cs atoms, multiphoton absorption in GaN, organic dyes, thermal nonlinearities in liquids, liquid crystals, photorefractive materials, etc., to name a few. *z*-scan measurements have been made using non-Gaussian incident beams, and *z*-scans have been performed using both CW and pulsed laser sources.

The first extensive series of work on the *z*-scan technique, including analysis and application to the measurement of the cubic nonlinearity, was performed by the group of Van Stryland at the Center of Electro-Optics and Lasers (CREOL) at the University of Central Florida. Other investigators later performed similar measurements and characterization during the study of nonlinear optical properties of a solution of chlorophyll in acetone, and Chinese tea.

Theory of the Thin Sample *z*-Scan

We will first analyze propagation of a (circularly symmetric) Gaussian beam which is initially focused by an external lens and is then incident on a 'thin' slice of a cubically nonlinear Kerr medium. This case is important because, as explained below, it provides a basis for the measurement of the nonlinear refractive index coefficient n_2.

Figure 1 shows a simple ray diagram to demonstrate what happens if the cubically nonlinear material is thin. The propagating Gaussian beam induces its own lens, which is positive for a material having a positive n_2, for reasons that will become clear to the reader later on in this section. Note that if the position of the induced lens is at the back focal plane of the external lens, the former does not affect the propagation of the beam behind the nonlinear material. The situation is thus the same as the propagation of the externally focused Gaussian beam in a linear diffraction-limited environment. However, if the separation between the external lens and the sample is less than the focal length f of the external lens, the beam in the far field is wider than the linear diffraction-limited case. Conversely, if the lens-sample separation is larger than f, the beam width is smaller. This is the basis of the *z*-scan: for a material with a positive n_2, the scanning of a thin nonlinear sample through the back focal plane of the external lens, starting from a position to the left of the focus, yields far-field profiles which are initially larger and eventually smaller than the width in the linear diffraction-limited case. The opposite is true for materials with a negative n_2. For very large displacements of the sample from the back focal plane of the

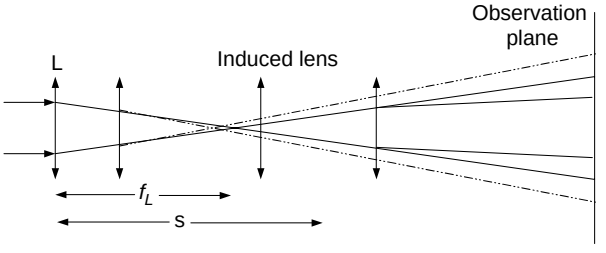

Figure 1 Geometrical optics picture of *z*-scan setup for nonlinear refractive index n_2. Reproduced with permission from Banerjee PP (2004) *Nonlinear Optics: Theory, Numerical Modeling, and Applications.* New York: Marcel Dekker.

external lens, the beam power is small enough that nonlinear lensing is negligible, and hence the beam widths return to the linear diffraction-limited case. The variation of the on-axis intensity or transmittance as a function of scan distance is complementary to the variation of the width, due to conservation of power, to be explained further below. A sketch of the on-axis transmittance during a z-scan for a positive n_2 material, is shown in Figure 2.

The simpler ray picture described above can be augmented by using a q parameter approach to Gaussian beam propagation. For the sake of simplicity, we prefer to introduce the q parameter approach here, instead of the more rigorous Gaussian decomposition of the induced phase as computed by Van Stryland's group. The q of a Gaussian beam in air is defined through the relation $1/q = 1/R - \mathrm{i}(2/k_0 w^2)$, where R and w denote the radius of curvature and the beamwidth, respectively, and k_0 is the propagation constant in air. Assume a Gaussian beam with a waist w_0 (implying initially planewave fronts) incident on the external lens. The Gaussian can be described by $q = q_0 = \mathrm{i}z_{R0}$, where $z_{R0} = k_0 w_0^2/2$ is called the Rayleigh length of the incident Gaussian. The laws of q transformation of a Gaussian beam are:

(i) for translation through a distance d, the q changes to $q + d$; and
(ii) for a Gaussian with q-parameter q incident on a lens, the q immediately behind the lens, is given by $(1/q - 1/f)^{-1}$.

Using these laws, the $q = q_{\mathrm{obs}}$ of the Gaussian at a distance d from the nonlinearly induced lens of the focal length f_{ind}, which is located at a distance $s = f + \Delta s$ behind the external lens, can be found as:

$$q_{\mathrm{obs}} = \frac{f_{\mathrm{ind}}[q_0 f + (f - q_0)(f + \Delta)]}{f_{\mathrm{ind}}(f - q_0) - [q_0 f + (f - q_0)s]} + d \qquad [3]$$

In deriving eqn [3], we have used the laws of q transformation on the initial Gaussian beam of q-parameter q_0 passing through the external lens, being translated a distance $f + \Delta s$, passing through the induced lens, and finally being translated a distance d to the observation plane.

To determine $f_{\mathrm{ind}}(\Delta s)$, assume a Gaussian of the form:

$$|E_{\mathrm{p}}^{\omega_0}(x, y, z)| = E(z)\exp(-(x^2 + y^2)/w^2(z)) \qquad [4]$$

Since

$$n = n_0 + n_2|E_{\mathrm{p}}^{\omega_0}|^2 \approx n_0 - 2n_2E^2(z)(x^2 + y^2)/w^2(z) \qquad [5]$$

the nonlinearly induced phase change is

$$\Delta\phi = k_0 n\Delta z \approx k_0[n_0 - 2n_2E^2(z)(x^2 + y^2)/w^2(z)]\Delta z \qquad [6]$$

so that

$$f_{\mathrm{ind}}(z) = n_0 w^2(z)/4n_2a^2(z)\Delta z \qquad [7]$$

Note that $f_{\mathrm{ind}}(z)$ is inversely proportional to $n_2E^2(z)$ and Δz. The longer the sample length, the more the nonlinear induced phase, implying a stronger lensing (smaller f_{ind}). Also, the stronger the nonlinearity parameter n_2 and/or on-axis intensity ($E^2(z)$), the stronger the focusing since the change in n is larger.

We must point out that the focal length f_{ind} of the induced lens is also a function of Δs, since it depends on the beam intensity at the location of the nonlinear sample. In fact, the focal length f_{ind} of the nonlinearly induced lens can be expressed in terms of the beam power P, the beam width w at the position Δs, f (the focal length of the external lens), the linear refractive index n_0, the nonlinear refractive index coefficient n_2 defined through eqn [1] where $|E_{\mathrm{p}}^{\omega_0}| = E$ is the optical field in the nonlinear material of length L, assumed 'thin' for now. The term 'thin' means that the sample length is smaller than the depth of focus of the

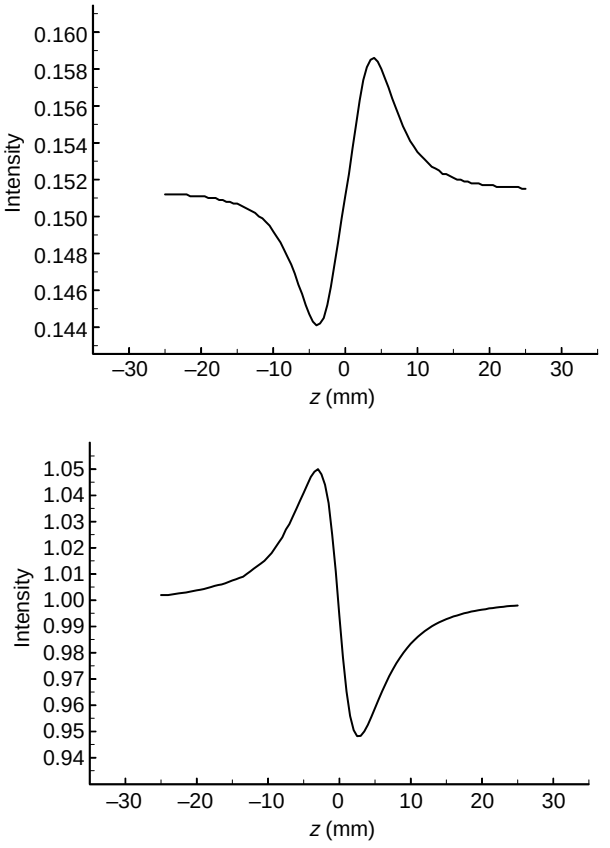

Figure 2 Typical z-scan plots for positive (top) and negative (bottom) cubic nonlinearities. The vertical axis is in arbitrary units.

externally focused Gaussian beam. In this case, we can assume that the beam width is a constant through the sample, and the induced focal length is then only directly dependent on the total thickness L of the sample. The focal length of a nonlinearly induced 'thin' Kerr lens can be written as

$$f_{\text{ind}}(\Delta s) = \frac{n_0 w^2(\Delta s)}{4n_2|E|^2 L} \approx \frac{\pi f^4 n_0}{k_0^4 w_0^4 \eta_0 P L n_2} \qquad [8]$$

for small Δs, where η_0 is the (linear) characteristic impedance of the nonlinear medium. Note that in eqn [8], the beam width w is given by

$$w^2(\Delta s) = w_{\text{f}}^2\left[1 + \frac{4(\Delta s)^2}{k_0 w_{\text{f}}^4}\right] \text{ and } w_{\text{f}} \cong \frac{2f}{k_0 w_0} \qquad [9]$$

In eqn [9], w_{f} denotes the waist size of the Gaussian beam at the back focal plane of the external lens. In deriving eqn [8], one has to use the power conservation relation $|E|^2 w^2 = (4/\pi)\eta P$ to re-express the dependence of the induced focal length on the field amplitude in terms of the corresponding width at the same point.

Our final interest is to find the imaginary part of $1/q_{\text{obs}}(= -2/k_0 w_{\text{obs}}^2)$, in order to ascertain the width w_{obs} of the Gaussian beam on the observation plane. Simple but tedious algebra leads us to the relation:

$$\frac{\frac{k_0 w_{\text{obs}}^2}{2}}{= \frac{[(ff_{\text{ind}}d - f^2 d + f^2 f_{\text{ind}}) + f(f_{\text{ind}} - d)\Delta s]^2 + z_{R0}^2[(f_{\text{ind}} - d)\Delta s + f_{\text{ind}} d]^2}{z_{R0} f^2 f_{\text{ind}}^2}} \qquad [10]$$

It can be shown simply that when $\Delta s = 0$, and for $|f_{\text{ind}}| \gg f$, $w_{\text{obs}} = w_0 d/f$ for large d. In other words, in the linear case, i.e., when $f_{\text{ind}} = \infty$, as well as in the nonlinear case when $\Delta s = 0$, the far-field width of the Gaussian beam is what is predicted by geometrical optics. Furthermore, from eqn [10], the rate of change of the width with Δs around $\Delta s = 0$, (assuming $z_{R0} \gg f$, and for large d) can be found as

$$\frac{\text{d}w_{\text{obs}}}{\text{d}\Delta s} = \frac{-2d^2 z_{R0}}{k_0 w_{\text{obs}} f^2 f_{\text{ind}}} = -\frac{w_0 d}{f f_{\text{ind}}} \qquad [11]$$

provided we invoke the relation for w_{obs} derived above. In eqn [11], f_{ind} refers to the value of the induced focal length (eqn [8]) with $\Delta s = 0$. Equation [11] may be written as

$$\frac{\text{d}w_{\text{obs}}}{\text{d}\Delta s} = -\frac{k_0^4 w_0^5 P L n_2}{2\pi n_0 f^5} \qquad [12]$$

This means that in a material with a positive (negative) n_2, implying a positive (negative) induced lens, the rate of change of the observed width with the position of the nonlinear sample about the focal plane of the external lens will be negative (positive), in agreement with the results from geometrical optics. Furthermore, the rate of change is proportional to the angle of convergence w_0/f of the externally focused Gaussian, and to the position d of the observation plane.

In z-scan, it is often important to relate the on-axis transmittance in the far field to the scan distance s for measurement purposes. Since for power conservation, the intensity is inversely proportional to the width of the beam in the far field, a positive n_2 would imply a positive slope as a function of scan distance with increasing s, and a negative slope for negative n_2. The value of the slope of the on-axis transmittance could give the information of the n_2 of the material. Note that the z-scan graph in this case is an odd function of the scan distance, measured about the back focal plane of the external lens.

In practice, a detector with a finite aperture area is placed on-axis, and the detected power monitored as a function of scan distance. The transmitted power through the aperture is obtained by

$$\begin{aligned} P_{\text{T}} &= \frac{1}{2}\int_0^{2\pi}\int_0^{r_{\text{a}}} \frac{E_{\text{a}} E_{\text{a}}^*}{\eta_0}\text{d}A \\ &= \frac{\pi w_0}{2}\left(\frac{E_0^2}{2\eta_0}\right)\left(1 - \exp\left(-\frac{2r_{\text{a}}^2}{w_{\text{obs}}^2}\right)\right) \\ &= P\left(1 - \exp\left(-\frac{2r_{\text{a}}^2}{w_{\text{obs}}^2}\right)\right) \end{aligned} \qquad [13]$$

where r_{a} is the radius of aperture. The rate of change of P_{T} with Δs can be found as

$$\frac{\text{d}P_{\text{T}}}{\text{d}\Delta s} = \frac{-4r_{\text{a}}^2 P}{w_{\text{obs}}^3}\exp\left(-\frac{2r_{\text{a}}^2}{w_{\text{obs}}^2}\right)\frac{\text{d}w_{\text{obs}}}{\text{d}\Delta s} \qquad [14]$$

Substituting eqn [12] into eqn [14] and using the approximation $w_{\text{obs}} = w_0 d/f$, eqn [14] can be rewritten as

$$\frac{\text{d}P_{\text{T}}}{\text{d}\Delta s} \cong \frac{4r_{\text{a}}^2 f^2 P}{f_{\text{ind}} d^2 w_0^2}\exp\left(-\frac{2r_{\text{a}}^2 f^2}{d^2 w_0^2}\right) \qquad [15]$$

from which

$$\frac{\text{d}P_{\text{T}}}{\text{d}\Delta s}(\Delta s \approx 0) \cong \frac{4k_0^4 w_0^2 \eta_0 r_{\text{a}}^2 P^2 L}{\pi f^2 d^2 n_0}\exp\left(-\frac{2r_{\text{a}}^2 f^2}{d^2 w_0^2}\right) n_2 \qquad [16]$$

When r_a approaches 0;

$$\frac{dP_T}{d\Delta s}(\Delta s \approx 0) = 4\left(\frac{k_0^2 w_0 r_a P}{fd}\right)^2 \frac{\eta_0 L}{\pi n_0} n_2 \qquad [17]$$

Therefore, n_2 can be estimated as

$$n_2 = \left(\frac{\pi n_0}{\eta_0 L}\right)\left(\frac{d}{2k_0^2 w_0 P}\right)^2 \left(\frac{f}{r_a}\right)^2 \frac{dP_T}{d\Delta s} \qquad [18]$$

Thus, if one knows the slope of the z-scan graph around $\Delta s \approx 0$, the value of n_2 can be found. Another way to state this result is to say that the n_2 is related to the peak-to-valley change in the on-axis transmittance ΔT_{p-v}, which is proportional to $dP_T/d\Delta s$.

In passing, we comment that the z-scan method can be also adapted to determine the nonlinear absorption coefficient α_2 of a material, defined through the relation $\alpha = \alpha_0 + \alpha_2 I$, where α is the total absorption coefficient and I denotes the intensity. In order to achieve this, the aperture is assumed to be completely open, in order to collect all the light behind the nonlinear absorptive sample. For $\alpha_2 > 0$, maximum absorption is experienced when the nonlinear sample, assumed thin, is at the back focal plane of the lens since the optical intensity is a maximum due to the external focusing. The z-scan graph is an even function of scan distance, measured about the back focal plane of the external lens.

Thick Sample *z*-Scan

Contrary to the thin sample case, a thick sample is defined as one whose thickness may be comparable to the depth of focus of the externally focused Gaussian beam. In this case, the beamwidth changes during propagation through the sample, so that the induced focal length also changes with propagation. This makes the problem substantially more involved. Indeed, to track the far-field profile in this case, one needs to describe the propagation of the Gaussian beam inside the nonlinear sample using the q parameter formalism. Since both the width and the radius of curvature of the beam at the exit face of the sample are required to predict the far-field behavior, one can write a simple differential equation describing the variation of the q through the nonlinear sample. This equation can be composed from the laws of q-transformation described earlier, and the effects of propagation and nonlinear lensing can be added assuming each is small over an infinitesimal distance of propagation, much like the numerical method called the split step beam propagation method (BPM), often used to analyze such problems. We will not present details of the computation, rather show calculation results for a typical thick sample case, and point out differences with the thin sample predictions for z-scan.

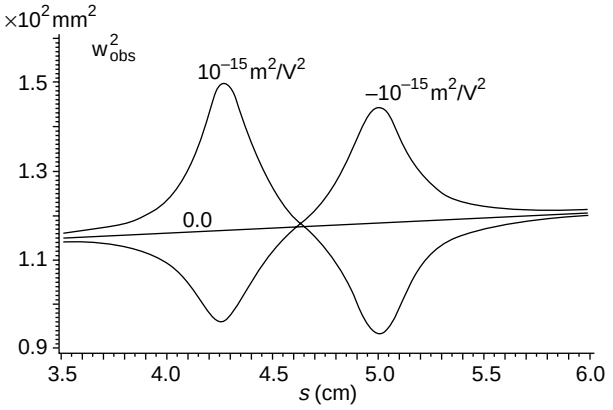

Figure 3 Plot of width of the beam in the far field as a function of the scan distance s. The light wavelength is 640 nm. Reproduced with permission from Banerjee PP (2004) *Nonlinear Optics: Theory, Numerical Modeling, and Applications*. New York: Marcel Dekker.

Figure 3 shows the beamwidth as a function of scan distance for the case where the observation plane is at a distance $d = 1$ m from the exit face of a 1 cm thick. Assume that a hypothetical sample with $n_0 = 1$, $n_2 = \pm 10^{-15}$ m^2/V^2 is scanned about the back focal plane of an external lens with focal length $f = 5$ cm. For comparison, the case of a linear sample is also superposed on the same graph. Note that with the variation of s, the far-field width initially increases, and then decreases before starting to increase again, for a material with a positive n_2. Note that around the point where the variations intersect the graph for the linear case, the slope of the curves are negative and positive for materials with positive and negative n_2, respectively. The graphs for the variation of on-axis transmittance are opposite to the variation of the widths, as mentioned earlier. This is also in agreement with the results predicted from geometrical optics and the q formalism for a thin sample, described earlier.

How do thick and thin sample z-scans differ? Important differences are: (i) the position of the points where the graphs for positive and negative, $n_2 s$, intersect the graph for the linear case; and (ii) the slope of the graphs, predicted from thin and thick sample calculations. For instance, for the thin sample approximation, the value of the slope around $s = f$ is about -4 for a material with a $n_2 = 10^{-15}$ m^2/V^2. Recall from the previous section, the z-scan plot for a thin sample always intersects the graph for the linear case at the back focus of the external lens,

and therefore, it is easy to determine the slope of the z-scan at this point. From the graph in the thick sample case, it is perhaps difficult to ascertain at exactly which point one must determine the slope. A figure of merit would be the minimum value, which occurs for a value of s slightly smaller than $f = 5$ cm. A conservative estimate yields a slope of approximately -1 for this particular example. Note, however, that in the thick lens analysis, we have taken a paraxial approximation to the Gaussian at every stage of its propagation through the nonlinear sample. Strictly speaking, this is not true, and to alleviate this problem, Van Stryland's group included a correction factor with the width of the Gaussian beam.

We would like to mention that values of $n_2 \approx -10^{-15}$ m^2/V^2 can indeed be measured for thermal nonlinearities in liquids. In fact, this is a typical value that we measured for our solution of chlorophyll in ethanol during our first experiments on z-scan. Values of effective $n_2 \approx 10^{-14}$ m^2/V^2 can be measured for liquid crystals with orientational nonlinearities, and will be described below.

Example of z-Scan: Effective Cubic Nonlinearity of Liquid Crystals

The induced refractive index in a nematic liquid crystal, due to reorientational nonlinearity, is a function of position in the crystal and depends on the intensity of the incident optical plane wave, its angle with respect to the direction of propagation, and on the applied voltage. Because of the fact that the nonlinearity depends on the direction of propagation of the planewave and the director axis of the crystal, modeling Gaussian beam propagation is rather complicated. Moreover, the director axis has a certain distribution in the material due to the applied voltage, and hence, the electrostatic field in the material, as well as the optical field. This poses a level of complexity a degree higher than that discussed above for the simple thick sample case. Since the induced refractive index is not a constant, and more importantly, a function of the spatial frequency of the optical beam (which determines the angle between a planewave component of the Gaussian beam spectrum and the director axis distribution under external field), one is compelled to analyze optical propagation using split-step BPM. A typical set of simulated z-scan plots is shown in Figure 4, assuming one transverse dimension for simplicity, and the same parameters as in the experiment described below. Actual experimental results from a z-scan of a biased liquid crystal sample is shown in Figure 5 for transmitted power versus

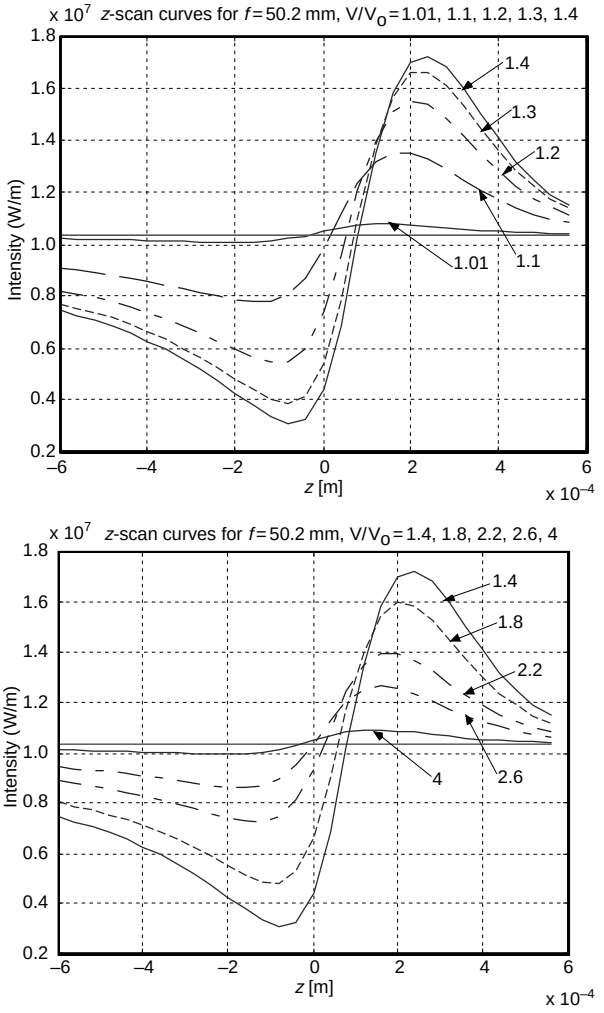

Figure 4 z-scan simulation results for $f = 50.2$ mm and $V/V_o = 1.01$, 1.1, 1.2, 1.3, 1.4 with $E_{op} = 2 \times 10^5$ V/m. z-scan simulation results for $f = 50.2$ mm and $V/V_o = 1.4$, 1.8, 2.2, 2.6, 4 with $E_{op} = 2 \times 10^5$ V/m. Reproduced with permission from Banerjee PP (2004) *Nonlinear Optics: Theory, Numerical Modeling, and Applications.* New York: Marcel Dekker.

sample position in a z-scan experiment for a liquid crystal sample for applied voltages 0.8, 1.0, 1.2, 1.8, and 2.2 V. In this case, the focal length of the external lens is approximately 50 mm and aperture diameter on the observation plane is 1 mm. The scan range is 0.15 inches or approximately 4 mm. The scan step, ΔZ, is varied from about 0.002 inches to about 0.01 inch, depending on the position of the sample. This is done so as to get the maximum information around the back focal plane of the external lens where the measurement values are to be used to find the slope of the z-scan graph, and hence the effective nonlinear refractive index coefficient.

The plots of the effective $n_2 = n_{2\text{eff}}$ (simulated and measured) are shown in Figure 6a and b, respectively. As seen from both plots, the $n_{2\text{eff}}$ increases and

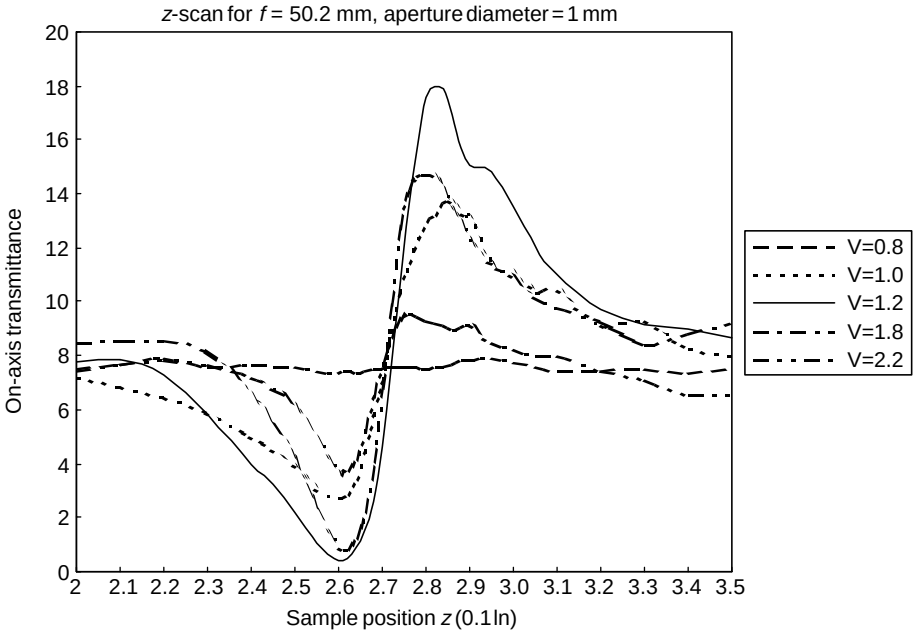

Figure 5 Measured *z*-scan graph for $f = 50.2$ mm and aperture diameter $= 1$ mm. Reproduced with permission from Banerjee PP (2004) *Nonlinear Optics: Theory, Numerical Modeling, and Applications.* New York: Marcel Dekker.

reaches a maximum at $V/V_o = 1.4$, before starting to decrease. Simulated and experimental $n_{2\text{eff}}$ have similar trends. Furthermore, there is reasonable agreement between the calculated and measured values of $n_{2\text{eff}}$.

Discussion: Effective n_2 of Other Materials

The *z*-scan is a powerful tool in the measurement and characterization of effective cubic nonlinearities of different materials. The method is simple and easy to set up, and can be readily automated. We provide two other examples of *z*-scans below, as examples. For instance, photorefractive materials are commonly used for dynamic holography, in order to record and reconstruct volume holograms. Photorefractive materials are doped light-sensitive electro-optic materials in which optical radiation creates mobile charge carriers which redistribute themselves to create an induced space-charge field. This electrostatic field in turn modulates the refractive index which phase modulates the optical beam. A figure of merit for the effectiveness of such a material, e.g., lithium niobate, for holographic storage, is the donor to acceptor ratio in such materials. It turns out that this ratio, along with the photovoltaic coefficient, can be related to an effective n_2 in lithium niobate. This is also responsible in producing an elliptic beam in the far field by starting out from a circularly symmetric Gaussian beam focused onto the sample. The ellipticity stems from the tensor nature of the electro-optic coefficients. Typical simulated *z*-scan plots for lithium niobate are shown in Figure 7, and carries the signature variation of the scan in the variation of the beam ellipticity with scan distance. From this plot, we are able to determine the effective n_2 and hence, the donor to acceptor concentration ratio.

In other photorefractive materials, such as barium titanate, in which diffusion of charge carriers plays a dominant effect, the induced change in the refractive index is proportional to the gradient of the intensity, rather than the intensity itself, as was the case in all previous examples. In this case, as seen in Figure 8, it can be shown that the *z*-scan plot for on-axis transmittance with a small finite aperture on the observation plane is an even function of scan distance. This, however, should not be confused with the open aperture *z*-scan that is also even, but which yields information of the nonlinear absorption coefficient, as described earlier. Experiments with a new material, manganese aluminum oxide, which is thought to have both photovoltaic and diffusive contribution to space charge field distribution, yields a *z*-scan that has both odd and even components. Through careful analysis of the *z*-scan results, one is able to determine the relative contributions of each of these effects. Care should be taken in the interpretation of the results in this case, since in an actual experiment, the aperture size cannot be infinitely small, and thus, an optimum aperture size must be determined that allows for sufficient detected power,

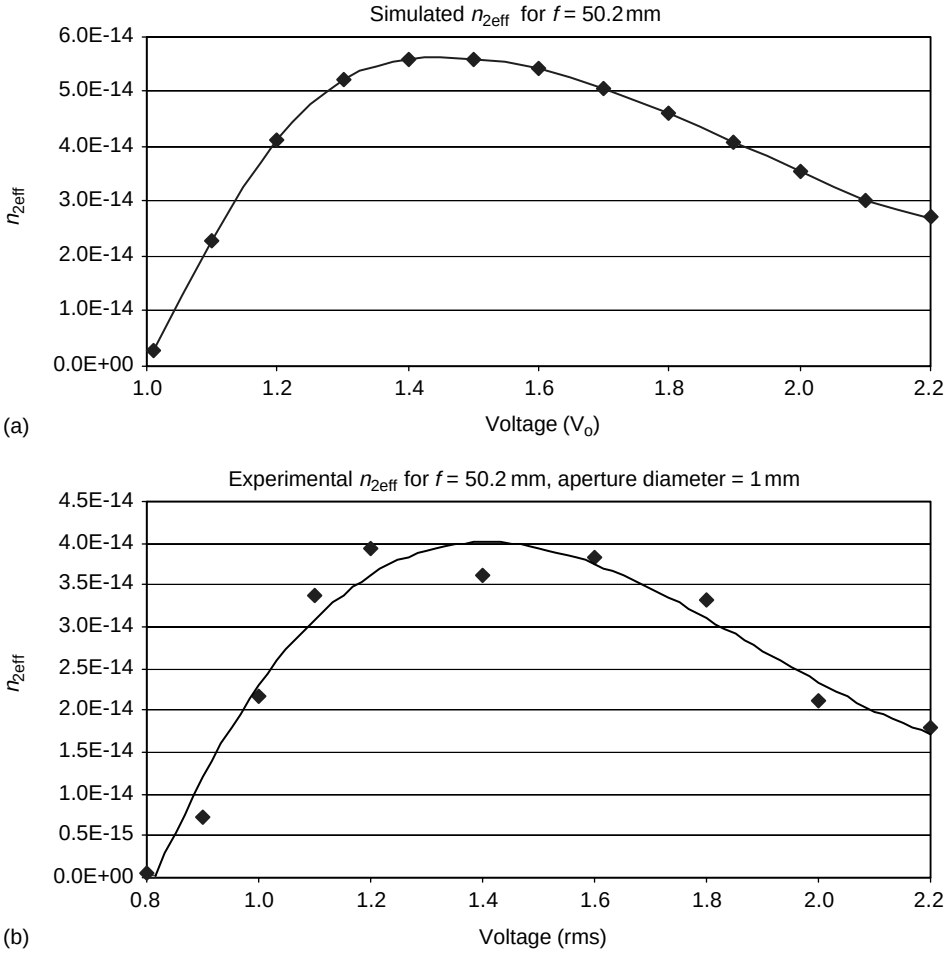

Figure 6 (a) Calculated n_{2eff} for $f = 50.2$ mm with $E_{op} = 2 \times 10^5$ V/m; (b) Experimental n_{2eff} for $f = 50.2$ mm with aperture diameter = 1 mm. but at the same time allows one to neglect any effects of nonlinear absorption.

In summary, it is hoped that this article illuminates readers on the history of the *z*-scan, its application to thin and thick samples, its effectiveness in measurement and characterization of effective third-order optical nonlinearities for a wide class of nonlinear materials, such as $\chi^{(3)}$ materials, materials with cascaded second-order nonlinearities, liquid crystals, photorefractives, etc., and its potential for automation, while at the same time pointing out areas where care should be taken in the interpretation of the measured data. With appropriate modification in the theory, it can also be applied to characterization of linear lenses, possibly voltage controllable lenses and lenslet arrays, suitable for dynamic imaging in biomedical applications.

Introduction

Liquid crystals are complex organic molecular systems that exhibit various mesophases characterized by the degree of order. In this review, we shall focus mainly on thermotropic liquid crystals which exhibit various mesophases in the temperature range between the crystalline and the isotropic liquid states. In particular, we shall discuss the extraordinarily large optical nonlinearities of nematic liquid crystals, as well as the electronic nonlinearities of isotropic-phase liquid crystals. Recent studies have shown that these materials are promising candidates for advanced photonic applications.

Nematic liquid crystals (NLC) possess directional ordering, i.e., when placed in thin cells with surface

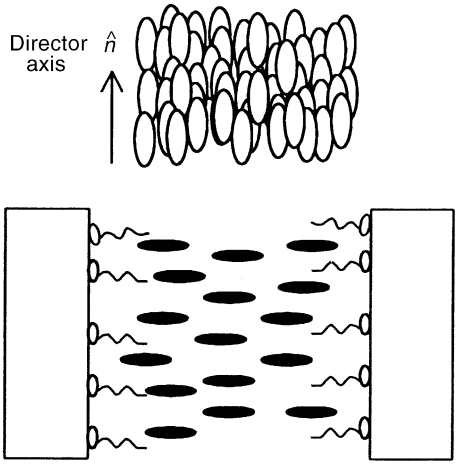

Figure 1 Nematic liquid crystals (NLC) which exhibit directional ordering characterized by the director axis. The lower figure shows how the NLC molecules are aligned in a typical cell with surfactant coated windows.

treated boundaries, the NLC molecules will self-assemble into a birefringent crystal characterized by a so-called director axis $\hat{n}$, cf. Figure 1. For light polarized parallel to $\hat{n}$, the refractive index is n_e, while for light polarized perpendicular to $\hat{n}$, the refractive index is n_0. Typically n_e is ~1.7 and n_0 is ~1.5. This large birefringence $\Delta n = n_e - n_0$ of NLC holds throughout the near UV to the far infrared spectral regime, cf. Figure 2. Perhaps the most important characteristics of NLCs is the easy susceptibility of the birefringent director (crystalline) axis orientation to externally applied fields, which has led to their ever increasing widespread use in various opto-electronics information and image display and processing devices. In analogy to dc and ac field effects, the director can easily be reoriented by an optical field, and thus cause a large optically induced index of refraction change. By doping the NLC with photosensitive or photo-charge producing agents, this process of refractive index change can be enhanced considerably. The refractive indices of NLC are also very strongly temperature dependent.

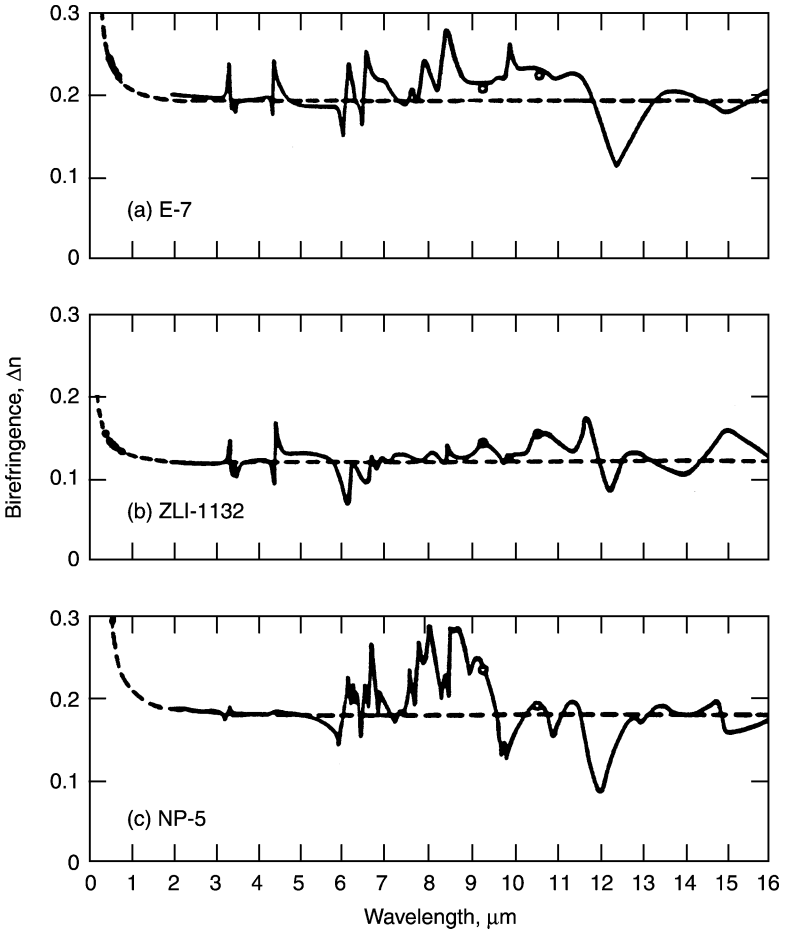

Figure 2 Broadband birefringence of nematic liquid crystals from the near ultraviolet to far infrared.

Accordingly, a large refractive index change can also be generated with laser absorption induced density and order parameter changes. In the following sections, we will broadly classify these nonlinear optical processes originating from the collective response of NLC to external fields as *nonelectronic nonlinearities*.

On the other hand, individual NLC molecules also respond to an optical field through the electronic dipolar interaction. A typical electronic energy level structure of liquid crystal molecules is shown in Figure 3. The dipolar interaction gives rise to the usual nonlinear polarization characterized by the second, third and higher-order nonlinear susceptibilities $\chi^{(2)}, \chi^{(3)}, \ldots$ etc. The complex imaginary parts of these linear and nonlinear susceptibilities account for the photonic absorption processes. Most liquid crystalline molecules possess small linear absorption in the visible region (400–700 nm), and begin to absorb near the UV region (<350 nm), cf. Figure 4. This absorption spectrum translates into a (usually) large nonlinear two-photon absorption spectrum in the visible. In some organic molecules, the intermediate absorption cross-section σ_i or the excited state absorption cross-section σ_e is much larger than the ground state linear absorption σ_g, giving rise to reverse saturable absorption (RSA) and excited state

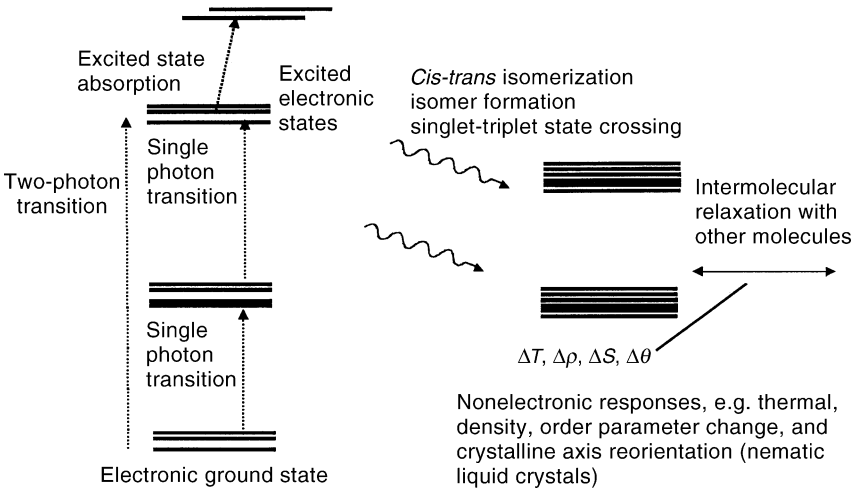

Figure 3 Schematic depiction of the typical energy level structure of liquid crystal molecules and various linear and nonlinear optical processes.

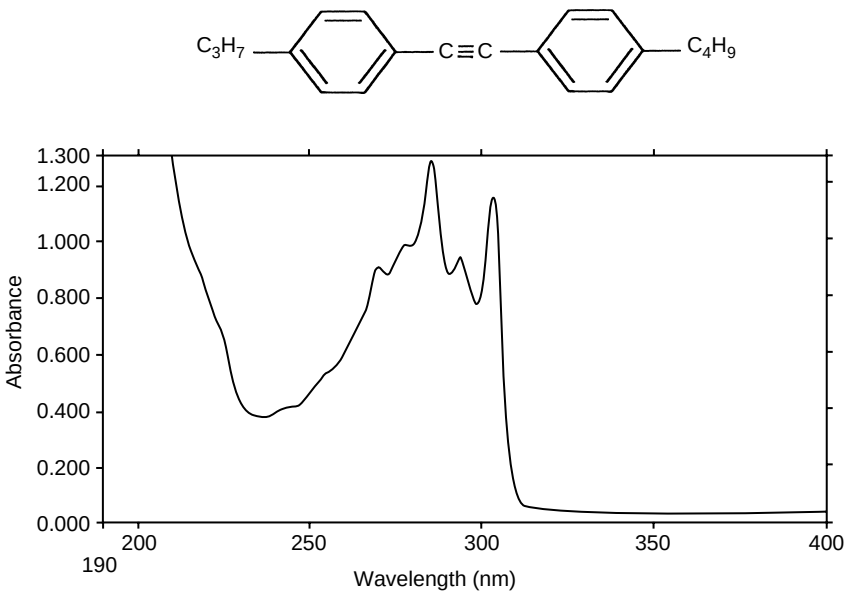

Figure 4 Molecular structure and absorption spectrum of typical isotropic liquid crystal molecules.

absorption (ESA), respectively. As we will see presently, these so-called *electronic nonlinearities* are quite useful for optical limiting applications.

Following photo-absorption, the liquid crystal molecules could undergo intersystem crossing, *cis-trans* or other conformational changes, and form isomers or charge transfer complexes. These processes will contribute to the nonelectronic nonlinearities such as reorientational, order parameter changes and thermal effects.

Orientational Nonlinearities

Purely Optically Induced Orientation

Figure 5 depicts schematically various processes that could occur in an aligned nematic film upon irradiation by an optical field. The reorientation of the director axis $\hat{n}$ is governed by the system's tendency to minimize the overall free energy, which consists of several bulk and surface interaction terms, and the interaction energy with the applied field. In purely dielectric nonabsorbing nematic liquid crystals, director axis reorientation is caused by the torque Γ_{opt} between the anisotropic nematic and the optical electric field,

$$\Gamma_{opt} = \left(\frac{\Delta\varepsilon}{8\pi}\right)(\hat{n}\cdot\mathbf{E}^*)(\hat{n}\times\mathbf{E}) \qquad [1]$$

which competes with the elastic restoring torque Γ_{el} of the surrounding NLC molecules:

$$\Gamma_{el} = \frac{(K_1\sin^2\theta + K_3\cos^2\theta)\mathrm{d}^2\theta}{\mathrm{d}z^2} + \left[(K_1 - K_3)\sin\theta\cos\theta\right]\left(\frac{\mathrm{d}\theta}{\mathrm{d}z}\right)^2 \qquad [2]$$

where the K's are the elastic constants, and $\Delta\varepsilon$ is the (optical) dielectric anisotropy.

As a result of the director axis reorientation, an optical wave propagating through the medium will 'see' a refractive index change. A frequently employed method for measuring the refractive index change in nematic liquid crystal films is the grating diffraction setup, as shown in Figure 6a. Two polarized coherent writing beams are overlapped on a nematic film, which is probed by a polarized reading beam. If the writing beams are copolarized, they impart an optical intensity grating onto the nematic film $I = I_0(1 + \cos qx)$, where q is the grating wavevector, cf. Figure 6b. On the other hand, if the writing beams are orthogonally polarized, the resulting intensity is uniform over the illuminated area, and instead a polarization grating is created, cf. Figure 6c. The polarization state of the light in the overlapped region varies from circular, through elliptical to linear in accordance to the phase difference between the two coherent writing beams. Using a linearly polarized probe beam, this setup allows one to distinguish various intensity and reorientation dependent effects, and assess their contribution to the induced refractive index change Δn.

The magnitude of the induced reorientation angle, and therefore the extraordinary index change, depends on whether the interaction is transient or steady state. In the steady state case, to the first order of approximation, Δn is proportional to the optical intensity I, i.e., $\Delta n = n_2^{SS} I$. Under some experimental conditions, one can also show that the transient nonlinear index coefficient $n_2\ (\tau_p)$ is given by $n_2\ (\tau_p) \sim n_2^{SS}\tau_p/\tau_r$, where $\tau_r = \gamma d^2/K\pi^2$ is the orientational relaxation time constant. For $d = 100\ \mu$m, $\gamma = 0.1$ poise and $K = 10^{-6}$ dynes, we have $\tau_r \sim 1$ s. Typical observed values of $n_2^{SS}(\theta)$ are

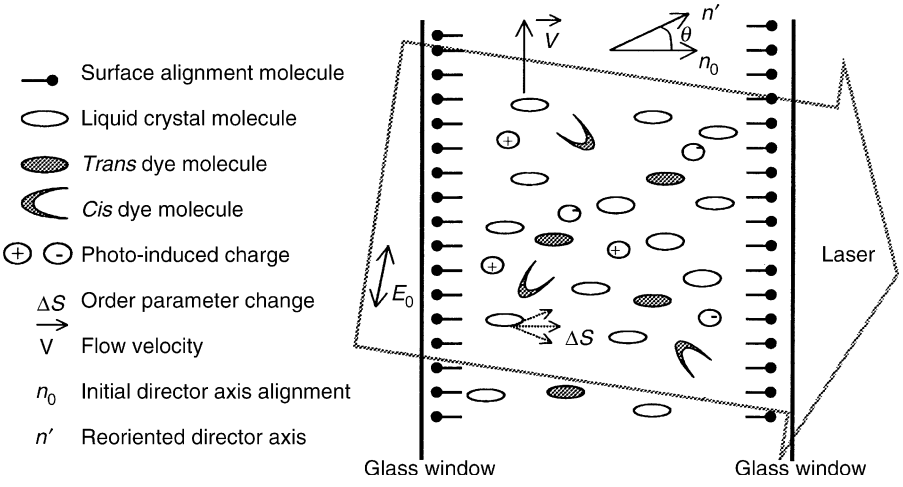

Figure 5 Schematic depiction of various laser-induced optical processes in a nematic liquid crystal film.

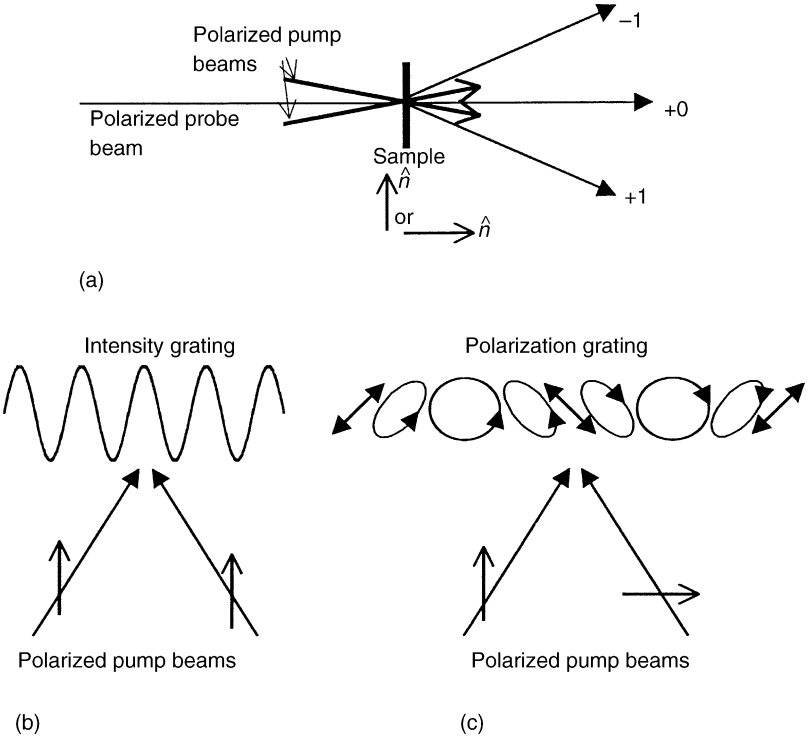

Figure 6 (a) Schematic depiction of grating formation and probe diffraction from the index grating induced in a nematic film. (b) Optical intensity grating formed by interfering two coherent copolarized writing beams. (c) Optical polarization grating formed by interfering two coherent crossed-polarized writing beams.

in the range of 10^{-5}–10^{-4} cm^2 W^{-1}. In the transient case, if $\tau_p = 1$ ns, then n_2 $(\tau_p) \sim 10^{-12}$ cm W^{-1} [$\chi^{(3)} \sim 2 \times 10^{-11}$ esu].

Excited Dye-Dopant Induced Intermolecular Torque

Studies of nematic liquid crystals doped with anthraquinone or dichroic dyes have shown that the excited dye molecules could exert an intermolecular torque Γ_{mole} that could be much larger in magnitude than Γ_{op}. By considering the interaction energies between ground and excited dyes with the surrounding LC molecules, one can show that Γ_{mole} may be written as:

$$\Gamma_{mole} = \zeta \Gamma_{op} \qquad [3]$$

where the proportionality constant ζ can be much larger than unity. The nonlinear index coefficients n_2 obtained in these films are on the order of 10^{-3} cm^2 W^{-1}. The response times for the director axis reorientation and relaxation are similar to the optically induced reorientation process discussed in the preceding section.

Photorefractive Effect

Another mechanism, namely, orientational photorefractivity, could also result in a very large optical nonlinearity. This effect occurs in nematic liquid crystals doped with photo-charge producing agents such as fullerene C_{60} or rhodamine 6G dye, in conjunction with a small applied dc field. For a 25 μm thick film with a dc bias voltage of ~1 V, the observed nonlinear coefficient n_2 is in the range of 10^{-3}–10^{-2} cm^2 W^{-1}. Figure 7 illustrates the orientational photorefractive effect. An incident optical field excites the doped liquid crystals to form charge transfer complexes (CTCs). The CTCs subsequently dissociate and create dc space charge fields through ionic diffusion, migration and other electrodynamical processes. The space charge fields, in combination with the applied dc field, create a dc field induced torque of the form:

$$\Gamma_{dc} = \left(\frac{\Delta\varepsilon_{dc}}{8\pi}\right)(\hat{n}\cdot\mathbf{E}^*_{int})(\hat{n} \times \mathbf{E}_{int}) \qquad [4]$$

Here the total internal dc field $\mathbf{E}_{int}$ contains the applied dc field $\mathbf{E}_{dc}$ and the generated dc space charge fields $\mathbf{E}_{sc}$. This causes director axis reorientation and refractive index change.

The space charge fields consist of one photorefractive and two anisotropy components. For an incident optical intensity grating function of the form $I_{op} = I_0(1 + m \cos q\xi)$, the photorefractive space charge

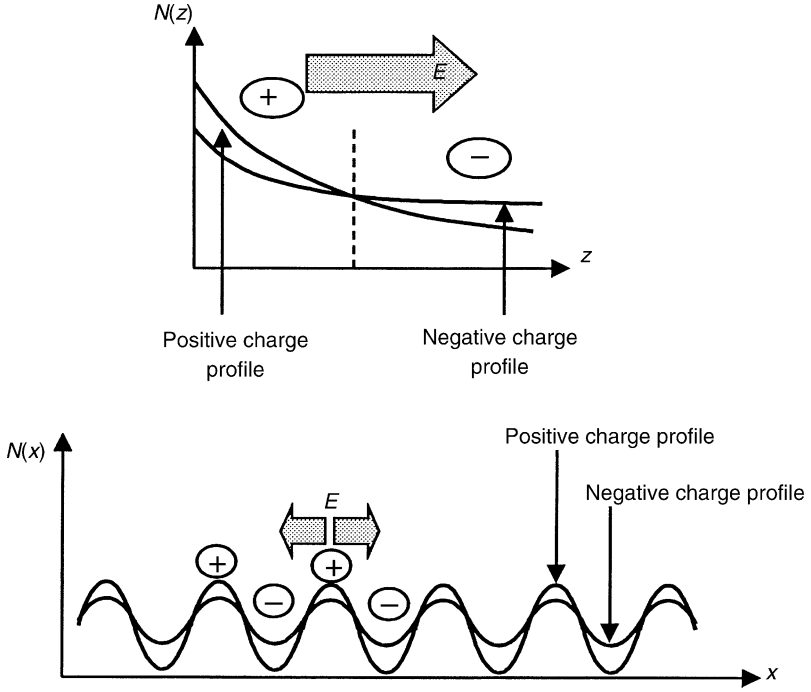

Figure 7 Schematic depiction of photo-induced space charge field formation in a nematic liquid crystal illuminated by a monotonic (upper curve) or a sinusoidal (lower curve) laser intensity function.

field is given by:

$$E_{\mathrm{ph}} = q\nu\, mk_{\mathrm{B}}T\left(\frac{\sigma-\sigma_{\mathrm{d}}}{2e\sigma}\right)\cos\left(\frac{q\xi-\pi}{2}\right) \qquad [5a]$$

where k_{B} is the Boltzmann constant, σ is the illuminated conductivity, σ_{d} is the dark state conductivity, $\nu = (D_+ - D_-)/(D_+ + D_-)$, where D_+ and D_- are the diffusion constants for the positively and negatively charged ions, respectively; m is the optical intensity modulation factor, $q = 2\pi/\Lambda$ is the magnitude of the grating wavevector, and ξ is the coordinate along q.

Two other sources of space charge fields are also at work, and they arise from the conductivity and dielectric anisotropies of the nematic under the action of the dc bias field E_{dc}:

$$E_{\Delta\sigma} = E_{\mathrm{dc}}\left(\frac{(\sigma_{//}-\sigma_{\perp})\sin\theta\cos\theta}{\sigma_{//}\sin 2\theta + \sigma_{\perp}\cos 2\theta}\right) \qquad [5b]$$

$$E_{\Delta\varepsilon} = E_{\mathrm{dc}}\left(\frac{(\varepsilon_{//}-\varepsilon_{\perp})\sin\theta\cos\theta}{\varepsilon_{//}\sin 2\theta + \varepsilon_{\perp}\cos 2\theta}\right) \qquad [5c]$$

where $(\sigma_{//} - \sigma_{\perp})$ is the low-frequency **conductivity anisotropy** and $(\varepsilon_{//} - \varepsilon_{\perp})$ the **dielectric anisotropy** of the liquid crystal, and θ is the reorientation angle of the director axis.

In addition to these space charge field induced effects, the **flows** of the charged ions and complexes under the applied dc field and the generated space charge fields also contribute significantly to reorienting the director axis. For an interaction geometry similar to Figure 5, the flow creates a shear torque Γ_{shear} of magnitude proportional to the velocity gradient

$$\Gamma_{\mathrm{shear}} = \frac{\mathrm{d}\mathbf{v}(\zeta)}{\mathrm{d}\zeta}(\alpha_2\sin^2\theta - \alpha_3\cos^2\theta) \qquad [6]$$

where the α's are the viscosity coefficients, and $\mathbf{v}(\zeta)$ is the flow velocity. The combined action of the above space charge fields and the flow effects on director axis reorientation have been quantitatively formulated and shown to describe experimental results very well, including, in particular, the observation that maximal diffraction is obtained for a grating constant $\lambda_{\mathrm{g}} \sim 2d$. Furthermore, the flow-reorientation and adsorption of the excited dopant molecules on the surfaces are believed to be responsible for quasi-permanent and permanent director axis reorientation in rhodamine 6G- and C_{60}-doped nematic films, respectively.

Supra-Nonlinear Methyl-Red Doped NLC – Observed Phenomena

Recent studies in methyl-red doped nematic liquid crystals (MRNLCs) have ushered in the era of supra-nonlinearity. Unlike photorefractive nematic liquid

crystals, no external bias field is needed. The observed n_2 values could be as large as $10\,\mathrm{cm^2\,W^{-1}}$. In MRNLC, a large photovoltage drop across the sample is also observed upon irradiation. The polarity of the photovoltage is reversed if the light impinges from the opposite cell window. The extremely nonlinear optical response of MRNLC is attributed to nematic director axis reorientation by the optically induced space charge fields, similar to the effect discussed in the previous section. The unusually large response is possibly due to several factors, including the higher photo-charge producing abilities of methyl red, and the large difference in the positive and negative photo-ion diffusion constants. Another cause of director axis reorientation is the intermolecular torque exerted by the photo-excited dye molecules on the NLC. This is particularly evident in experiments using an input polarization grating on planar aligned samples. Because the laser excited dye molecules are adsorbed and strongly 'anchored' on the cell walls, they cause permanent realignment of the nematic liquid crystal. This process usually occurs upon prolonged illumination of the liquid crystal cells with a low-power laser, and can be sped up with higher laser power.

Trans–Cis Isomerization and Order Parameter Change

Some nematic liquid crystals are azo-compounds, i.e., their molecular structures are analogous to the typical one depicted in Figure 8. An azo-compound when irradiated at its absorption wavelength will change from the *trans* to the *cis* form, cf. Figure 8. *Trans–cis* isomerization of these azo-nematic liquid crystals or azo-dopants in NLC's could also give rise to a refractive index change through modification of the NLC's order parameter and/or director axis reorientation. The *trans* species are oblong in shape, and align parallel to the director axis. On the other hand, the 'bent' structure of the *cis* species is incongruous to the nematic order, and thus causes an order parameter change, and therefore a refractive index modification. Such refractive index changes owing to order parameter modification are similar to thermal effects discussed in the next section. The response [on-] time for these *trans–cis* isomerization induced order-parameter changes can be quite fast (as fast as nanoseconds in some cases). The relaxation time (typically in the millisecond regime) is decided by the director axis relaxation rate as discussed earlier.

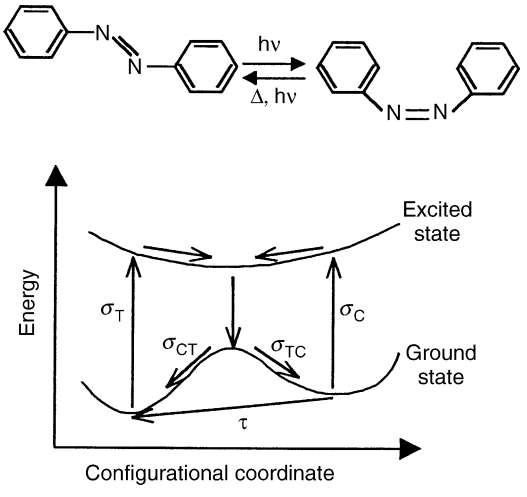

Figure 8 *Trans–cis* isomerization of azo-molecules upon optical illumination. The upper diagram depicts molecular structural changes; the lower diagram shows the excitation energy versus the molecular coordinate associated with these photo-excited processes.

The other index-changing mechanism is the tendency of the *trans* molecule to align with its transition moment perpendicular to the optical polarization in order to minimize the interaction (absorption) energies. This in turn causes the NLC director axis to realign through the intermolecular torque effect. Both mechanisms are characterized by a nonlinear index coefficient n_2 on the order of $10^{-3}\,\mathrm{cm^2\,W^{-1}}$.

Thermal and Density Effect

Laser induced temperature and density changes are described by time-dependent coupled hydrodynamics equations. In grating diffraction experiments, cf. Figure 6, the problem can be simplified to a one-dimensional one, i.e., along the grating wavevector direction, if the grating spacing is smaller than the nematic film thickness and the beam size. In that case, the thermal and Brillouin (sound wave) decay time constants are given by, respectively:

$$\tau_T = \frac{\rho_0 C_v}{\lambda_T q^2} \qquad [7a]$$

$$\tau_B = \frac{2\rho_0}{\eta q^2} \qquad [7b]$$

where $q = 2\pi/\lambda_q$ is the grating wavevector, ρ_0 the unperturbed density, C_v the specific heat, λ_T the thermal conductivity, and η the viscosity. The values of these parameters depend on the director axis alignment relative to the optical fields, thermal diffusion and sound propagation directions. For typical values of $\eta = 7 \times 10^{-2}\,\mathrm{kg\,m^{-1}\,s^{-1}}$, $\rho_0 = 10^3\,\mathrm{kg\,m^{-3}}$, $D = \lambda_T/\rho_0$, $C_v \sim 1.6 \times 10^{-7}\,\mathrm{m^2\,s^{-1}}$ and a grating spacing $\lambda_q = 20\,\mu\mathrm{m}$, we have $\tau_T \sim 50\,\mu\mathrm{s}$, whereas $\tau_B \sim 200\,\mathrm{ns}$. Such a vast difference between the relaxation times allows one to distinguish the contribution from thermal and density origins.

Table 1 Nonelectronic nonlinearities of nematic liquid crystals

Nonlinear processes	*Typical magnitude*	*Time-scale*	*Liquid crystal*
Orientational nonlinearities			
Purely optically induced n_2	10^{-4} cm^2 W^{-1}	ms	pure 5CB
Excited dopant assisted n_2	10^{-3} cm^2 W^{-1}	ms	dyed 5CB
Photorefractive	10^{-3} cm^2 W^{-1}	ms	5CB
Photorefractive + Methyl-red doped 5CB	10 cm^2 W^{-1}	ms	
Trans–Cis and order parameter modification	10^{-4} cm^2 W^{-1}	ms	dyed 5CB
Thermal nonlinearities			
n_2	10^{-6} cm^2 W^{-1}	ms	E7
n_2	10^{-11} cm^2 W^{-1}	ns	E7
Density effect			
electrostrictive n_2	10^{-11} cm^2 W^{-1}	ns	E7

In the steady state, i.e., when the laser–nematic interaction time is much longer than τ_T and τ_B, the nonlinear index coefficient is given by:

$$n_2^{SS}(\Delta T) = \left(\frac{dn}{dT}\right)\frac{\alpha\tau_r}{\rho_0 C_V} \qquad [8]$$

where dn/dT is the appropriate thermal index coefficient. The absorption constant α of liquid crystals varies widely in the visible–infrared spectrum. Near the phase transition temperature, $dn_{//,\perp}/dT$ also changes dramatically. The magnitude of $n_2^{SS}(\Delta T)$ could therefore vary by several orders of magnitude. For $\alpha = 100\ \text{cm}^{-1}$, $dn_{//,\perp}/dT \sim 10^{-3}\ \text{K}^{-1}$, and $\lambda_q = 20\ \mu\text{m}$, we have $n_2^{SS}(\Delta T) \sim 10^{-6}\ \text{cm}^2\ \text{W}^{-1}$. This is the typical value observed in wave mixing experiments with infrared [CO_2] or visible lasers.

In the transient regime ($\tau_p \ll \tau_r, \tau_B$), the nonlinear index coefficient is proportional to the laser pulse duration:

$$n_2(\tau_p) = n_2^{SS}(\Delta T)\tau_p/\tau_r \qquad [9]$$

With $\tau_r \sim 0.5 \times 10^{-4}$ s and $\tau_p = 1$ ns, $n_2(\tau_p) \sim 5 \times 10^{-11}\ \text{cm}^2\ \text{W}^{-1}$. Such nonlinearities have been observed in transient dynamic grating diffraction studies involving nanosecond laser pulses. In these studies, it is found that the contribution from the electrostrictive effect (movement of the nematic due to the optical intensity gradient) to the refractive index change can be as large as the absorptive thermal component.

In Table 1, we give a concise summary of these nonelectronic optical nonlinearities observed in nematic liquid crystals.

Electronic Nonlinearities

Second and Third Order Nonlinear Susceptibilities

Electronic interaction involves the perturbation of the electronic wavefunctions by the impinging optical fields. The induced dipole moment of a molecule is given by:

$$\mathbf{d} = \boldsymbol{\alpha}:\mathbf{E} + \boldsymbol{\beta}:\mathbf{EE} + \boldsymbol{\gamma}:\mathbf{EEE} + \cdots \qquad [10]$$

where $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, and $\boldsymbol{\gamma}$ are the linear, second-order and third-order nonlinear polarizability tensors, $\mathbf{E}$ is the optical electric field and : denotes tensorial operation. The macroscopic polarization $\mathbf{P}$ (dipole moment per unit volume) is

$$\mathbf{P} = \varepsilon_0\boldsymbol{\chi}^{(1)}:\mathbf{E} + \boldsymbol{\chi}^{(2)}:\mathbf{EE} + \boldsymbol{\chi}^{(3)}:\mathbf{EEE} + \cdots \qquad [11]$$

where $\boldsymbol{\chi}^{(1)}$, $\boldsymbol{\chi}^{(2)}$, and $\boldsymbol{\chi}^{(3)}$ are the linear, second and third-order nonlinear susceptibilities, respectively. The macroscopic parameters $\boldsymbol{\chi}$ are related to $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ by the local field correction factors.

A well-known process associated with the second-order nonlinear polarization is second harmonic generation, in which two incident photons of frequency ω are converted into a photon of frequency 2ω. Symmetry rules require that a material should be non-centrosymmetric in order to exhibit second-order nonlinear polarization. In centrosymmetric nematic liquid crystals, an applied dc field or discontinuity at a surface or interface, or director orientational curvature, could provide the required symmetry-breaking mechanism.

In ferroelectric or smectic C^* liquid crystals, the molecules possess permanent polarization, i.e., the centrosymmetry is broken, and it is possible to observe second harmonic generation associated with the second-order nonlinear polarization. Typically, the observed nonlinear coefficients β_{2HG} are on the order of $\sim 10^{-14}\ \text{mV}^{-1}$. In contrast to inorganic crystals of much larger dimensions, these thin liquid crystal films are not useful for practical devices. Nonetheless, because of the sensitivity of second harmonic generation to surface and interface conditions, second harmonic generation has been proven to be an effective spectroscopic tool.

In dc field induced second harmonic generation, the nonlinear polarization involved is actually the

Table 2 Electronic optical nonlinearities of nematic liquid crystals

Nonlinear optical phenomena and nonlinearities	*Magnitude*	*Time-scale (pulse duration of laser used)*
Second harmonic generation (dc field induced),		
$\chi_{//}^{(3)}$	2.7×10^{-12} esu	ns
$\chi_{\perp}^{(3)}$	0.55×10^{-12} esu	ns
Second harmonic generation β_{2HG}	10^{-12} mV^{-1}	ps (ferroelectric)
Two-photon absorption, β	5 cm GW^{-1}	80 ps
Effective nonlinear absorption, β_{eff}	200 cm GW^{-1}	10 ns
Degenerate four-wave mixing		
electronic $\chi^{(3)}(\omega; \omega, -\omega, \omega)$	10^{-12} esu	ns

third-order nonlinear polarization given by $P(2\omega) = \boldsymbol{\chi}^{(3)}E(0)E(\omega)E(\omega)$. Typically measured values of $\boldsymbol{\chi}^{(3)}$ are $\sim 10^{-12}$ esu, expressed in the commonly used cgs units. The conversion factor between cgs and SI unit is given by

$$\boldsymbol{\chi}^{(3)}[\text{esu}] = 3^4 \times 10^{17} \boldsymbol{\chi}^{(3)}[\text{SI unit}] \qquad [12]$$

There is relatively little work done on measuring or studying the third-order nonlinear electronic polarizabilities of nematic liquid crystals. Most of the studies are centered on the molecular correlation effects associated with the nematic–isotropic phase transition. The typical magnitude of electronic $\boldsymbol{\chi}^{(3)}$ is 10^{-12} esu.

Nonlinear Absorption and Limiting

Two-photon absorption occurs where the molecule is excited to a real electronic excited state by simultaneous absorption of two photons from the incident light. Since the absorption is proportional to the square of the optical intensity, the incident light will experience an increasing absorption effect, and its transmission at high intensity will be 'quenched' to an almost constant level. Two-photon absorption is usually characterized by the two-photon absorption coefficient β, which is related to the imaginary part of $\boldsymbol{\chi}^{(3)}$. For liquid crystals, they are on the order of 5×10^{-12}–10^{-11} mW^{-1} (equivalent to 0.5–5 cm GW^{-1} in the more commonly used units).

Liquid crystalline materials in their (less scattering) isotropic phase have been extensively studied in the last few years for application in optical limiting devices as a result of their large nonlinear absorption constant. In the nanosecond time regime, the RSA and ESA effects, cf. Figure 3, act to give rise to a very large effective nonlinear absorption coefficient β on the order of several hundreds of cm GW^{-1}. In combination with special device structure such as a nonlinear fiber array, it has become possible to clamp the transmitted nanosecond laser pulse energy to below the retina damage level (below 0.5 μJ).

In Table 2, we give a concise summary of these electronic optical nonlinearities of nematic liquid crystals.

Concluding Remarks

We have presented a concise review of the nonlinear optics of liquid crystals in their nematic and isotropic phases. Nematic liquid crystals in their various pure and doped forms possess many interesting nonlinear optical responses, with nonlinearities ranging over 16 orders of magnitude. Some of the extraordinarily large nonlinearities enable the performance of several all-optical switching and limiting, image modulation and sensing processes at unprecedented low threshold power. In particular, self-defocusing and optical limiting effects with nanowatt-power lasers, and incoherent–coherent image conversion at μW cm^{-2} optical intensity have been demonstrated. Liquid crystal films have been used in selective attenuation of glares and blinding laser light. Stimulated scattering that used to be the domain of high-power lasers can now be performed in thin nematic films with mW-power cw laser. Readers can consult the Further Reading section for some of these advanced photonic devices and applications based on nonlinear optics of liquid crystals. Current active studies by several research groups worldwide are likely to result in even more interesting nonlinear optical effects and useful applications in the near future.

List of Units and Nomenclature

Absorption coefficient	α [cm^{-1}]
Density	ρ_0 [kg m^{-3}]
Eleastic constant	K [dynes]
Intensity (optical)	I [W cm^{-2}]
Nonlinear susceptibility	$\chi^{(3)}$ [esu]
Second harmonic generation coefficient	β_{2HG} [mV^{-1}]
Specific heat	C_V [m^2 s^{-1}]
The nonlinear index coefficients	n_2 [cm^2 W^{-1}]
Time constants	τ [s]

Two-photon absorption constant	β [cm GW^{-1}]
Viscosity	η [kg m^{-1} s^{-1}]
Viscosity coefficient	γ [poise]

Nonlinear Medium Polarization

Macroscopic

Photons are neutral, noninteracting bosons. Interaction is possible only through a material medium. Indeed, photons can be absorbed by electrons leading to excited states. A reverse transition may go through radiative channels, with emission of photons, usually with a different energy than the excitation energy. Interaction of photons with matter may also lead to other types of excitation, such as vibronic, rotational, libronic, etc., or just to a change in the medium polarization. This change may be expanded in the power series of the electric forcing field strength with *i*th component given by:

$$P_I(\omega_\sigma) = P_{0I}(\omega_\sigma) + \varepsilon_0[K_1\chi^{(1)}_{IJ}(-\omega_\sigma;\omega_\sigma)E^{\omega_\sigma}_J + K_2\chi^{(2)}_{IJK}(-\omega_\sigma;\omega_1,\omega_2)E^{\omega_1}_J E^{\omega_2}_K + K_3\chi^{(3)}_{IJKL}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)E^{\omega_1}_J E^{\omega_2}_K E^{\omega_3}_L + \cdots] \quad [1]$$

where the expansion coefficients $\chi^{(n)}$ are $(n+1)$ rank three-dimensional tensors, describing linear $(n=1)$ and nonlinear $(n>1)$ responses of the medium, $P_{0i}(\omega_\sigma)$ is its permanent polarization (at frequency ω_σ) and the coefficients K_i $(i=1,2,3,\ldots)$ take account of the conventions for the Fourier transform of electric field and polarization vectors used, as well as the degeneracy of nonlinear optical processes. For historical reasons two conventions in quantitative description of NLO processes are used:

$$\mathrm{E}(\mathrm{r},t) = \tfrac{1}{2}[\mathrm{E}(\mathrm{r})\mathrm{e}^{\mathrm{i}\omega t} + \mathrm{c.c.}] \qquad \text{(Convention I)} \qquad [2]$$

and

$$\mathrm{E}(\mathrm{r},t) = \mathrm{E}(\mathrm{r})\mathrm{e}^{\mathrm{i}\omega t} + \mathrm{c.c.} \qquad \text{(Convention II)} \qquad [3]$$

and similarly for the polarization field. As researchers often use different conventions, it is important to bear this in mind when comparing NLO properties of materials coming from different sources. The tabulated data and the formulas used here are within convention I, with the permutation factors included explicitly in coefficients K_i (eqn [1]). In centrosymmetric media and in dipolar approximation, the static polarization P_0, as well as all even order NLO susceptibilities, are equal to zero, as it follows from time reversal symmetry.

Relations Between Macroscopic and Microscopic Polarizations

Microscopic Polarization

Similar expansions to eqn [1] also obey the conventions on a molecular level. Similarly, as for bulk polarization, the ith component of the molecule dipole moment can also be expanded into the series of the local field strength giving:

$$\begin{aligned}\mu_i(\omega_\sigma) &= \mu_{0i}(\omega_\sigma) + K_1\alpha_{ij}(-\omega_\sigma;\omega_\sigma)E_j^{\omega_\sigma} \\ &\quad + K_2\beta_{ijk}(-\omega_\sigma;\omega_1,\omega_2)E_j^{\omega_1}E_k^{\omega_2} \\ &\quad + K_3\gamma_{ijkl}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)E_j^{\omega_1}E_k^{\omega_2}E_l^{\omega_3} + \cdots \\ &= \mu_{0i}(\omega_\sigma) + \mu_{\text{ind}}(\omega_\sigma,\omega_1,\omega_2,\ldots,\omega_n,\alpha,\beta\ldots,\zeta, \\ &\quad E^{\omega_1},E^{\omega_2},\ldots,E^{\omega_n}) \qquad [4]\end{aligned}$$

where α is the linear molecular polarizability, β is the first order and γ is the second molecular hyperpolarizability. μ_{in} in eqn [4] denotes the induced dipole moment. The expansions [1] and [4] may be also considered as the Tamm–Dancoff perturbation development as functions of an increasing number of interacting photons. In this case, the second term on the right-hand sides of eqns [1] and [4] describes the interaction of two photons, the third term that of three photons, etc. The electric field in eqn [4] is the effective field experienced by the molecule and is given by

$$E = fE \qquad [5]$$

where f is the local field factor, depending on the form of molecule. In eqns [1] and [4] Einstein's notation is used.

For a single crystal and for noninteracting molecules there exists a straightforward relationship between the macroscopic and microscopic quantities given by:

$$\begin{aligned}\chi^{(2)}_{IJK}(-\omega_\sigma;\omega_1,\omega_2) &= \sum_n f_n^{\omega_\sigma}f_n^{\omega_1}f_n^{\omega_2}N_n \\ &\quad\times\sum_{ijk} a_{Ii}a_{Jj}a_{Kk}\beta^n_{ijk}(-\omega_\sigma;\omega_1,\omega_2) \qquad [6]\end{aligned}$$

for the second-order NLO susceptibility and

$$\begin{aligned}\chi^{(3)}_{IJKL}(-\omega_\sigma;\omega_1,\omega_2,\omega_3) &= \sum_n f_n^{\omega_\sigma}f_n^{\omega_1}f_n^{\omega_2}f_n^{\omega_3}N_n \\ &\quad\times\sum_{ijkl} a_{Ii}a_{Jj}a_{Kk}a_{Ll}\gamma^n_{ijkl}(-\omega_\sigma;\omega_1,\omega_2,\omega_3) \qquad [7]\end{aligned}$$

for the third-order NLO susceptibility, respectively. The coefficients a_{Ij} in eqns [6] and [7] are Wigner rotation matrix elements, N_n denoting the number density of species (n). The subscripts ($ijkl$) refer to the molecule, and ($IJKL$) to the laboratory reference frames, respectively.

For disordered (or partly ordered) materials, the macroscopic NLO susceptibility depends on the orientation average of nonzero molecular hyperpolarizability components:

$$\begin{aligned}\chi^{(2)}_{IJK}(-\omega_\sigma;\omega_1,\omega_2) &= \sum_n f_n^{\omega_\sigma}f_n^{\omega_1}f_n^{\omega_2}N_n \\ &\quad\times\sum_{ijk} <\beta^n_{ijk}(-\omega_\sigma;\omega_1,\omega_2)>_{IJK} \qquad [8]\end{aligned}$$

and similarly for $\chi^{(3)}$ susceptibility. The average in eqn [8] is taken over all NLO molecule orientations and all β tensor components. Fortunately, the number of the nonzero β tensor components (21 for β tensor) is limited by the molecular symmetry and in the case of charge transfer (CT) molecules, only the component in the charge transfer direction β_{xxx} may be retained. The others are usually significantly smaller and can be neglected with respect to this one.

Second-Order Nonlinear Optical Materials

The research on nonlinear optical materials is boosted by the potentiality of their applications in photonics, and particularly in optical signal processing, image recognition, frequency conversion, and light amplification. New fields of applications open in biology, medicine (photodynamic therapy), material processing (optical engineering), etc. Depending on the targeted application, the materials showing enhanced second-, third-, and/or higher-order nonlinear optical properties are developed and optimized. The optimization is performed on both molecular and macroscopic levels. Indeed, the bulk nonlinear optical response depends not only on the individual hyperpolarizabilities but also on the way the molecules are assembled into the bulk material. As already mentioned, only the noncentrosymmetric materials exhibit the second-order nonlinear optical response.

Molecules

The most promising molecules for the application in second-order NLO devices are intramolecular CT compounds, composed from an electron donating (D), an electron accepting (A) part, linked by a π conjugated backbone (**Figure 1**). The CT molecules exhibit a large first-order susceptibility β tensor component β_{xxx}, enhanced in the charge transfer direction x. The value of β_{xxx} depends on the strength of electron donating and electron accepting groups (amount of the charge transfer)

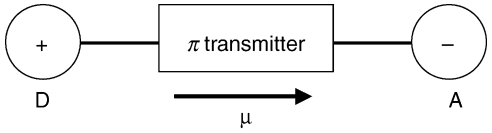

Figure 1 Schematic representation of a charge transfer molecule.

Table 1 Chemical structures of commonly used electron donating and electron accepting groups

Donors	*Acceptors*
$-N(CH_3)_2$	$-NO$
$-NH_2$	$-NO_2$
$-OCH_3$	$-CHO$
$-OH$	$-CN$
$-CH_3$	$-SO_2CH_3$
$-SCH_3$	$-SO_2CF_3$
$-N(CH_3)_2$	$=C(CN)_2$

and on the conjugation length of the transmitter. Table 1 shows the chemical structures of typical electron donating and electron accepting groups. Chemical structures of selected CT molecules are given in Table 2, together with the values of the β_{xxx} tensor component, as determined by the electric field induced second-harmonic generation technique (EFISH).

The dependence of β_{xxx} on the conjugation length L of the conjugated transmitter is given by the scaling law:

$$\beta_{xxx} \propto L^{\alpha_s} \qquad [9]$$

with $\alpha_s > 1$. Usually the conjugated backbone is composed of a number of alternate single/double (or single/triple) bonds and in this case, the scaling law is tested as a function of the number of double (or triple) bonds N:

$$\beta_{xxx} \propto N^{\alpha_\beta} \qquad [10]$$

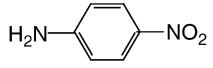
For a number of CT oligomers with the same electron donating and electron accepting groups, differing only in the length of the conjugated transmitter, the exponent $\alpha_\beta \sim 2.5$. The β_{xxx} value saturates for a larger number of double bonds ($N > 4$, in the case of phenyl oligomers used as transmitter).

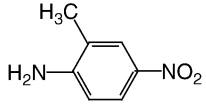
A number of studies are in progress on octupolar molecules which exhibit large β hyperpolarizabilities. However, their processing into efficient, noncentrosymmetric bulk materials is still at its initial stage and up to now no practical application has been demonstrated.

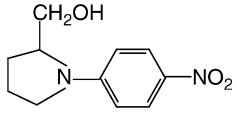
Bulk Materials

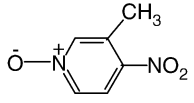
In order to obtain noncentrosymmetric materials, different approaches are used such as:

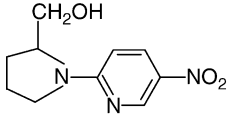
(i) single crystals growth;
(ii) epitaxy or heteroepitaxy;
(iii) Langmuir–Blodgett films;
(iv) self-assemblies;
(v) intermolecular charge transfer structures;
(vi) poled polymers; and
(vii) chiral structures.

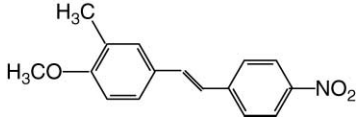


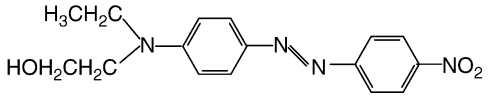


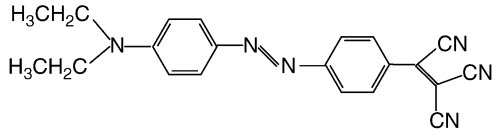








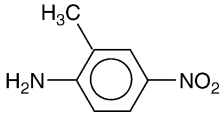


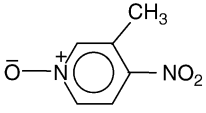


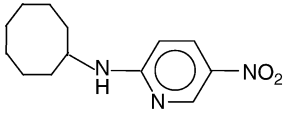
The growth of good-quality optical single crystals is costly and difficult, especially as the charge transfer molecules usually exhibit a large ground state dipole moment (Table 2). The strong dipole–dipole interaction usually leads to their antiparallel alignment, and as a consequence, a centrosymmetric bulk structure. Only a few molecules crystallize in a noncentrosymmetric structure. One of the approaches used consists of design and synthesis of molecules with a negligible ground state dipole moment such as POM (Table 3). Therefore, a lot of effort has been put into forcing molecules to build into noncentrosymmetric bulk materials (ii)–(vi). Owing to the fact that most of applications are targeted in waveguiding configuration, a significant effort has been made to grow noncentrosymmetric thin films (ii)–(vi). While the chiral molecules form spontaneously noncentrosymmetric films, in other techniques, this is obtained more easily by application of an external electric field (poled polymers), by use of an adequate substrate (epitaxy, pseudoepitaxy, self assembly), intramolecular charge transfer in ordered layered structures (v), and interaction between molecules and molecules–substrate (Langmuir–Blodgett films). In the last case, three types of well-ordered structures, with controllable thickness are obtained: X, Y, Z (Figure 2). Only X and Z type structures give noncentrosymmetric thin films exhibiting second-order NLO properties.

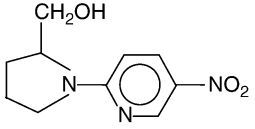
Poled polymers

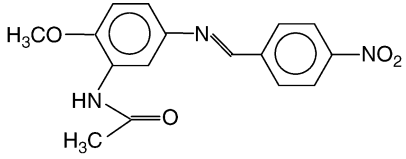
Up to now, the best results in getting efficient materials for second-order NLO application are obtained with poled polymers. The materials consist of a polymer matrix, exhibiting excellent optical properties, functionalized with active NLO chromophores (CT molecules). Four kinds of structures, shown schematically in Figure 3, are realized:

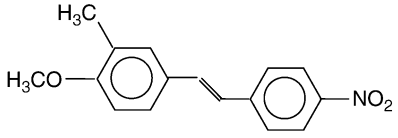












(i) guest–host systems;
(ii) side chain polymers;
(iii) main chain polymers; and
(iv) thermally or photo-crosslinked polymers.

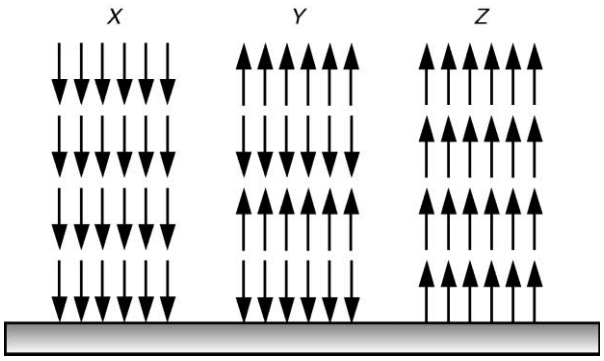

Figure 2 Schematic representation of *X, Y, Z* type Langmuir–Blodgett films. The arrows symbolize the direction of dipole moments, which usually are tilted with respect to the normal to film surface.

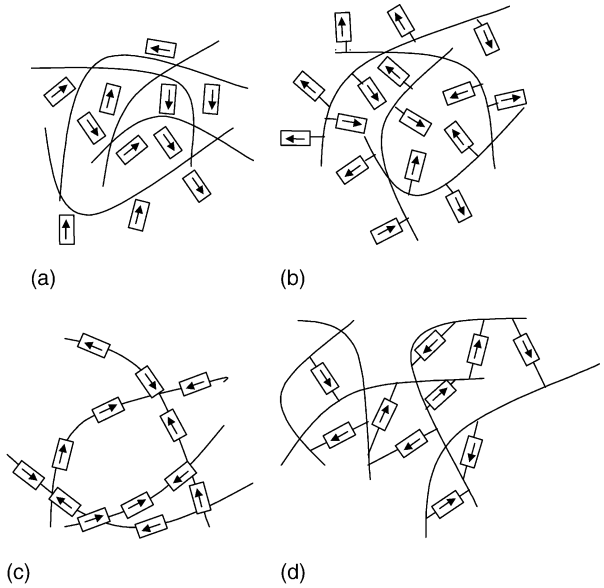

Figure 3 Schematic representation of functionalized polymers for second-order NLO effects: guest–host systems (a), side chain polymers (b), main chain polymers (c), photo and thermally cross-linking polymers (d). Arrows represent the NLO chromophores.

The guest–host systems are just solid solutions of NLO chromophores in an inert matrix. The concentration of NLO chromophores is limited because of already-mentioned strong dipole–dipole interaction leading to antiparallel alignment, resulting in an increase in propagation losses and decrease of $\chi^{(2)}$ susceptibility. The polar order is obtained by applying an external field. In order to increase the rotational mobility of chromophores, the material is heated to the glass transition temperature of polymer. The interaction of dipole moments with the external field forces them to orient in its direction. The orientation is frozen by cooling the material (usually a thin film) to room temperature. However, the stability induced in this way results in a polar order that is poor. Better stability and higher concentration of chromophores is obtained by attaching chemically the NLO active molecules to the polymer backbone (side-chain polymers). However, it requires a significant effort in chemical synthesis. The stability of induced order depends strongly on the difference between the glass transition and the operation temperatures. The larger the difference, the less relaxation is observed. Therefore, a lot of effort is going into developing functionalized high glass transition temperature polymers such as polyimides, polyurethanes, polyvinyl carbazoles, etc.

The main-chain polymers (iii) attract a relatively weak interest. This is due, not only to the difficulties encountered with chemical synthesis, but also with the efficient chromophore orientation. More promising is the last class of functionalized polymers (iv). Here the active chromophores are used to link covalently the polymer chains through a thermal or photo-crosslinking process. However, the poling process is very delicate as the glass transition temperature is increasing with the poling time, so the time process has to be carefully monitored. Also the cross-linking may lead to shrinkage and crackling of thin films and as a consequence, to the increase of propagation losses.

A special class of functionalized materials, similar to poled polymers, represent sol–gels. Here the active chromophores either fill the pores of sol–gel or are chemically bonded to the matrix. The poling process is very similar to that applied to the thermally and photo cross-linking polymers and also has to be carefully monitored. The main advantage of these materials consists of excellent optical properties, and the disadvantage on a relatively low chromophore content, limiting the bulk $\chi^{(2)}$ susceptibility value. The representative values of second-order nonlinear optical susceptibility $\chi^{(2)}_{ijk}$ for different materials for second-order NLO optics, are listed in Table 3.

Poling efficiency

The DC poling of functionalized polymers leads to birefringent noncentrosymmetric materials with two nonzero $\chi^{(2)}$ tensor components: the diagonal:

$$\chi^{(2)}_{ZZZ}(-\omega_0;\omega_1,\omega_2) = NF\beta_{xxx}(-\omega_\sigma;\omega_1,\omega_2) \times \langle\cos^3\Theta\rangle \quad [11]$$

and the off-diagonal:

$$\chi^{(2)}_{XXZ}(-\omega_\sigma;\omega_1,\omega_2) = \frac{1}{2}NF\beta_{xxx}(-\omega_\sigma;\omega_1,\omega_2) \times \langle\sin^2\Theta\cos\Theta\rangle \quad [12]$$

where we assumed for simplicity, that only one nonlinear species, as is usually the case. Z, in eqns [11] and [12], is the direction of the applied external field and Θ is the angle between the electric field and the molecule dipole moment. The efficiency of poling is measured by the ratio:

$$a = \frac{\chi^{(2)}_{ZZZ}(-\omega_\sigma; \omega_1, \omega_2)}{\chi^{(2)}_{XXZ}(-\omega_\sigma; \omega_1, \omega_2)} \qquad [13]$$

It varies between 1 and ∞ (perfect alignment). For isotropic poled polymers $a = 3 \div 6$ and for nematic liquid crystal side-chain polymers, values of $a \propto 18$ were obtained.

Usually, the second-order NLO susceptibility is measured by the second-harmonic generation technique ($\omega_\sigma = 2\omega$; $\omega_1 = \omega_2 = \omega$), giving the electronic part of $\chi^{(2)}$ susceptibility, with ultrafast response time as the generated harmonic wave has to follow the fundamental one. This susceptibility is important, not only for frequency conversion through the second-harmonic generation, but also for sum and difference frequency generation as well as for optical parametric oscillation (OPO) and amplification (OPA). Another important effect described by $\chi^{(2)}(-\omega; \omega, 0)$ susceptibility is the linear electro-optic effect (Pockels effect). It finds application in electro-optic modulation for signal transmission. Traditionally, this effect is described by the electro-optic coefficient r_{ijk}, which is a third-rank three-dimensional tensor. The variation of the medium refractive index under the applied electric field is given by the following formula:

$$\Delta n_i = -\frac{2}{n_i^3} r_{ij} E_j \qquad [14]$$

The electro-optic coefficient is directly linked to the $\chi^{(2)}(-\omega; \omega, 0)$ susceptibility:

$$r_{ijk} = -\frac{2\chi^{(2)}_{ijk}(-\omega; \omega, 0)}{(n_i n_j)^2} \qquad [15]$$

The measured values of electro-optic coefficient for some selected organic single crystals and thin films are also given in Table 3.

Third-Order Nonlinear Optical Materials

There is no symmetry restriction on molecules and materials for third- (or higher-odd-) order nonlinear optical effects. These materials are used in significantly larger classes of applications than the materials for second-order NLO effects, particularly in logic systems, all optical switching, frequency conversion (e.g., frequency tripling in third-harmonic generation), light amplification, optical bistability, all optical switching, etc. In the case of organic materials, it was shown that the conjugated quasi 1D π electron systems, such as semiconducting polymers (Figure 4) exhibit an enhanced third-order NLO response.

Molecules

Similarly, as in the case of second-order NLO materials, the NLO response depends strongly on the conjugation length. In the case of conjugated quasi 1D molecules, such as polymers with a chemical structure as shown in Figure 4, the γ tensor component in the conjugation direction (largest hyperpolarizability) is strongly enhanced and described by a scaling law:

$$\gamma_{xxxx} \propto L^{\alpha_t} \qquad [16]$$

where L is the conjugation length and the exponent $\alpha_t > 1$. The scaling law, eqn [16], can also be presented as dependent on γ on a number of π conjugated double or triple bonds N:

$$\gamma_{xxxx} \propto N^{\alpha_\gamma} \qquad [17]$$

It was extensively studied for a series of conjugated oligomers polyenes, oligothiophenes, etc., and the exponential coefficients are listed in Table 4, together with the calculated values. For a larger value of double (or triple) bonds, a saturation in $\chi^{(3)}$ susceptibility is observed.

The molecular second hyperpolarizability measurements are derived from solution measurements. Some typical values, obtained by the third-harmonic generation technique (THG) are listed in Table 5. Although other NLO property determination techniques were used, the THG method gives the fast, electronic part of molecular hyperpolarizability.

Bulk Materials

Importance of Order

Similarly, as in the case of materials for second-order NLO effects for practical applications the value of $\chi^{(3)}$ susceptibility is important, which on the other hand depends on the molecular second hyperpolarizability γ. Although the noncentrosymmetry is not required in the case of third-order NLO materials, the values of the bulk $\chi^{(3)}$ susceptibility depend on the order, as it follows from eqn [7]. This is particularly clear in the case of conjugated molecules, with enhanced γ_{xxxx} component. In the case of parallel polarizations

of $\omega_\sigma, \omega_1, \omega_2, \omega_3$ fields, the bulk susceptibility is given by:

$$\chi^{(3)}(-\omega_\sigma; \omega_1, \omega_2, \omega_3) = NF\gamma_{xxxx}(-\omega_\sigma; \omega_1, \omega_2, \omega_3) \times \langle \cos^4 \Phi \rangle \quad [18]$$

where F is the total field factor and Φ is the angle between the polarization direction of $\omega_\sigma, \omega_1, \omega_2, \omega_3$ fields and a chosen direction in the laboratory reference frame. The value of $\langle \cos^4 \Phi \rangle$ varies between 0.2 for an isotropic distribution of polymer chains and 1 for perfectly aligned, respectively. It gives a factor of 5 difference in the macroscopic $\chi^{(3)}$ susceptibility. Some examples of third-order NLO susceptibilities for representative conjugated polymers are given in Table 6. These were obtained by third-harmonic generation technique which measures the fast, electronic contribution to $\chi^{(3)}$.

Two-Photon Absorbing Materials

Two-photon absorbing (TPA) materials are a special class of third-order NLO materials exhibiting a complex Kerr susceptibility $\chi^{(3)}(-\omega; \omega, -\omega, \omega)$. In this case, the nonlinear refractive index, derived from eqn [1] is complex too.

$$n = n_0 + n_2 I = n_0 + (n_2^r + \kappa_2) I \quad [19]$$

where I is the light intensity, n_2^r is the real part and κ_2 is the imaginary part (nonlinear extinction coefficient) of the nonlinear index of refraction, respectively. The nonlinear index of refraction is directly related to the Kerr susceptibility $\chi^{(3)}(-\omega; \omega, -\omega, \omega)$:

$$n_2 = \frac{3\chi^{(3)}(-\omega; \omega, -\omega, \omega)}{4\varepsilon_0 c n_0^2} \quad [20]$$

where c is the light velocity. If $\chi^{(3)}(-\omega; \omega, -\omega, \omega)$ is complex (close to a resonance) then n_2 is complex too and the light beam propagating in such a medium in direction z is attenuated through the two-photon absorption process:

$$I(z) = I_0 \, e^{-(\alpha_L + \alpha_{TPA} I)z} \quad [21]$$

λ_{max} corresponds to the maximum linear and λ_{TPA} to the maximum nonlinear absorption wavelengths, respectively, DCNP: 3-(1,1-dicyanoethenyl)-1-phenyl-4,5-dihydro-1H-pyrazole, for other molecules see **Figures 4** and **5** and preceding tables.

where α_L is the linear and α_{TPA} is the two-photon absorption coefficient, respectively. The last coefficient can be explicitly expressed by the imaginary part of the nonlinear index of refraction:

$$\alpha_{TPA} = \frac{2\pi\kappa_2}{\lambda_\omega} \qquad [22]$$

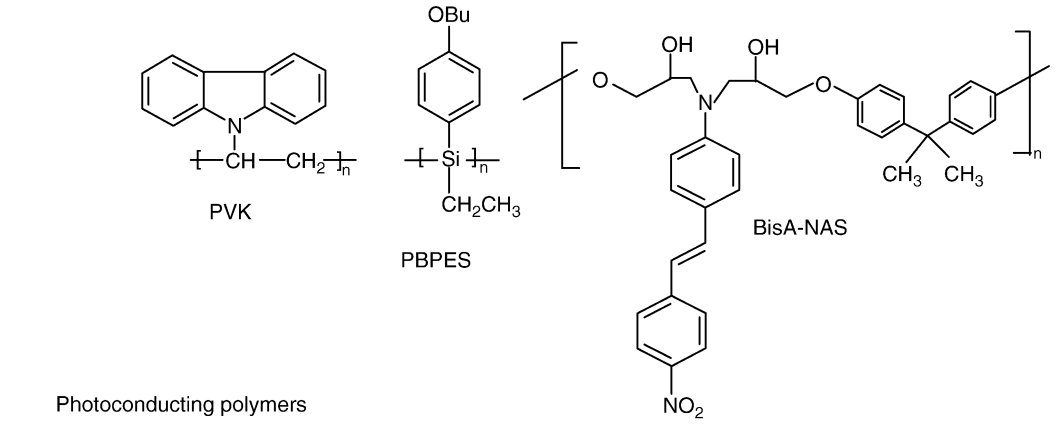
where λ_ω is the wavelength of the propagating beam. On the molecular level one also defines the two-photon absorption cross-section given by

$$\sigma_{TPA} = \frac{\hbar\omega}{N}\alpha_{TPA} \qquad [23]$$

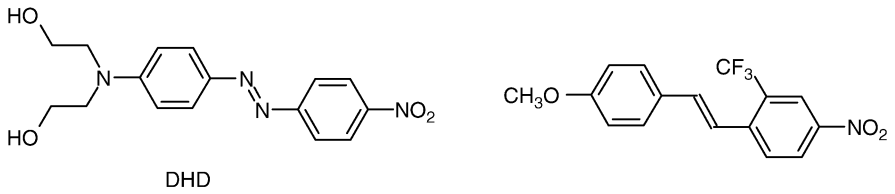
where N is the number density of molecules. The values of TPA absorption cross-sections and two-photon absorption coefficients for selected organic molecules and solids are listed in Tables 7 and 8, respectively.

Photorefractive Materials

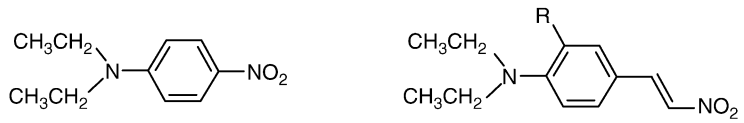
The photorefractive effect consists of the generation of a refractive index grating in an NLO material by its inhomogeneous illumination. This is a necessary condition but not a sufficient one. The sufficient condition consists of the possibility of creating the space charge field, which combined with the applied external field, leads to the refractive index modulation through the Pockels effect. In that case, the refractive index grating is phase mismatch with the intensity grating, leading to the transfer of photons from one beam to another, as occurs in two-beam coupling experiments, and thus applies to light amplification. Although the photorefractive effect was first observed in ferroelectric single crystals, the researchers at IBM demonstrated, at the beginning of 1990s, the photorefractive effect in organic composite materials. However, the main contribution in these materials comes from the rotational mobility of nonlinear optical (NLO) chromophores under the applied external electric field. Thus, to exhibit a photorefractive effect, the organic material has to possess the following properties:



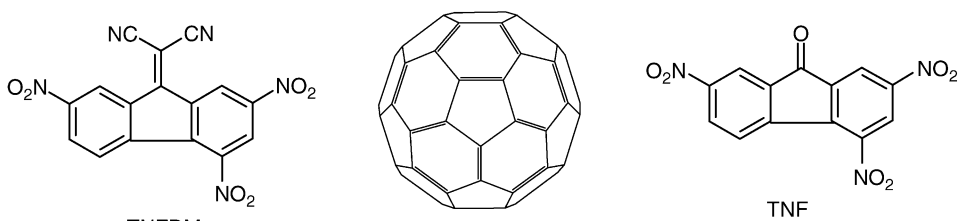
(i) charge generation and separation capacity;
(ii) charge mobility;
(iii) linear electro-optic (Pockels) effect; and
(iv) rotational mobility.



Composite Materials



The different properties satisfying the above requirement to exhibit a photorefractive effect, are obtained by mixing together four types of molecules:



(i) photoconducting polymer;
(ii) highly second order nonlinear CT molecules;
(iii) photoensitizer for charge generation under illumination; and
(iv) plasticizer, lowering the glass transition temperature, thus increasing the rotational mobility.

Some examples of different types of molecules used are shown in **Figure 5**. Although these structures exhibit large exponential gain coefficients Γ and high diffraction efficiencies η, their main disadvantage consists of slow, seconds-duration response times

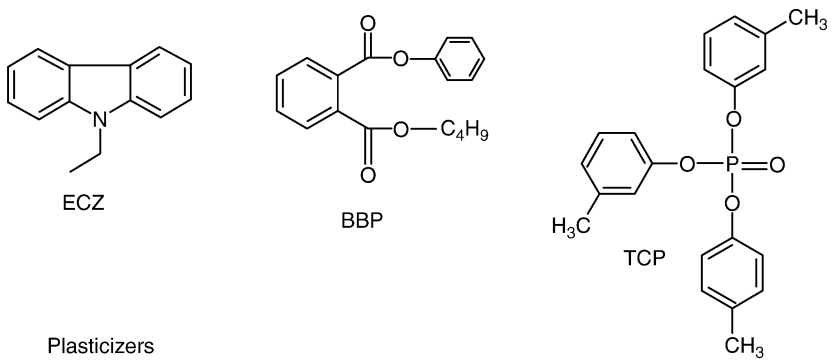


Figure 5 Chemical structures of photoconducting polymers, CT chromophores, photosensitizers and plasticizers commonly used for the fabrication of photorefractive polymers.

and require large external operation electric fields (~100 V/μm).

Photorefractive Liquid Crystals

In order to improve the performances of organic photorefractive materials the use of nematic liquid crystals was proposed as active media. These materials exhibit a large rotational mobility, requiring a relatively small electric field with response time of milliseconds. The reorientation of domains requires $2 \div 3$ orders of magnitude electric fields as compared with the composite materials (reorientation of individual molecules). Several types of structures of liquid crystal based photorefractive structures are realized, such as:

- composite materials in which the liquid crystals mesogens are NLO chromophores;
- polymer dispersed liquid crystals (PDLCs);
- hybrid photoconducting polymers – liquid crystals (HPCPLCs), in which the rotational mobility is separated from the charge mobility. Moreover the use of photoconducting polymer allows the modulation of the electric field on the liquid crystal layer, enhancing the effect.

The performances of different, representative, organic photorefractive structures are listed in Table 9.

Introduction

The basic construction and imaging properties of the optical microscope, one of the most important optical instruments, are described. But the restrictive meaning of a microscope as a device that the user looks down to see a magnified image is far from the present terminology that includes scanning systems (where the image is stored in a computer), nonvisible radiation, such as electrons or X-rays, and a variety of different contrast mechanisms.

According to the *Oxford English Dictionary* a microscope is 'an instrument magnifying objects by means of lenses so as to reveal details invisible to the naked eye'. Thus, basically a microscope forms a magnified image of an object. The first microscopes used visible light and formed an image showing variations in the intensity of light scattered by the object. This intensity is in general related to the optical properties of the object in a complicated way.

Nowadays there are many different types of microscope. Our understanding of a microscope must therefore be generalized in the following ways.

- The microscope may not be a conventional imaging system using lenses or mirrors. For example, it may be a scanning imaging system. A confocal system is a combination of a conventional and a scanning system. Another important category of microscopes is that of probe microscopes, including near-field optical microscopes. Some probe microscopes, for example the atomic force microscope (AFM) do not even seem at first glance to rely on the direct use of radiation.
- The microscope may not use visible light, but other electromagnetic radiation, or even other forms of radiation.
- The image can be formed using a variety of different contrast mechanisms. Some of these, such as phase contrast, are designed to image particular optical properties of the sample. Others image the generation of a form of radiation when the object is stimulated by another form of radiation. In particular, in principle, virtually any form of spectroscopy can be the basis of building up an image by measuring the spatial variations in the signal.

Different Forms of Microscopes

The Conventional Microscope

In a simple microscope, an objective lens forms a real, magnified, and inverted image of an object. In a compound microscope, an eyepiece is added, forming a virtual image that is viewed by eye to give real image on the retina. The eye can be replaced by CCD camera to record moving or still images. In early microscopes, the objective lens and eyepiece are mounted in the two ends of a brass tube. The objective screws into the tube using an RMS (Royal Microscopical Society) thread (0.8″ Whitworth 36 threads per inch), until its mounting face is flush with the end of the tube. The length of the tube is the mechanical tube length. The distance from the mounting face of the objective to the plane of the real image is the optical tube length, which varied according to different manufacturers in the range 160–210 mm. Now most objectives have infinity tube length, so that they collimate the light from

the object. The collimated light is brought to a focus by an additional tube lens. An objective of correct tube length should always be used as otherwise spherical aberration is introduced. As the objective, tube lens, and eyepiece are designed together as a system, great care should be exercised when mixing components from different manufacturers.

Abbe showed that in order to form a perfect lateral image the objective must satisfy a different condition called the Herschel condition. Otherwise the image of an off-axis point will suffer from coma. An aberration-free system satisfying the sine condition is called an aplanatic system. A microscope produces a three-dimensional (3D) image of a 3D object. A point of the object closer to the lens appears further from the lens in the image. If the lateral magnification is M, the longitudinal magnification is approximately equal to M^2. However, it can be shown that it is impossible to devise an instrument that can produce a perfect 3D image of a 3D object, because to have a perfect transverse image the system must satisfy Abbe's sine condition, but to have a perfect axial image the system must satisfy the Herschel condition. These two conditions are not mutually compatible. Actually, we find that the longitudinal magnification is not exactly equal to M^2, and is not even constant in space. Different depths of the object are imaged differently: the microscope objective only produces a good image for one plane of focus, and other planes will exhibit spherical aberration. However, all of these problems can be overcome by bringing the part of the object under observation into focus, without refocusing the eye or other detector. A 3D image can thus be generated by scanning the object stage in the axial direction, and recording a stack of images from different depths in a computer. For modern objectives of infinite tube length, focusing can be alternatively achieved by piezoelectric scanning of the objective lens.

Resolution

For an object consisting of a single bright point object in a dark background, the image produced by a perfect microscope, according to paraxial diffraction theory, is the so-called Airy disk, consisting of a bright central spot, surrounded by a series of rings. The intensity in a meridional cross-section through the Airy disk is the same for any aperture of objective, or wavelength of light, but its width varies. The intensity of the first bright ring is 1.75% of that at the peak. The radius of the first dark ring of the Airy disk is

$$r_0 = \frac{0.61\lambda}{n \sin \alpha} \qquad [1]$$

where λ is the wavelength, n is the refractive index of the immersion medium, and α is the angle subtended at the edge of the objective aperture. The radius depends on $n \sin \alpha$, which is called the numerical aperture and should be as large as possible for good resolution. Thus, high-magnification lenses often use an immersion fluid, usually oil with a refractive index of 1.518 (ISO 8036/1).

The optical coordinate v is defined as

$$v = \frac{2\pi}{\lambda} rn \sin \alpha \qquad [2]$$

so that the dark ring of the Airy disk occurs at a value of v of $2\pi \times 0.61 = 3.83$. Resolution is sometimes expressed in terms of the full width at half maximum (FWHM) of the image of a point object, which is 3.232 in optical coordinates. A full nonparaxial theory does not give a very different figure.

Resolution of a microscope is often specified by two-point resolution, which describes whether the image of two points can be distinguished from that of a single point. According to the Rayleigh criterion of two-point resolution, two points are just resolved if the second point is placed on the first dark ring of the first. The separation is then $0.61\lambda/(n \sin \alpha)$. A cross-section through the image in an incoherent optical system of two bright point objects of equal strength and different separations is shown in **Figure 1**. The intensity in the image between the points decreases as the separation is increased. The ratio of the intensity midway between the points to that at the points for the Rayleigh criterion to be satisfied is then found to be 0.735.

The concept of resolution should be distinguished from sensitivity or precision. An object much smaller than the resolution limit can still be detected, perhaps weakly, in a microscope: this detection of weak contrast depends on the sensitivity of the microscope rather than its resolution. The size of an object can also be measured with a precision much greater than the resolution of the microscope.

Illumination

If the object is not self-luminous, in order to be imaged in a microscope it must be illuminated. A semitransparent object, such as a biological slice, is illuminated in transmission. For observation of bulk objects, or surfaces, we use illumination in the reflection geometry, called epi-illumination. Either a tungsten halogen lamp or an arc source is usually used. In critical illumination, the source is focused on to the object by a condenser lens. The disadvantage of this approach is that variations in emission of the source are imaged directly into the image.

Cheaper microscopes avoid this problem by using a diffuser. Better microscopes use instead the Köhler illumination system, where the source is placed in the front focal plane of the condenser lens. Figure 2 shows a Köhler illumination system in which the source is imaged into the front focal plane of the condenser lens by another, projector, lens. The system incorporates a separate field stop and aperture stop. In practice, the size of the field stop should be reduced to illuminate as small a region of the object as necessary in order to minimize stray light. An important part of setting up a microscope to operate properly consists in centering the aperture stop of the condenser. This is often done using a so-called Bertrand lens that allows imaging of the aperture stop.

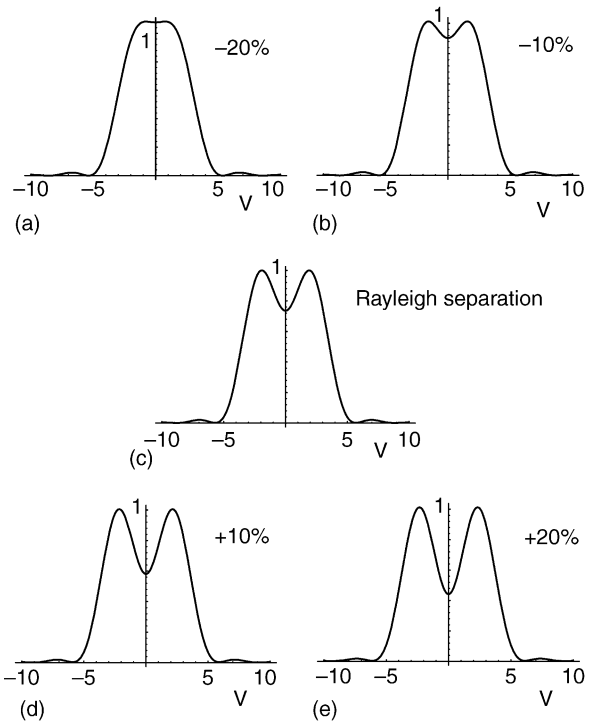

Figure 1 A cross-section through the image of two equal point objects in an incoherent microscope. The separation of the points is that for the Rayleigh criterion to be satisfied, and for changes of ±10, 20% of the Rayleigh separation.

Image formation

The Rayleigh criterion was originally specified for an incoherent optical system. It is thus applicable in fluorescence microscopy, as fluorescence is an incoherent process as two fluorescent point objects fluoresce independently. But for the image of a trans-illuminated object, the resolution depends on the coherence of the illumination. This is controlled by the numerical aperture of the condenser lens as compared with that of the objective. The ratio of these numerical apertures is called the coherence parameter, S, so that

$$S = \frac{n_c \sin \alpha_c}{n \sin \alpha} \qquad [3]$$

For $S = 0$ the illumination is purely coherent, while for $S \rightarrow \infty$ imaging becomes purely incoherent, thus corresponding to the Rayleigh criterion, so S should really be called an incoherence parameter. An important in-between case is when $S = 1$, when the apertures of objective and condenser are equal. This is termed matched, full, or complete illumination. According to the generalized Rayleigh criterion, the points are just resolved when the ratio of the intensity midway between the points to that at the points is 0.735, which is called the generalized Rayleigh criterion. We require that the distance between the points is as small as possible when this occurs. The generalized Rayleigh separation is the same for incoherent illumination and for $S = 1$, and corresponds to a distance of $2v_0 = 3.83$ in optical coordinates. Note, however, that for other separations of the points, the ratio is different for these two cases: it is not true, but often erroneously stated, that $S = 1$ corresponds to incoherent imaging. Resolution improves as the aperture of the condenser is increased ($2v_0 = 5.15$ in optical coordinates for coherent illumination) reaching a maximum when $S = 1.46$, when resolution is 9% better than for incoherent imaging ($2v_0 = 3.58$). This maximum in resolution is achieved when the numerical aperture of the condenser is larger than that of the objective, which is not

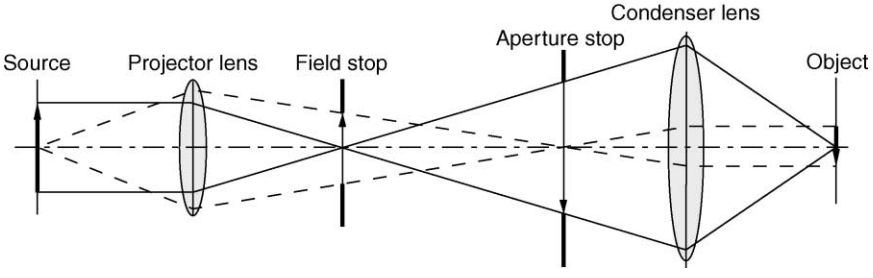

Figure 2 Geometry of the Köhler illumination system. In practice an arrangement with a smaller number of lenses is usually used.

physically achievable if the objective has the highest possible numerical aperture. Similarly, it is impossible to achieve incoherent illumination with very large objective numerical apertures.

The effect of coherence on the resolution of an image depends on the form of the object, and on the particular resolution criterion employed. In practice, contrast also depends on the aperture of the condenser. Usually, opening the condenser improves resolution, but reduces contrast, so there will be an optimum condenser aperture size.

Abbe theory of microscope imaging

Abbe argued that for coherent illumination of a grating, the grating spectra can be observed in the back focal plane of the objective. The tube lens then forms an image from the grating components. Thus, this is an early description of Fourier optics. The strength of the grating components can be altered in the back focal plane to give various optical effects, such as phase contrast. Abbe's theory was not properly appreciated at the time because it was known that in practice, resolution could be improved by using a larger condenser aperture, which does not give coherent illumination. There was much controversy about the merits of Köhler versus critical illumination, and different sizes of condenser aperture.

We now know that Köhler and critical illumination are in principle equivalent. The aberrations of the condenser lens are not important, so that the source and condenser together behave simply as a partially coherent effective source. Imaging can still be described by Fourier optics within the framework of partially coherent imaging theory.

Although Köhler and critical illumination are equivalent in principle, Köhler illumination is in practice better because of its improved illumination uniformity.

Depth of focus

The longitudinal image of a point object is found to be approximately invariant when expressed in terms of an optical coordinate u, defined as

$$u = \frac{8\pi}{\lambda} zn \sin^2 \frac{\alpha}{2} \qquad [4]$$

The axial resolution, and thus also the depth of focus, varies strongly with aperture. The FWHM for longitudinal imaging is 11.13 in optical coordinates.

Microscope objectives

Because microscope objectives often have large apertures, aberrations will be very strong, unless the objective is designed correctly. The basic design principle for a high aperture lens is the aplanatic front element (Figure 3). It is found that all rays from a point A in a sphere of refractive index n, where A is a distance r/n from its center, appear to come from a point B, distance rn, without any aberration. This principle is used by employing a front element that has one surface of the same radius of curvature as the sphere. The front surface is a sphere centered on A (Figure 3b), so that the rays are not deviated on crossing it.

A low-power achromat uses just two components with different optical dispersion to cancel chromatic aberration and correct for other aberrations (an achromatic doublet). For higher powers, two separated doublets are necessary. For the highest apertures, an aplanatic front is used. However, this can never converge the light, but only makes it less divergent. It is thus used together with an achromatic doublet. For oil immersion, the interface between the oil and the front element is not very important, so it is made planar to simplify manufacture. In practice, it is

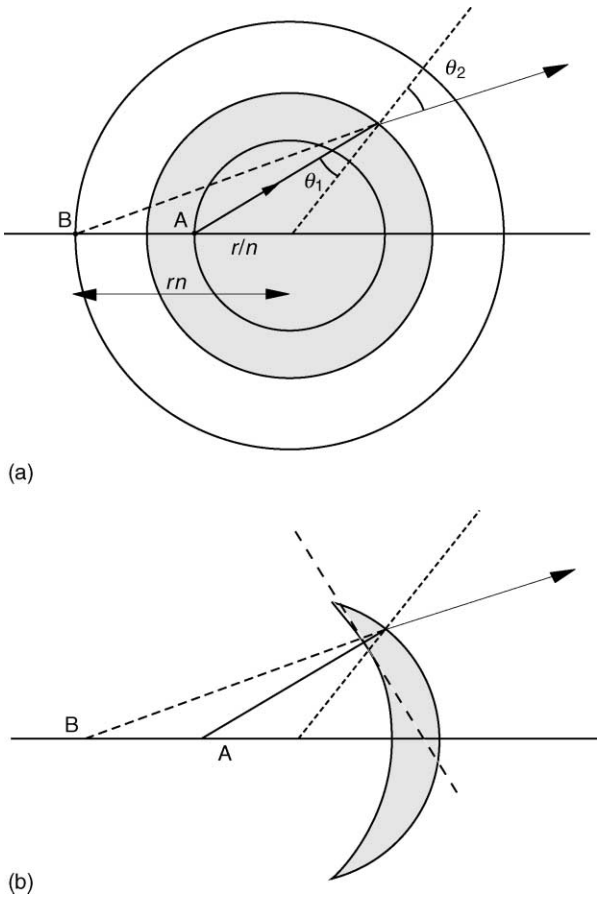

Figure 3 The principle of the aplanatic front: (a) an aplanatic surface; (b) a meniscus lens that acts as an aplanatic system.

usually made planar even for a dry lens, and the resulting aberrations cancelled out elsewhere in the objective. Apochromats, corrected for three colors, use more elements, which may include two or more stages of aplanatic front. The final objective thus consists of a number of elements that must be accurately aligned relative to one another. The objective is adjusted by the manufacturer to give a good star image (image of a point object). First a spacer is selected to optimize spherical aberration. Then a sleeve is adjusted to make the objective parfocal with others. Finally a screw is used to center the assembly to remove coma.

Conventional and Scanning Microscopes

Conventional microscope

Various different types of transmission microscope are illustrated in Figure 4. We consider image formation in a conventional microscope as illustrated schematically in Figure 4a, showing a microscope with critical illumination. A large area incoherent source is focused by the condenser lens on to the specimen, illuminating a comparatively large area of the specimen, corresponding to the whole field of view of the objective. Information from each illuminated point in the specimen is simultaneously transmitted by the objective lens to form the primary image. The objective is responsible for forming the image, with the condenser playing only a secondary role in determining the resolution of the system, through control of the coherence of the illumination. Figure 4b shows a conventional microscope in which the image is measured point by point by a detector. In practice this could be achieved by using a CCD detector.

Scanning microscope

An image can be generated by a scanning system, as illustrated in Figure 4c. A probe of light is formed by demagnification of a source, and is scanned over the object in a raster. The transmitted (or reflected) light is detected by a photodetector and thus builds up an image. The size of the probe of light limits the resolution of the system, that is, the smallest detail in the object that can be seen in the image. It should be noted that the magnification of the image is given simply by the ratio of the distance scanned in the image to the distance scanned by the probe. It is thus unrelated to the demagnification of the source. The image magnification can be altered without changing the lens and is not in any way related to the resolution.

It has been shown that the imaging properties of scanning and conventional microscopes are identical under analogous conditions, this being known as the principle of equivalence. This property is based on the principle of reciprocity, which is a very general physical law that holds even with diffraction,

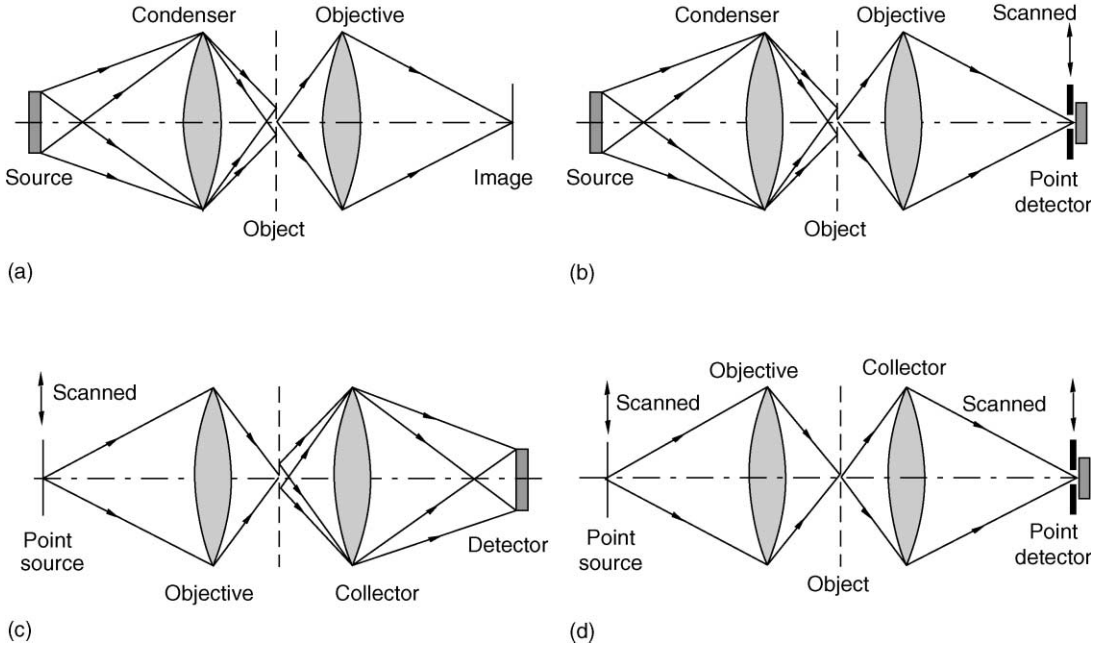

Figure 4 Different geometries of transmission microscope: (a) a conventional microscope; (b) a conventional microscope with a point detector; (c) a scanning microscope; (d) a confocal microscope.

absorption, multiple scattering, and stray light. The principle of equivalence is generally valid except if there are nonreciprocal magnetic or polarization effects, or energy losses involved (such as in fluorescence microscopy, and with inelastic scattering in electron microscopy).

Scanning systems exhibit a number of important advantages over conventional systems. Broadly, these are based on two classes of property. First, in a scanning system the image is in the form of an electronic signal. As a result, this is advantageous for quantitative measurements, as well as for image processing, including image enhancement, image restoration, and image analysis. Second, in a scanning system the object is illuminated by a focused spot, which extends the range of imaging modes available.

Confocal microscope

Finally in Figure 4d, we combine the arrangements of Figures 4b and c to give a confocal scanning optical microscope, in which a point source illuminates just a small region of the object, and a confocal point detector detects light from this illuminated region. If the point source and detector are scanned in unison, a two-dimensional image is generated. However, this system now behaves very differently from the previous ones. The confocal microscope is thus not a special case of the general partially coherent conventional imaging system. From the symmetry of Figure 4d, it is clear that the two lenses play an equal part in the imaging process. This results in an improvement in resolution. In fact, the confocal system behaves as a coherent imaging system, but with a sharper effective point spread function than in a conventional coherent microscope.

Although Figure 4 is drawn for the transmission geometry, in practice most confocal systems operate in the reflection or epi-illumination mode, in which the same objective lens is used both for illumination and detection. For a specimen placed in the focal plane, the properties of confocal transmission and reflection systems are identical. However, once the object is moved from the focal plane, certain differences arise: in particular in confocal reflection a strong optical sectioning effect occurs that allows a single section through a thick object to be imaged. This is the major advantage of the confocal microscope arrangement. Figure 4 also applies equally well to fluorescence imaging. However, in this case, because of the incoherent nature of fluorescence emissions after excitation by coherent light, imaging is then incoherent.

Confocal microscopes can be achieved by using either a point detector, in practice performed by placing a pinhole in front of a photodetector, or by using a coherent detector. Such a coherent detector, sensitive to the amplitude of the incident radiation, is not directly available for light, but is available for acoustic radiation, as in a scanning acoustic microscope. For light, a confocal effect can also be achieved by using an interferometric method to synthesize a coherent detector. Thus, in interference microscopes using the high aperture condenser and objective lenses, an optical sectioning effect arises similar to that in the confocal microscope. Another way of producing a coherent detector is to use a single-mode optical fiber.

Probe Microscopes

Scanning tunneling microscope

The scanning tunneling microscope was the first of the family of probe microscopes, relying on a fundamentally different principle from the usual forms of microscope. A physical tip in the nanometer range is brought close, also in the nanometer range, to a conducting sample. If an electric potential is applied, electrons can tunnel across between the sample and the tip. By scanning the tip mechanically across the sample, an image can be generated with a resolution in the subnanometer range. The surface topography can also be measured with subnanometer sensitivity. While interference microscopy can measure surface topography with subnanometer sensitivity, in this case the profile is averaged over the lateral resolution of the microscope, of the order of the wavelength in dimensions. The scanning tunneling microscope can image individual atoms. The signal is related to the work function of the material. Altering the bias voltage allows the band structure of the material to be investigated.

Atomic force microscope

In the atomic force microscope, the force between the surface and the tip is measured using a cantilever beam and used to build up an image. Atomic force microscopy can be performed in either a contact or noncontact mode. It can be used with insulating specimens. Optical methods, often using a position-sensitive detector, are used to measure displacements of the cantilever.

Near-field scanning optical microscope (NSOM)

In a near-field scanning optical microscope, a very small tip or aperture is scanned relative to the specimen to attain resolution greater than the classical limit set by the wavelength of the radiation. As Figure 5 shows, various different designs of near-field microscope have been proposed. It is evident that

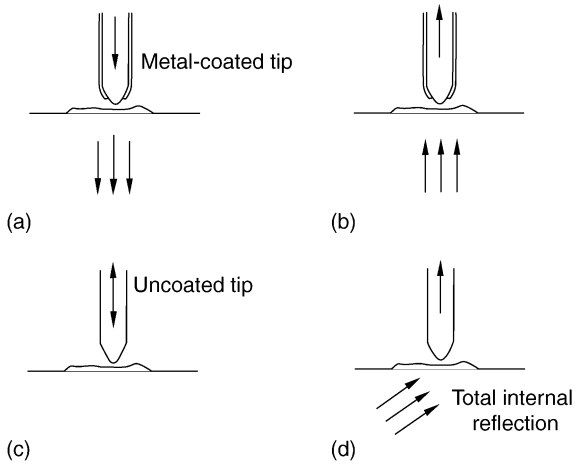

Figure 5 Different forms of near-field microscope: (a) illumination-mode NSOM; (b) collection-mode NSOM; (c) a near-field probe used for both illumination and collection in a confocal arrangement; (d) photon tunneling microscope (PTM). Reproduced with permission from Sheppard CJR (1978) The scanning optical microscope. *The Physics Teacher* 16: 648–651. © 1978 American Association of Physics Teachers.

these again form into the conventional/scanning categories described earlier. The sample can be illuminated using the near-field probe, as in Figure 5a. This is called the illumination-mode NSOM. Or the sample can be uniformly illuminated, and a signal detected using a near-field probe as in Figure 5b, giving a collection-mode NSOM. Or a confocal arrangement can be used, with a near-field probe used for both illumination and collection (c). In this case, an uncoated tip can be used; as otherwise the detected signal will be very small. Finally, Figure 5d shows the photon tunneling microscope (PTM), in which the sample is illuminated with evanescent waves produced by total internal reflection and an uncoated tip used to probe the evanescent field in the presence of the sample.

Different Types of Radiation

Electromagnetic Radiation

UV radiation and X-rays

The first microscopes used visible light, but, in fact, we do not need to use visible light, but can use any electromagnetic radiation, over a broad range of different available wavelengths. In Figure 6 we show the wavelength of the electromagnetic spectrum, illustrating how the wavelength in air varies with frequency. Instead of using visible light, shorter wavelengths allow greater resolution to be achieved. Ultra-violet light is commonly used to excite fluorescence. X-rays have also successfully been used to image biological samples.

IR and microwave radiation

In the longer wavelength region, infra-red radiation is used for observation of semiconductors or for molecular spectroscopic imaging. Imaging of emitted midinfra-red radiation can show up variations in temperature, such as hot spots in semiconductors. Microwaves have also been used, but resolution is limited by the long wavelength. For this reason microwaves (and mid-IR) have also been used for near-field microscopy.

Other Radiation

Electron microscope

The other important class of radiation that can be used for illumination is matter waves. The most common of these, of course, is electrons, the wavelength of which, as a function of acceleration voltage, is shown in Figure 7. The bend in the curve at very high voltages is caused by relativistic effects. The wavelength of the electrons is very small: even for 100 V electrons, the wavelength is only 0.1 nm. But aberrations caused by the electron lenses limit

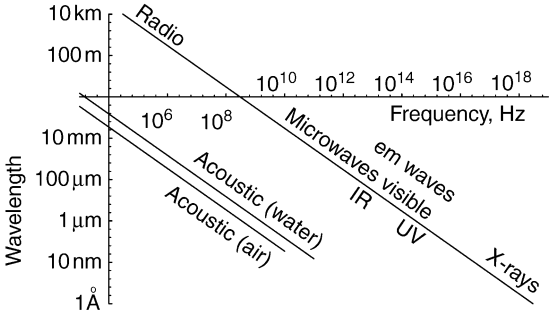

Figure 6 The wavelength of different forms of electromagnetic radiation and acoustic radiation. Reproduced with permission from Sheppard CJR (2002) The generalized microscope. In: Diaspro A (ed.) *Confocal and Two-Photon Microscopy: Foundations, Applications and Advances*, pp. 1–18. New York: Wiley-Liss.

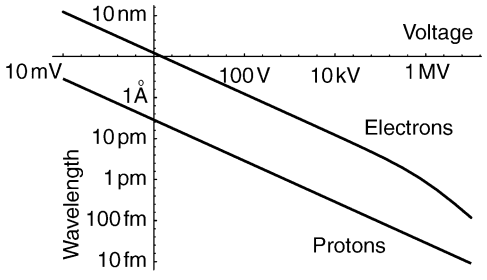

Figure 7 The wavelength of matter waves (electrons and protons) as a function of accelerating voltage. Reproduced with permission from Sheppard CJR (2002) The generalized microscope. In: Diaspro A (ed.) *Confocal and Two-Photon Microscopy: Foundations, Applications and Advances*, pp. 1–18. New York: Wiley-Liss.

resolution so that at present atomic resolution is only just achievable, even with much higher voltages.

In a transmission electron microscope (TEM), a beam of electrons is produced by an electron gun. The specimen is illuminated via a condenser lens (or lenses). Usually these are magnetic lenses in which a current in a coil produces a magnetic field that focuses the electrons. The electrons that are transmitted through the specimen are then focused by a series of lenses to form a final image that can be viewed directly on a phosphor screen. An X-ray detector can be used to characterize the elements in the specimen. An electron-energy-loss spectrometer, together with a detector, can measure the energy of the electrons in a particular region of the image.

Other matter radiation

Instead of electrons, other particle beams can be used for illumination. Figure 7 shows the wavelength of a beam of protons, as function of the accelerating voltage. Because of the larger mass of protons, relativistic effects are not apparent for protons in the curve in Figure 7. Microscope images have also been formed using ions, and even neutral particles such as neutrons. Neutral atom microscopes are also under development.

Acoustic radiation

Instead of electromagnetic waves, acoustic radiation can be used to form a scanning acoustic microscope (SAM). Ultrasonic waves are focused into a water immersion medium. Mechanical scanning is again used to build up an image. Figure 6 shows the wavelength of the acoustic wave as a function of frequency. By using microwave frequencies, wavelengths, and therefore resolution, in the submicron range, can be generated. The SAM acts as a confocal microscope because the detector is sensitive to the amplitude of the acoustic wave. The acoustic microscope provides information on variations in the elastic properties (viscosity and elasticity) of the sample.

Different Contrast Mechanisms

The bright field microscope detects the intensity of the light transmitted through the object. A microscope with a condenser aperture of appreciable size behaves as a partially coherent system, and the image will, in general, depend on the phase of the light coming from the object as well as its intensity. Many objects are weakly scattering, so the contrast of this phase information is weak. In this case, the microscope effectively images variations in the transmittance or reflectance of the sample. Different designs of microscope can be used to image various properties of the object, thus providing new and complementary information. Phase contrast microscopy provides but one example of a different contrast mechanism. In fact, in general, any physical or chemical interaction of the illuminating radiation with the sample can be used as the basis for a contrast mechanism. These different contrast mechanisms can be performed in either a conventional or scanning arrangement, or in a confocal system.

Phase Contrast Microscopy

Phase contrast is a widely used technique in both biological microscopy (in transmission) and materials microscopy (in reflection). Its importance in biological microscopy stems, firstly, from the fact that contrast may otherwise be too weak to be visible, but secondly because the phase variations are caused by changes in optical thickness, related to physical density. In reflection microscopy, phase is related to surface height variations, but also depends on the optical material properties of the sample.

Polarization Microscopy

The polarization state of light transmitted through or reflected from a sample can also be changed. This change is detected in polarization microscopy, for example by placing the sample between crossed polarizers. The birefringence detected can be either material birefringence, or form birefringence (caused by the shape of the microstructure). Polarization microscopy is widely used in biological microscopy, and in mineralogy.

Fluorescence Microscopy

In fluorescence microscopy, electrons excited by illumination decay to the ground state and emit photons of light. Autofluorescence is natural fluorescence of the sample. Fluorescent dyes can be used as labels for particular biological or chemical constituents. Fluorescence microscopy is usually performed in the epi-illumination geometry to assist rejection of light from the source. Often it is performed in a confocal microscope, allowing 3D localization of the fluorescent labels.

Raman Microscopy

Raman spectroscopy can be performed on a microscopic scale to produce images of presence of particular molecular bonds. It is usually performed in a scanning system, often of the confocal type.

This is one example of the wider class of spectroscopic microscopies: in principle, any form of spectroscopy can be used as the basis for a microscope contrast mode.

Nonlinear Microscopy

Another class of contrast mechanisms is based on nonlinear optical interactions. Again, any nonlinear mechanism can be used as the basis for a contrast mechanism. These include two- (or multiphoton) fluorescence, second- (or higher-order) harmonic generation, sum or difference frequency generation, and coherent anti-Stokes Raman scattering (CARS). Probably other nonlinear optical mechanisms will be exploited in microscopy in the future.

Other Contrast Mechanisms

The contrast mechanisms described above, all rely on illumination and detection of light. But in many other modes, radiation of one form can be converted into another. These include cathodoluminescence microscopy (electrons to light), X-ray microanalysis (electrons to X-rays), photo-emission microscopy (light, usually UV, to electrons), photo-acoustic microscopy (light to ultrasonics), photothermal microscopy (light to thermal waves), optical or electron beam induced current (OBIC/EBIC). Again, in many of these, the illuminating or emitted radiation can be focused, or a combination can be used in a confocal arrangement.

Introduction

It is probably fair to say that the development and wide commercial availability of the confocal microscope has been one of the most significant advances in light microscopy in the recent past. The main reason for the popularity of these instruments derives from their ability to permit the structure of thick specimens of biological tissue to be investigated in three dimensions. It achieves this important goal by resorting to a scanning approach together with a novel (confocal) optical system.

The traditional wide-field conventional microscope is a parallel processing system which images the entire object field simultaneously, which is a severe requirement for the optical components. We can relax this requirement if we no longer try to image the whole object at once. The limit of this relaxation is to require a good image of only one object point at a time. The price that we have to pay is that we must scan in order to build up an image of the entire field.

A typical arrangement of a scanning confocal optical microscope is shown in Figure 1 where the system is built around a host conventional microscope. The essential components are some form of mechanism for scanning the light beam (usually from a laser) relative to the specimen and appropriate photodetectors to collect the reflected or transmitted light.

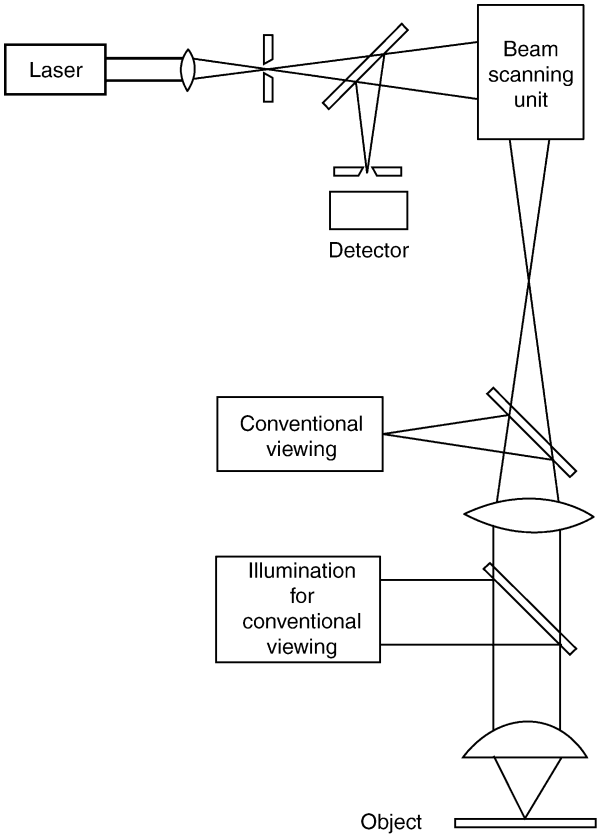

Figure 1 Schematic diagram of a confocal microscope.

Most of the early systems were analog in nature, but it is now universal, due to the serial nature of the image formation, to use a computer both to drive the microscope and to collect, process, and display the image.

In the beam scanning confocal configuration of Figure 1, the scanning is typically achieved by using vibrating galvanometer-type mirrors or acousto-optic beam deflectors. The use of the latter gives the possibility of TV-rate scanning, whereas vibrating mirrors are often relatively slow when imaging an extended region of the specimen, although significantly higher scanning speeds are achievable over smaller scan regions. We should note that other approaches to scanning may be implemented, such as specimen-scanning and lens-scanning. These methods, although not generally available commercially, do have advantages in certain specialized applications. Since this article is necessarily limited in length much additional material may be found in other sources listed in the Further Reading at the end of this article.

Image Formation in Scanning Microscopes

We will not discuss the fine detail of the optical properties of confocal systems. However, the essence is shown in Figure 1 where we see that the confocal optical system consists simply of a point source of light which is then used to probe a single point on the specimen. The strength of the reflected or fluorescence radiation from the single object point is then measured via a point, pinhole detector. The confocal – point source and point detector – optical system therefore merely produces an 'image' of a single object point and hence some form of scanning is necessary to produce an image of an extended region of the specimen. However, the use of single-point illumination and single-point detection results in novel imaging capabilities which offer significant advantages over those possessed by conventional wide-field optical microscopes. In essence, these are enhanced lateral resolution and, perhaps more importantly, result in a unique depth discrimination or optical sectioning property. It is this latter property which leads to the ability to obtain three-dimensional images of volume specimens.

The improvement in lateral resolution may at first seem implausible. However, it can be explained simply by the principle which states that resolution can be increased at the expense of field of view, which can then be increased by scanning. One way of taking advantage of this principle is to place a very small aperture extremely close to the object. The resolution is now determined by the size of the aperture rather than the radiation. In the confocal microscope we do not use a physical aperture in the focal plane but rather use the back-projected image of a point detector in conjunction with the focused point source. Figure 2 indicates the improvement in lateral resolution that may be achieved.

The confocal principle was introduced in an attempt to obtain an image of a slice within a thick specimen which was free from the distracting presence of out-of-focus information from surrounding planes. The confocal optical systems fulfills this requirement and its inherent optical sectioning or depth discrimination property has become the major

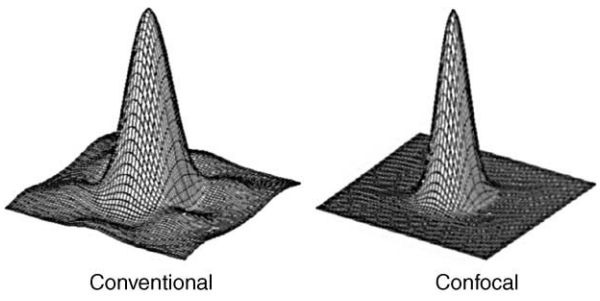

Figure 2 The point spread functions of the conventional and confocal microscopes showing the improvement in lateral resolution which may be obtained in the confocal case.

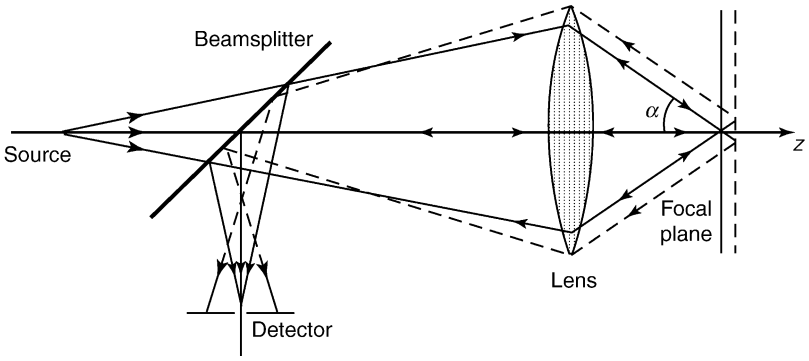

Figure 3 The origin of the optical sectioning or depth discrimination property of the confocal optical system.

motivation for using confocal microscopes, and is the basis of many of the novel imaging modes of these instruments. The origin of the depth discrimination property may be understood easily from Figure 3, where we show a reflection-mode confocal microscope and consider the imaging of a specimen with an undulating surface. The full lines show the optical path when an object feature lies in the focal plane of the lens. At a later scan position, the object surface is supposed to be located in the plane of the vertical dashed line. In this case, simple ray tracing shows that the light reflected back to the detector pinhole arrives as a defocused blur, only the central portion of which is detected and contributes to the image. In this way the system discriminates against features which do not lie within the focal region of the lens. A very simple method of both demonstrating the effect and giving a measure of its strength is to scan a perfect reflector axially through focus and measure the detected signal strength. Figure 4 shows a typical response. These responses are frequently termed the $V(z)$, by analogy with a similar technique in scanning acoustic microscopy. A simple paraxial theory models this response as

$$I(u) = \left[\frac{\sin(u/2)}{u/2}\right]^2 \qquad [1]$$

where u is a normalized axial coordinate which is related to real axial distance, z, via

$$u = \frac{8\pi}{\lambda} nz \sin^2(\alpha/2) \qquad [2]$$

where λ is the wavelength and $n \sin \alpha$ the numerical aperture. As a measure of the strength of the sectioning, we can choose the full width at half intensity of the $I(u)$ curves. Figure 5 shows this value as a function of numerical aperture for the specific case of imaging with red light from a helium neon laser. These curves were obtained using a high aperture theory which is more reliable than eqn [1]

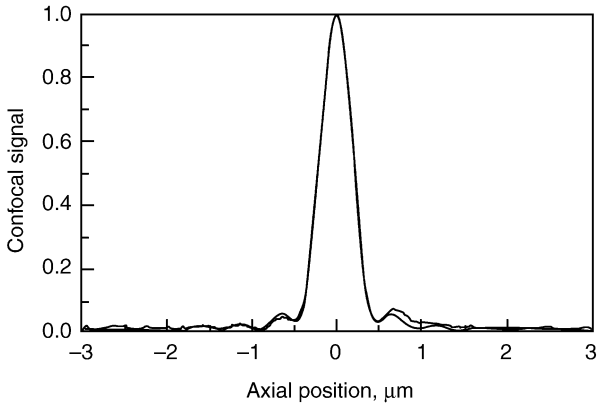

Figure 4 The variation in detected signal as a plane reflector is scanned axially through focus. The measurement was taken with a 1.3 numerical aperture objective and 633 nm radiation.

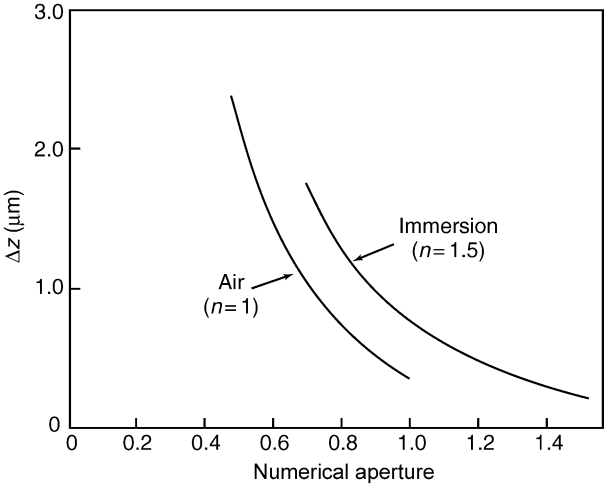

Figure 5 The optical sectioning width as a function of numerical aperture. The curves are for red light (0.6328 μm wavelength). Δz is the full width at the half-intensity points of the curves of $I(u)$ against u.

at the highest values of numerical aperture. We note, of course, that these numerical values refer to nonfluorescence imaging. The qualitative explanation of optical sectioning, of course, carries over to the fluorescence case but the actual value of the optical sectioning strength is different in the fluorescence case.

Applications of Depth Discrimination

Since this property is one of the major reasons for the popularity of confocal microscopes, it is worthwhile, at this point, to review briefly some of the novel imaging techniques which have become available with confocal microscopy.

Figure 6 illustrates the essential effect: Figure 6a shows a conventional image of a planar microcircuit which has deliberately been mounted with its normal at an angle to the optic axis. We see that only one portion of the circuit, running diagonally, is in focus. Figure 6b shows the corresponding confocal image: here the discrimination against detail outside the focal plane is clear. The areas which were out of focus in Figure 6a have been rejected. Furthermore, the confocal image appears to be in focus throughout the visible band, which illustrates that the sectioning property is stronger than the depth of focus.

This suggests that if we try to image a thick translucent specimen, we can arrange, by the choice of our focal position, to image detail exclusively from one specific region. In essence, we can section the specimen optically without having to resort to mechanical means. Figure 7 shows an idealized schematic of the process. The portion of the beehive-shaped object that we see is determined by the focus position. In this way it is possible to take a through-focus series and obtain data about the three-dimensional structure of the specimen. If we represent the volume image by $I(x, y, z)$, then by focusing at a position $z = z_1$, we obtain, ideally, the image $I(x, y, z_1)$. This, of course, is not strictly true in practice because the optical section is not infinitely thin.

It is clear that the confocal microscope allows us to form high-resolution images with a depth of focus sufficiently small that all the detail which is imaged appears in focus. This suggests immediately that we can extend the depth of focus of the microscope by adding together (integrating) the images taken at different focal settings without sacrificing the lateral resolution. Mathematically, this extended-focus image is given by

$$I_{\mathrm{EF}}(x, y) = \int I(x, y, z)\mathrm{d}z \qquad [3]$$

As an alternative to the extended-focus method, we can form an auto-focus image by scanning the object axially and, instead of integrating, selecting the focus at each picture point by recording the maximum in the detected signal. Mathematically, this might be written as

$$I_{\mathrm{AF}}(x, y) = I(x, y, z_{\max}) \qquad [4]$$

where $z_{\max}$ corresponds to the focus setting giving the maximum signal. The images obtained are somewhat similar to the extended focus and, again, substantial increases in depth of focus may be obtained. We can go one step further and turn the microscope into a noncontacting surface profilometer. Here we simply display $z_{\max}$.

It is clear by now that the confocal method gives us a convenient tool for studying three-dimensional structures in general. We essentially record the image as a series of slices and play it back in any desired fashion. Naturally, in practice it is not as simple as this, but we can, for example, display the data as an $x - z$ image rather than an $x - y$ image. This is somewhat similar to viewing the specimen from the side. As another

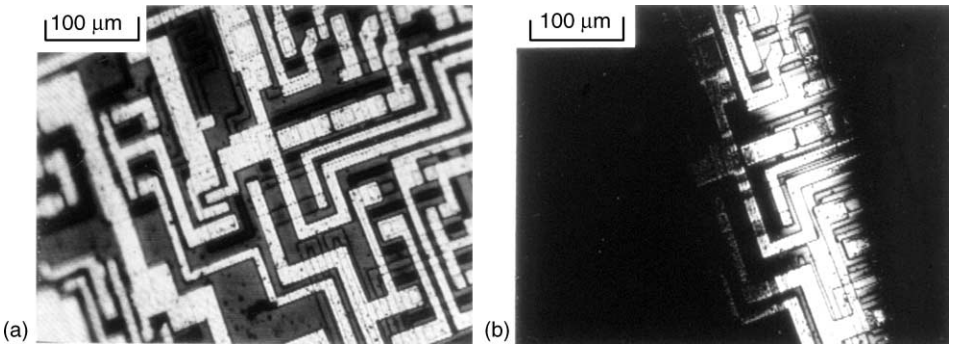

Figure 6 (a) Conventional scanning microscope image of a tilted microcircuit: the parts of the object outside the focal plane appear blurred. (b) Confocal image of the same microcircuit: only the part of the specimen within the focal region is imaged strongly.

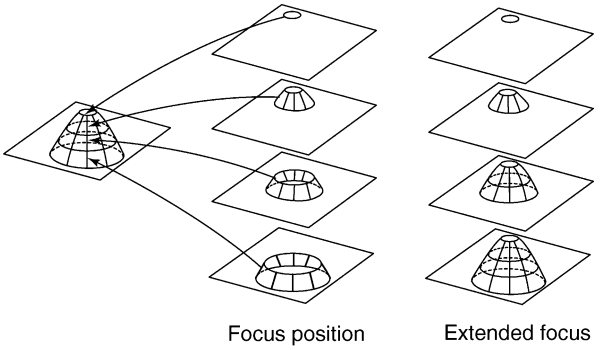

Figure 7 An idealization of the optical sectioning property showing the ability to obtain a through-focus series of images, which may then be used to reconstruct the original volume object at high resolution.

example, we might choose to recombine the data as stereo pairs by introducing a slight lateral offset to each image slice as we add them up. If we do this twice, with an offset to the left in one case and the right in another, we obtain, very simply, stereo pairs. Mathematically, we form images of the form:

$$\int I(x \pm \gamma z, y, z)\mathrm{d}z \qquad [5]$$

where γ is a constant. In practice it may not be necessary to introduce offsets in both directions to obtain an adequate stereo view.

Our discussion so far on these techniques has been by way of a simplified introduction. In particular, we have not presented any fluorescence images. The key point is that, in both brightfield and fluorescence modes, the confocal principle permits the imaging of specimens in three dimensions. The situation is, of course, more involved than we have implied. A thorough knowledge of the image formation process, together with the effects of lens aberrations and absorption, is necessary before accurate data manipulation can take place.

In conclusion to this section it is important to emphasize that the confocal microscope does not produce three-dimensional images. It essentially produces very high-quality two-dimensional images of a (thin) slice within a thick specimen. A three-dimensional rendering of the entire volume specimen may then be generated by suitably combining a number of these two-dimensional image slices from a through focus series of images.

Fluorescence Microscopy

We now turn our attention to confocal fluorescence microscopy, because this is the imaging mode which is usually employed in biological applications. Although we have introduced the confocal microscope in terms of bright-field imaging the comments we have made concerning the origin of the optical sectioning, etc., carry over directly to the fluorescence case although the numerical values describing the strength of the optical sectioning are, of course, different and we will return to this point later.

If we assume that the fluorescence in the object destroys the coherence of the illuminating radiation and produces an incoherent fluorescent field proportional to the intensity of the incident radiation, $I(v, u)$, then we may write the effective intensity point spread function, which describes image formation in the incoherent confocal fluorescence microscope, as

$$I(v, u)I\left(\frac{v}{\beta}, \frac{u}{\beta}\right) \qquad [6]$$

where the optical coordinates u and v are defined relative to the primary radiation and $\beta = \lambda_2/\lambda_1$ is the ratio of the fluorescence to the primary wavelength. We note that $v = (2\pi/\lambda)rn \sin \alpha$, where r denotes the actual radial distance.

This suggests that the imaging performance depends on the value of β. In order to illustrate this we show in Figure 8 the variation in detected signal strength as perfect fluorescent sheet scans through focus. This serves to characterize the strength of the optical sectioning in fluorescence microscopy in the same way that the mirror was used in the brightfield case. We note that the half-width of these curves is

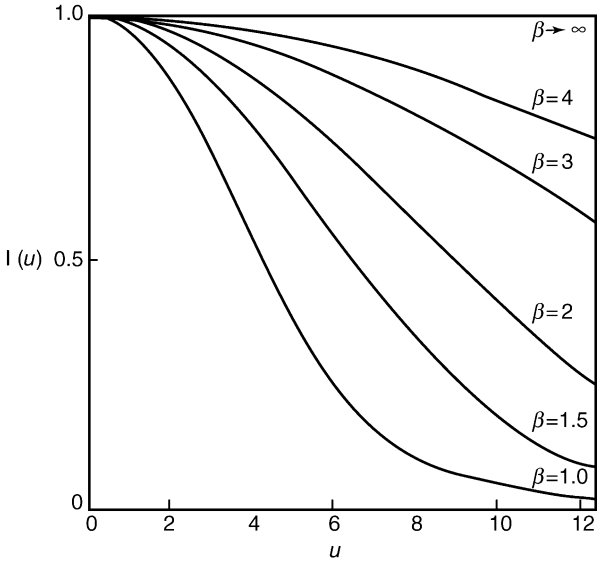

Figure 8 The detected signal as thin fluorescent sheet is scanned axially through focus for a variety of fluorescent wavelengths. We note that if we measure the sectioning by the half width of these curves, the strength of the sectioning is essentially proportional to β.

essentially proportional to β and so for optimum sectioning the wavelength ratio should be as close to unity as possible.

We have just discussed what we might call one-photon fluorescence microscopy in the sense that a fluorphore is excited by a single photon of a particular wavelength. It then returns to the ground state and emits a photon at the (slightly longer) fluorescence wavelength. It is this radiation which is detected via the confocal pinhole. Recently, however, much interest has centered on two-photon excitation fluorescence microscopy. This process relies on the simultaneous absorption of two, longer wavelength photons, following which a single fluorescence photon is emitted. The excitation wavelength is typically twice that used in the one-photon case. The beauty of the two-photon approach lies in the quadratic dependence of the fluorescence intensity on the intensity of the illumination. This leads to fluorescence emission which is always confined to the region of focus. In other words the system possesses an inherent optical sectioning property. Other benefits of two-photon fluorescence over the single photon case include the use of red or infra-red lasers to excite ultra-violet dyes, confinement of photo-bleaching to the focal region (the region of excitation), and the reduced effects of scattering and greater penetration. However, it should also be remembered that, compared with single photon excitation, the fluorescence yield of many fluorescent dyes under two-photon excitation is relatively low.

In order to make a theoretical comparison between the one- and two-photon modalities, we shall assume that the emission wavelength λ_{em} is the same, irrespective of the mode of excitation. Since the wavelength required for single-photon excitation is generally shorter than the emission wavelength, we may write it as $\gamma\lambda_{em}$ where $\gamma < 1$. Since two-photon excitation requires the simultaneous absorption of two photons of half the energy we will assume that the excitation wavelength may be written as $2\gamma\lambda_{em}$ which has been shown to be a reasonable approximation for many dyes.

If we now introduce optical coordinates u and v, normalized in terms of λ_{em}, we may now write the effective point spread functions in the one-photon confocal and two-photon case as

$$I_{1p\text{-}conf} = I\left(\frac{v}{\gamma}, \frac{u}{\gamma}\right)I(v,u) \qquad [7]$$

and

$$I_{2p} = I^2\left(\frac{v}{2\gamma}, \frac{u}{2\gamma}\right) \qquad [8]$$

respectively. We note that although a pinhole is not usually employed in two-photon microscopy it is possible to include one if necessary. In this confocal two-photon geometry the effective point spread function becomes

$$I_{2p\text{-}conf} = I^2\left(\frac{v}{2\gamma}, \frac{u}{2\gamma}\right)I(v,u) \qquad [9]$$

If we now look at eqns [7] and [8] in the $\gamma = 1$ limit, we find that

$$I_{1p\text{-}conf} = I^2(v,u) \qquad [10]$$

and

$$I_{2p} = I^2\left(\frac{v}{2}, \frac{u}{2}\right) \qquad [11]$$

We now see that because of the longer excitation wavelength used in two-photon microscopy the effective point spread function is twice as large as that of the one-photon confocal in both the lateral and axial directions. The situation is somewhat improved in the confocal two-photon case but it is worth remembering that the advantages of two-photon excitation microscopy are accompanied by a reduction in optical performance as compared to the single-photon case.

From the practical point of view it is worth noting that the two-photon approach has certain very important advantages over one-photon excitation, in terms of image contrast, when imaging through scattering media apart from the greater depth of penetration afforded by the longer wavelength excitation. In a single-photon confocal case it is quite possible that the desired fluorescence radiation from the focal plane may be scattered after generation in such a way that it is not detected through the confocal pinhole. Since the fluorescence is generated throughout the entire focal volume it is also possible that undesired fluorescence radiation, which was not generated within the focal region, may be scattered so as to be detected through the confocal pinhole. In either case this leads to a reduction in image contrast. The situation is, however, completely different in the two-photon case. Here the fluorescence is generated only in the focal region and not throughout the focal volume. Furthermore since all the fluorescence is detected via a large area detector – no pinhole is involved – it is not so important if further scattering events take place. This leads to high-contrast images which are less sensitive to scattering. This is particularly important for specimens which are much more scattering at the fluorescence ($\lambda/2$) wavelength than the excitation (λ) wavelength.

The Use of Structured Illumination to Achieve Optical Sectioning

An alternative approach to obtain optical sectioning is to use structured illumination in a conventional microscope. This approach is attractive since the conventional light microscope already possesses many desirable properties: real-time image capture, standard illumination, ease of alignment, etc. However, it does not produce optically sectioned images in the sense usually understood in confocal microscopy. In order to see how this deficiency may be corrected via a simple modification of the illumination system let us begin by looking at the theory of image formation in a conventional fluorescence microscope and start by asking in what way the image changes as the microscope is defocused. We know that in a confocal microscope the image signal from all object features attenuates with defocus and that this does not happen in a conventional microscope. However, when we look closely at the image formation process we find that it is only the zero spatial frequency (constant) component which does not change with defocus (Figure 9); all other spatial frequencies actually do attenuate with defocus to a greater or lesser extent. Figure 10 illustrates this by showing the image of a single spatial frequency one-dimensional bar pattern object for increasing degrees of defocus. When the specimen is imaged in focus, a good image of the bar pattern is obtained. However with increasing defocus the image becomes progressively poorer and weaker until it eventually disappears leaving a uniform gray level. This observation is the basis of a simple way to perform optical sectioning in a conventional microscope.

If we simply modify the illumination path of the microscope so as to project onto the object the image of a one-dimensional, single spatial frequency fringe pattern, then the image we see through the microscope will consist of a sharp image of those parts of the object where the fringe pattern is in focus together with an out-of-focus blurred image of the rest of the object. In order to obtain an optically sectioned image it is necessary to remove the blurred out-of-focus portion as well as the fringe pattern from the in-focus optical section. There are many ways to do this – one of the simplest involves simple processing of three images taken at three different spatial positions of the fringe pattern. The out-of-focus regions remain fairly constant between these images and the relative spatial shift of the fringe pattern allows the three images to be combined in such a way as to remove the fringes. This permits us to retrieve both an optically sectioned image as well as a conventional image in real time.

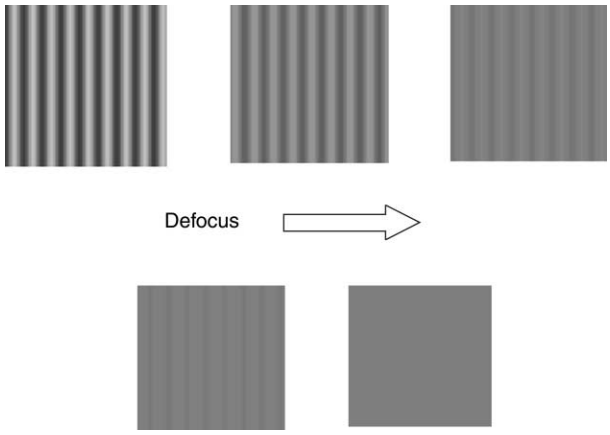

Figure 10 The image of a one-dimensional single spatial frequency bar pattern for varying degrees of defocus. We note that for sufficiently large values of defocus the bar pattern is not imaged at all.

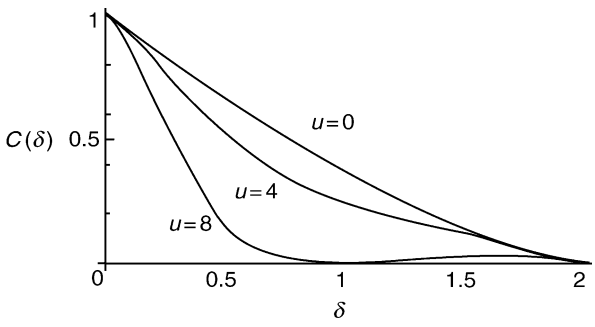

Figure 9 The transfer function for a conventional fluorescence microscope for a number of values of defocus (measured in optical units). We notice that the response for all nonzero spatial frequencies decays with defocus.

Since the approach involves processing three conventional microscope images, the image formation is fundamentally different from that of the confocal microscope. However, the depth discrimination or optical sectioning strength is very similar and this approach, which requires very minimal modifications to the instrument, has been used to produce high-quality three-dimensional images of volume objects which are directly comparable to those obtained with confocal microscopes. A schematic of the optical arrangement is shown in Figure 11a, together with experimentally obtained axial responses in Figure 11b. It will be noted that these responses are substantially similar to those obtained in the true confocal case. As an example of the kind of images which can be obtained with this kind of microscope, we show in Figure 12 two images

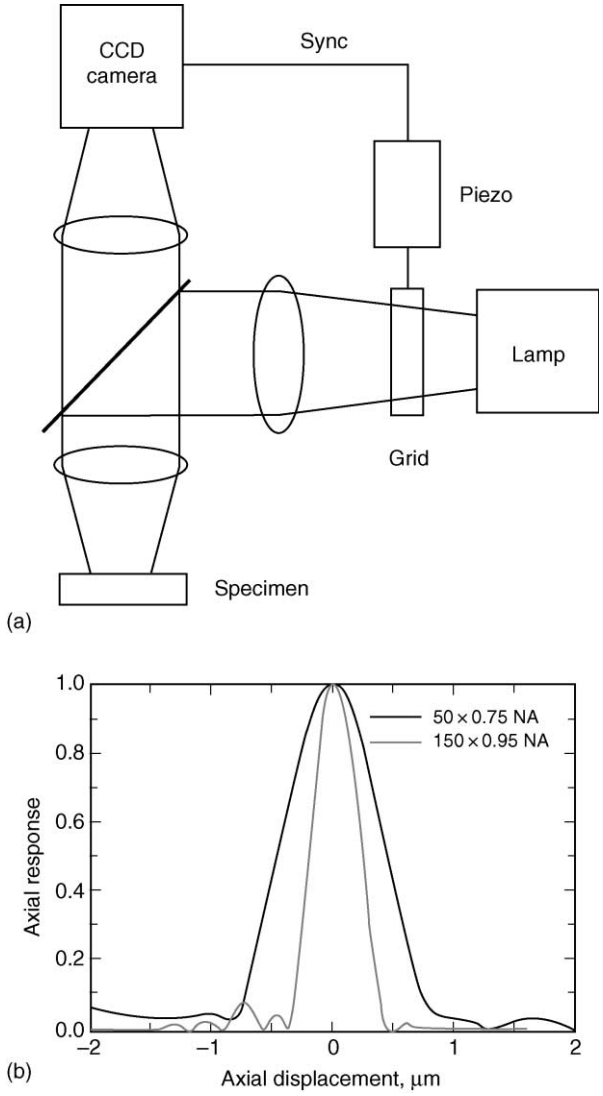

Figure 11 (a) Shows the optical system of the structured illumination microscope together with experimentally obtained axial responses in (b) which confirm the optical sectioning ability of the instrument.

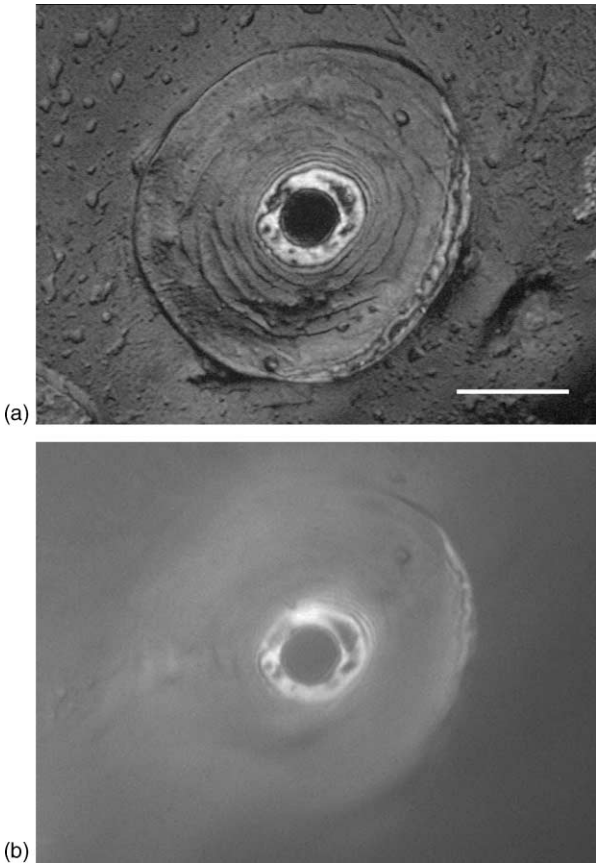

Figure 12 Two images of the region around the spiracle of a head louse. As in the previous figure, (a) is an autofocus image and (b) shows a mid-focus conventional image. The scale bar depicts a length of 10 μm.

of a spiracle of a head louse. The first is an auto-focus image of greatly extended depth of field constructed from a through-focus series of images. The second is a conventional image taken at mid-focus. The dramatic increase in depth of field is clear when compared with a mid-focus conventional image. We note that these images were taken using a standard microscope illuminator as light source. Indeed, the system is so light efficient that good-quality optical sections have been obtained or transistor specimens using simply a candle as light source!

Imaging using fluorescence light is also possible using this technique. However, an alternative approach that does not require a physical grid is possible if a laser is used as the light source. In this system the laser illumination is split into two beams which are allowed to interfere at an angle in the fluorescent specimen. This has the effect of directly 'writing' a one-dimensional fringe pattern in the specimen. Spatial shift of the fringe pattern is achieved by varying the phase of one of the interfering beams. As before, three images are taken from which both the optically sectioned image and conventional image may be obtained. The beauty of this approach is that no imaging optics are required at the illuminating wavelength and system.

Summary

We have discussed the origin of the optical sectioning property in the confocal microscope in order to introduce the range of imaging modes which this unique form of microscope leads to. A range of optical architectures have also been described. By far the most universal is that shown in Figure 1 where a confocal module is integrated around a conventional optical microscope. Other, more recent, real-time implementations have also been described. A number

of practical aspects of confocal microscopy have not been discussed. This is because they are readily available elsewhere, such as advice on the correct choice of detector pinhole size or because they are still the focus of active research, such as the development of new contrast mechanisms for achieving enhanced three-dimensional resolution such as the stimulated emission depletion method, STED or 4-Pi which are still under development but offer great promise.

Introduction

The field of light microscopy started with Ernst Abbe's introduction of the diffraction-limited objective lens in the late nineteenth century. Over the last 60 years, new imaging modalities, such as video, fluorescence, confocal, near field, and more recently multi-photon microscopy, have enabled the experimentalist to observe a plethora of new phenomena in the biological and physical sciences. Of these techniques, multi-photon microscopy has emerged not only as a valuable imaging technique but it also forms the technology base for emerging fields of optical memory and microfabrication.

The history of multi-photon microscopy (MPM) began with Göppert-Mayer's theoretical prediction of two-photon excitation in 1931. Although the theoretical groundwork was established, it took another 30 years for this process to be experimentally realized when Kaiser and Garrett observed two-photon absorption fluorescence emission from CaF_2:Eu^{+2}. Soon after this observation was made, Singh and Bradley witnessed higher-order multi-photon processes in 1964.

Historically, three-dimensional imaging was first achieved using confocal microscopy. In contrast to MPM, photo-interaction and fluorescence emission occurs throughout the excitation light path in confocal microscopy. Confocal microscopy selects the signal from the focal plane by the use of a conjugated pinhole aperture. In order to construct 3D images, successive planes must be imaged. As a result, the entire sample volume is exposed to the excitation light multiple times, and inevitably, photobleaching and photodamage occurs throughout the imaging volume. Furthermore, the pinhole aperture in the emission path causes additional signal reduction in optically thick specimens where the emission photon is scattered. Consequently, the utility of confocal microscopy is limited for imaging living biological specimens. The introduction of multi-photon microscopy, by Denk and Webb in 1990, addressed many of these limitations. By combining the methodology of multi-photon excitation with scanning microscopy, MPM offered advantages such as 3-D localized, femtoliter excitation volumes,

reduced scattering and absorption of the infrared excitation light by the specimen, and a large separation between the excitation and emission wavelengths. MPM can produce excellent three-dimensional images with increased signal to noise ratios.

Theoretical Basis of Multi-Photon Microscopy

Multi-photon Excitation Selection Rules

Unlike direct ground state to excited state one-photon transitions, multi-photon transitions depend on the presence of virtual electronic intermediate states to reach an excited state (see **Figure 1**).

Using perturbative expansion, the probability of excitation for one-photon transitions is described by the first-order solution, and multi-photon transitions can be determined by including the higher order solutions. The interaction of an electric field vector E_λ with a molecule's dipole, $\vec{r}$, is described by the respective one-photon and two-photon transition probabilities:

$$P_{1h\nu} \approx \langle \Psi_f | \vec{E}_\lambda \cdot \vec{r} | \Psi_i \rangle^2$$

$$P_{2h\nu} \approx \left| \sum_m \frac{\langle \Psi_f | \vec{E}_\lambda \cdot \vec{r} | \Psi_m \rangle \langle \Psi_m | \vec{E}_\lambda \cdot \vec{r} | \Psi_i \rangle}{\varepsilon_\lambda - \varepsilon_{m,i}} \right|^2 \quad [1]$$

where Ψ_i, Ψ_m, and Ψ_f are the initial, intermediate, and final transition states, $\vec{E}_\lambda$ is the electric field associated with the excitation light, ε_λ is the energy difference between the ground state and excited states, $\varepsilon_{m,i}$ is the energy difference between the intermediate state m and the ground state, i, and the summation is over all possible intermediate states m. Although electronic transitions, that result from the interaction of a strong electric field with a molecular dipole, are affected by vibrational mode overlap (Franck Condon factors) and anharmonic perturbative effects, the presence of intermediate transition states creates a set of general selection rules for multi-photon absorption processes.

Molecular states have eigenfunctions with a defined parity: 'gerade' describing even or symmetric states (no change in the sign of the wavefunction when the sign changes in the spatial coordinates) and 'ungerade' describing odd or antisymmetric states (the sign of the wavefunction changes when the sign changes in the spatial coordinates). Selection rules arise from the physics inherent in these even and odd eigenfunctions and the odd dipole operator that couples transitions between ground and excited states. In one-photon excitation, transitions are allowed for ground state and excited state transitions of opposite parity. In contrast, two-photon excitation occurs between ground and excited states with the same parity, by coupling through intermediate states with opposite parity. In general, ground and excited states with the same parity have a high excitation probability for an even number of photons; ground and excited states with different parity have a high transition probability for excitations involving an odd number of photons.

In the absence of major vibrational perturbations, inductive effects, or solvent relaxation, the probability of the transition depends on the magnitude of the integral overlap between the ground, intermediate, and excited states. As a result, molecule absorption cross-sections for one-photon, two-photon, three-photon, or multi-photon excitation processes can be estimated. Choosing fluorophores with higher multi-photon cross-sections allows more efficient excitation with lower excitation intensity. Finally, it should be noted that while the absorption cross-sections for one-, two-, and multi-photon excitation of a given fluorophores are different, the molecules rapidly relax to the same vibrational level in the excited electronic state. The excited state residence time (fluorescence lifetime), and the fluorescence decay processes depend only on the molecular structure and its microenvironment. Therefore, the fluorescence

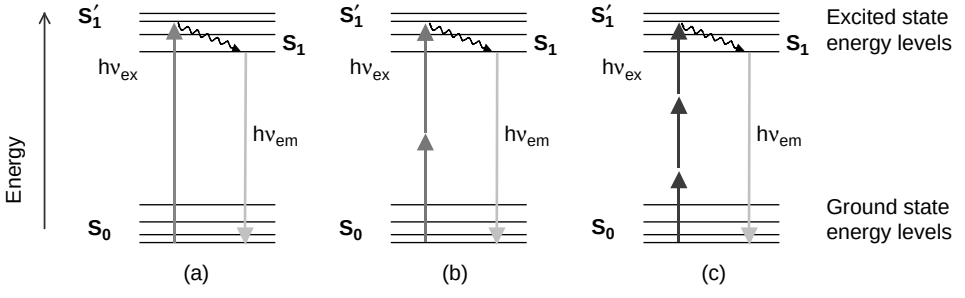

Figure 1 Jablonski diagram of a fluorescent dye molecule in one-, two- and *n*-photon excitation mode.

quantum yield and emission spectra is independent of the initial excitation process.

Enhanced Microscope Resolution Based on Multi-photon Excitation

The number of photons that are absorbed in a multi-photon process is proportional to the fluorophore concentration, $C(\vec{r},t)$, the molecule's absorption cross-section, σ_n, which depends on n, the number of photons involved in the absorption process, and the intensity of the excitation source, such that

$$N_{\text{abs}}(t) = \int \mathrm{d}\,\vec{r} I_0^n(\vec{r},t) C(\vec{r},t)\sigma_n \qquad [2]$$

When estimating $N_{\text{abs}}(t)$, the spatial and temporal intensity distribution of the excitation intensity are considered independently:

$$I_0(\vec{r},t) = S(\vec{r})I_0(t) \qquad [3]$$

such that for an n-photon process, $I_0(t)$ is the temporal dependence of the excitation intensity at the maxima of the spatial distribution and $S(\vec{r})$ is the unitless spatial distribution of the excitation light. Combining eqns [2] and [3] gives

$$N_{\text{abs}}(t) = \int \mathrm{d}\vec{r} S^n(\vec{r}) I_0^n(t) C(\vec{r},t)\sigma_n \qquad [4]$$

If it is assumed that fluorophore distribution is uniform and the system does not undergo photobleaching or ground-state depletion, $C(\vec{r},t)$ can be considered a constant and the previous equation can be rewritten as

$$N_{\text{abs}}(t) = C\sigma_n I_0^n(t) \int_V S^n(\vec{r})\mathrm{d}\vec{r} \qquad [5]$$

By expanding the incident laser beam and overfilling the back aperture of the objective lens, the paraxial form of the normalized intensity point spread function (PSF, $h^2[u,v]$) determines the properties for a diffraction-limited lens. The dimensionless radial distance, v, from the optic axis and the distance from the in-focus plane, u, are given by

$$v = \frac{2\pi(\text{NA})r}{\lambda} \qquad [6]$$

$$u = \frac{2\pi(\text{NA})^2 z}{n_0\lambda} \qquad [7]$$

where $\text{NA} = n_0 \sin\theta$ (θ being the half-angle of collection for the lens and n_0 is the index of refraction the medium) is the numerical aperture. Expressing the spatial distribution function with the optical units, v, u, and θ gives the following equation:

$$S(\vec{r}) = h^2[u,v] = 2\left|\int J_0(v\theta)\mathrm{e}^{-(1/2)\mathrm{i}u\theta^2}\theta\,\mathrm{d}\theta\right|^2 \qquad [8]$$

where J_0 is the zero-order Bessel function. If an oil immersion objective with a $\text{NA} < 1.0$ is used, the paraxial approximation accurately estimates the spatial distribution, and the integral of $S(\vec{r})$ evaluates as

$$\int_{V=\infty} S^n(\vec{r})\mathrm{d}\vec{r} = a_n\left[\frac{n_0\lambda^3}{8\pi^3(\text{NA})^4}\right] \qquad [9]$$

where $a_n = \int_0^\infty 2\pi v\,\mathrm{d}v \int_{-\infty}^{\infty} \mathrm{d}u[h(u,v)]^{2n}$. Since this integral cannot be solved analytically, the values of a_n are determined using numerical integrations of $h^2(u,v)$ over all space. As a result, the volume integral of the spatial distribution is always proportional to NA^{-4} and therefore independent of the number of photons involved in the excitation process. For higher NA objectives, the paraxial form of the normalized intensity PSF may no longer be an adequate approximation. The expression for temporal part of eqn [5] can be written as

$$I_0(t) = \left(\frac{\pi\text{NA}^2}{\lambda^2}\right)P(t) \qquad [10]$$

where $P(t)$ is the excitation power and λ is the center wavelength of the pulsed excitation source. The temporal dependence can be described with the time average expression:

$$\langle I_0^n(t)\rangle = \left(\frac{\pi\text{NA}^2}{\lambda^2}\right)^n \frac{1}{T}\int_0^T P^n(t)\mathrm{d}t \qquad [11]$$

where T is an arbitrary time interval for continuous wave lasers and $T = 1/f_{\text{p}}$ for a pulsed laser with a repetition rate, f_{p}. Since multi-photon microscopy uses pulsed laser systems, the integral in eqn [11] must be evaluated accordingly. For a pulsed laser with a pulse width, τ, repetition rate, f_{p}, and averaged power, P_0, the pulse profile can be approximated as

$$P(t) = \frac{P_0}{f_{\text{p}}\tau} \qquad \textit{for } 0 < t < \tau \qquad [12]$$

$$P(t) = 0 \qquad \textit{for} \qquad \tau < t < \frac{1}{f_{\text{p}}} \qquad [13]$$

such that eqn [11] can be expressed as

$$\langle I_0^n(t)\rangle = \left(\frac{\pi\text{NA}^2}{\lambda^2}\right)^n \left(\frac{P_0}{f_{\text{p}}\tau}\right)^n \frac{1}{T}\int_0^T \mathrm{d}t \qquad [14]$$

and evaluated as

$$\langle I_0^n(t)\rangle = \left(\frac{\pi \mathrm{NA}^2}{\lambda^2}\right)^n (P_0)^n \left(\frac{1}{f_\mathrm{p}\tau}\right)^{n-1} \qquad [15]$$

Assuming no stimulated emission and no self-quenching, the quantity of emitted photons collected per unit time, $F(t)$, is

$$F(t) = \frac{1}{n}\phi\eta N_\mathrm{abs}(t) \qquad [16]$$

where η and ϕ are the fluorescence quantum efficiency of the dye and collection efficiency of the system, respectively. Since n photons are needed for each individual excitation event, $1/n$ is a normalization factor for N_abs which describes the total number of photons absorbed. Rewriting this expression in terms of the average number of absorbed photons, $\langle N_\mathrm{abs}(t)\rangle$, gives the average fluorescence intensity:

$$\langle F(t)\rangle = \frac{1}{n}\phi\eta\langle N_\mathrm{abs}(t)\rangle \qquad [17]$$

where $\langle N_\mathrm{abs}(t)\rangle$ is

$$\langle N_\mathrm{abs}(t)\rangle = C\sigma_n\langle I_0^n(t)\rangle \int_V S^n(\vec{r})\mathrm{d}\vec{r} \qquad [18]$$

such that the measured fluorescence intensity or time averaged photon flux is expressed as

$$\langle F(t)\rangle = \frac{1}{n}\phi\eta C\sigma_n\langle I_0^n(t)\rangle \int_V S^n(\vec{r})\mathrm{d}\vec{r} \qquad [19]$$

Since the time averaged fluorescence is proportional to $\langle I_0^n(t)\rangle$, eqns [9] and [15] can be substituted into eqn [19] to give a practical expression that relates average fluorescence to measurable laboratory quantities, such as P_0, τ_p, f_p, C, σ_n, n, η, and ϕ, NA, and associated numerical constants such that

$$\langle F(t)\rangle = \frac{1}{n}\phi\eta C\sigma_n\left(\frac{\pi \mathrm{NA}^2}{\lambda^2}\right)^n (P_0)^n \left(\frac{1}{f_\mathrm{p}\tau}\right)^{n-1} \times a_n\left[\frac{n_0\lambda^3}{8\pi^3(\mathrm{NA})^4}\right] \qquad [20]$$

As eqn [19] shows, the fluorescence intensity has an nth order dependence on the spatial and temporal distribution of the excitation power. Therefore, appreciable multi-photon probability occurs only at a region of high temporal and spatial concentration of photons. Confocal pinholes can be eliminated making this technique better suited for 3D biological imaging.

The higher order (>2) dependence of the fluorescence signal upon the excitation intensity distribution results in axial confinement. Experimentally, it can be shown that over 80% of fluorescence signal emanates from a 1 μm thick region about the focal point for objectives with a numerical aperture of 1.25 under two-photon excitation. This confinement is significantly different from one-photon excitation where a spatially uniform fluorescent sample contributes equal fluorescence intensities from each z-section above and below the focal plane (assuming negligible excitation attenuation). For an excitation wavelength of 960 nm, the typical point spread function of two-photon absorption has FWHM of 0.3 μm in the radial direction and 0.9 μm in the axial direction. In comparison with confocal microscopy, the localization of the volume of excitation instead of the volume of observation, as in confocal microscope, allows 3D imaging with minimal photobleaching and damaging.

Basic Imaging Applications of Multi-Photon Microscopy

Multi-photon microscopy finds an increasingly broad range of applications, especially in biological and medical areas. For example, multi-photon microscopy has been utilized to study the physiological and biological states in various highly scattering tissues such as cornea, skin, and pancreas islet. Also, multi-photon microscopy is used in embryology to study the development of sea urchin, *Caenorhabditis elegans*, hamster, and zebra fish. Neurobiological applications include qualifying calcium dynamics dendritic spines, memory and structural plasticity, hemodynamics, and plaque evolution in Alzheimer's disease. MPM has been applied to study pharmacological distribution in tissues and in the quantification of transdermal drug delivery. Due to minimally invasive capability of multi-photon microscopy, intra-vital microscopy imaging into thick tissues of living animals is possible leading to applications in the study of cancer biology.

Although the advantages of MPM are less compelling in studying cell cultures where the specimen is optically thin, a number of uniquely exciting uses have been identified. For instance, the significantly broader two-photon absorption spectra of many fluorophores allow convenient imaging of specimens labeled with multiple color fluorophores. The localized excitation volume reduces photo-interaction with fluorophores outside the excitation volume allowing better 3D images to be obtained from cellular systems labeled with easily photobleachable fluorophores. The use of three and higher photon excitation has also allowed the excitation and imaging of important biomolecules with deep ultraviolet

absorption. Another interesting application of multi-photon excitation in cellular systems is based on the ability of this method to produce localized chemical reactions. Through the photoactivation or photolysis of 'caged' molecules, their chemical structures are altered to produce biologically active molecules, fluorescent species, or other observable chemical changes. Multi-photon excitation has been used to locally uncage neurotransmitters for mapping ion channels in neurons and to uncage calcium in studying signal transduction events. In cellular systems, MPM is being used to image normally nonfluorescent biomolecules, such as serotonin in neurons, based on multi-photon induced chemical conversion and multi-photon excitation. Finally, multi-photon microscopy has also found applications in studying the conformation, aggregation, diffusion, and transport of single molecules and proteins. Two-photon fluorescence correlation spectroscopy and photon counting histograms are powerful techniques that have been applied to study protein aggregation, conformation changes, and diffusion *in vitro* with applications ranging from cell biology to high throughput drug discovery. The large separation of excitation and emission spectra of two-photon excitation also allows high sensitivity detection of fluorescence from single chromophore; however, the higher photobleaching rate at the excitation volume for some chromophores may lessen or even reverse this advantage.

Advanced Multi-Photon Microscopy Techniques

As described in the previous sections, excitation processes involving multiple numbers of photons offers considerable advantages for the imaging process in fluorescent microscopy. 4Pi Confocal Microscopy and high-speed Multifocal Multi-photon Microscopy MMM are advanced multi-photon microscopy techniques that capitalize on these advantages to improve image resolution and acquisition times in fluorescence imaging.

4Pi Confocal Microscopy

In contrast to near-field microscopy, far-field light microscopes, i.e. confocal and multi-photon microscopes, can create three-dimensional images of the interior of cells. The lateral and axial resolution of these systems is limited between 180 nm and 300 nm and 500–1000 nm, respectively. This limitation is dictated by the Abbe theory where resolution is inversely proportional to the numerical aperture of the focusing lens. When focusing with a single lens, geometric constraints limit the numerical aperture to about 1. 4Pi microscopy was developed to overcome this limitation. By utilizing two opposing objective lenses whose spherical wavefronts are coherently combined, a greater total effective numerical aperture is achieved. This results in a higher axial resolution, while the lateral resolution of the 4Pi microscope remains unchanged with respect to its confocal counterpart.

In the setup of a 4Pi microscope, the illuminating wavefronts emanate from a common point light source. The path is split by a beamsplitter, guided through two optically identical paths, and through two opposing high NA lenses that share a common focus. The fluorescence light is then collected through one lens and a confocal pinhole. In the axial direction, this arrangement yields a PSF with one main maximum lobe that is 3–4 times sharper along the optic axis than the PSF of a conventional confocal microscope, and two undesired side-lobes.

These side lobes can produce artifacts in the image and their effect needs to be suppressed for unambiguous 3D imaging. Lobe suppression can be achieved in a 4Pi system using two-photon excitation resulting in a quadratic decrease in the ratio of the side-lobe and the main lobe amplitudes. Using an excitation wavelength of 800 nm and 1.4 NA oil-immersion objectives, a FWHM along the axial direction of the main lobe is about 145 nm and side lobes are approximately 25–35% of the maximum lobe intensity. These side lobes can be further mathematically reduced by means of a linear filter after (or during) image acquisition. The filter can be applied at lobe heights below 50%, and an effective 3D PSF consisting of a single spot with a 250 nm lateral and 145 nm axial FWHM is achieved. When combined with nonlinear image restoration, 4Pi confocal microscopy achieves a 3D resolution in the 100 nm range. This resolution is similar to that obtained with near-field optical microscopy in biological applications with an added advantage of 3D imaging of the cell interior.

Since resolution improvement in 4Pi microscopy can be negated by the presence of aberrations, the usage of oil immersion lenses requires the specimen to be fixed and mounted in glycerol to minimize aberrations resulted from index mismatch. The sample thickness is further limited in the range of 20–30 μm. Due to significant index mismatches between oil and water, the imaging of live cells in aqueous medium is extremely difficult, if not impossible. In order to circumvent this difficulty, water immersion objective lenses are introduced into the 4Pi system. These lenses have a lower aperture angle $\alpha = 62°$ (NA = 1.2) than oil immersion lenses

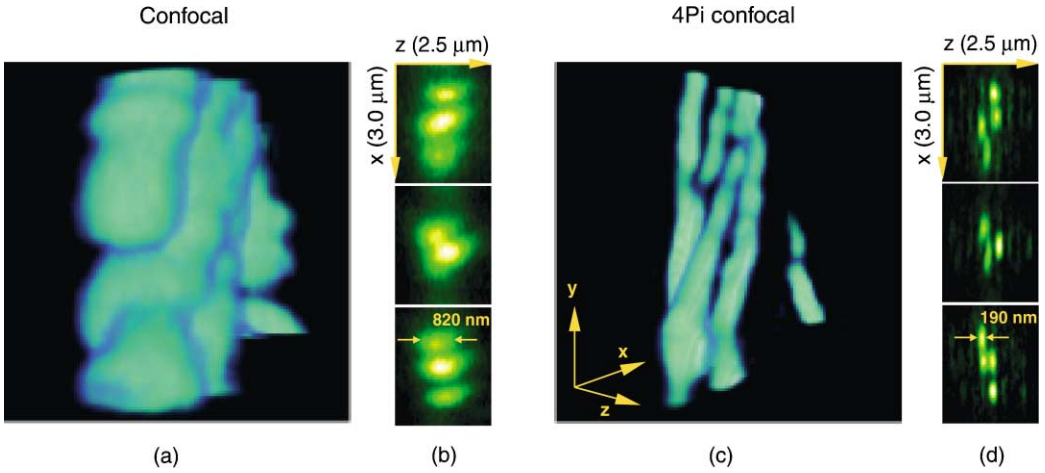

Figure 2 (a) Two-photon confocal and (c) 4Pi confocal point deconvolved images of an immunolabelled microtubule network in fixed NIH3T3 cells. The 3D rendered images in (a) and (c) were generated out of a large XZ-image-stack, partly shown in (b) and (d). As indicated in the XZ-images, the axial resolution is 820 nm and 190 nm for the two-photon confocal and the two-photon 4Pi confocal images, respectively. The images were taken with water immersion lenses (NA = 1.2). Reproduced from Bahlmann K, Jakobs S, *et al.* (2001) 4Pi-confocal microscopy of live cells. *Ultramicroscopy* 87(3): 155–164, with permission from Elsevier.

$\alpha = 68°$ (NA = 1.4) and therefore are expected to produce higher side lobes, which are reduced by 35% with careful aberration studies such that linear filtering is possible. Nonetheless, the use of water-immersion lenses solves two major problems. First, they extend the possible sample thickness to the working distance of the objective lens (~200 μm); second they allow the imaging of live cells in aqueous medium. As a result, microtubule networks (see Figure 2) and live bacteria can be imaged with a resolution of 280 nm in lateral and 190 nm in axial direction. The water immersion 4Pi microscope, utilizing two-photon excitation, is capable of the highest 3D resolution so far reported in live cell imaging to date.

Multifocal Multi-Photon Microscopy (MMM)

Improving imaging speed is critical for applying 3D microscopy in biological specimens. An MMM scans an object with an array of high-aperture foci whereas a conventional multi-photon microscope scans with a single beam. An MMM combines nonlinear fluorescence excitation with parallelized 3D imaging. The technical design consists of a densely packed microlens array; each microlens transmitting a collimated beam at a slightly different angle, overfilling the back aperture of the objective. Consequently, from the arrangement of the microlenses, an array of foci is reproduced in the image plane. The foci are scanned rapidly across the image plane to ensure full coverage of the focal plane and real-time imaging (a stack of 50 images of 30–70 μm diameter can be acquired within a few seconds). The foci's movements are either generated by rotating a microlens array that is arranged in a Lasserie pattern or by rectilinear scanning of a square microlens matrix.

MMM development was initiated because nonlinear optical damaging processes limit the usable focal peak intensity to about 200 GW/cm^2, which can be reached by a tightly focused 7–15 mW femtosecond laser beam. This power consumption makes use of only a fraction of the laser output of a typical mode-locked titanium-sapphire laser light source. The MMM better exploits the 1–2 W of the beam power by dividing the power among 25–40 foci and scanning each in parallel. With this method, typical acquisition times are cut from ~1000 ms to 10–50 ms. MMM provides an excellent method for real time 3D multi-photon imaging.

A fundamental problem in parallelized 3D microscopy is that increasing density of the foci over a certain level decreases the axial resolution. The reduction of the distance between the foci increases not only the speed or image brightness, but it also increases the interference between neighboring focal fields; especially in planes shortly before and after the focal plane. For neighboring foci in high NA objective lenses, interference effects can be significant. The relatively short laser pulses that are commonly used in multi-photon excitation provide a means to reduce this interference by using time multiplexing. Experimentally, the femtoseconds pulses of the Ti:sapphire laser, going through each lenslet, can be scheduled to arrive at the focal plane at different times by a mask of glass in front of each microlens, varying the optical path lengths of these beams. The different arrival

time eliminates interference effects. The resolution of the parallelized system remains unchanged as compared with the conventional one foci system. In conclusion, the MMM enables increased image acquisition speed by a factor of the number of foci in the optical plane without compromising image resolution.

Advanced Multi-Photon Microscopy Applications

As described by the previous section, MPM technology is undergoing rapidly development with improved resolution and increased instrument throughput. Recently, MPM has also found applications in exciting new areas of optical memory and microfabrication.

Multi-Photon 3D Optical Memory

Researchers in the field of optical memory are challenged to develop instrumentation that records three-dimensional, high density, robust bitwise information in low-cost and readily available storage materials. Initially, early optical memory techniques relied on higher energy pulsed recording beams and red shifted reading beams. Aided by the development of the Ti:sapphire laser and high numerical aperture objectives that can confine laser light to a volume of the order, λ^3, the power of the focused femtosecond pulses at the focal point can reach over 10^{18} W/cm^2 with electrical field strengths reaching 2.7×10^{10} V/cm. These fields are substantial enough to locally change the optical properties of selected materials. Thus, multi-photon processes were intertwined with the field of optical memory. Recent experiments showed that with properly chosen materials and instrumentation, high density, three-dimensional data storage was possible.

Optical memory is based on photochromic material whose optical properties are changed upon irradiation such that initial and final chemical states have different absorption spectra or indices of refraction. In 1989, Parthenopoulos and Rentzepis first showed that 3D information could be stored in a polymer film doped with photochromic molecules. Although the recorded information is lost when the photo-excited compound spontaneously reverts back to the original nonfluorescent compound, Dvornikov and Rentzepis later improved the material such that the stored information was stably recorded at room temperature.

For photochromic materials, the recording and reading mechanisms often required multiple laser sources and complex optical setups. Kawata *et al.* addressed these issues with the development of an alternative optical method that used photorefractive crystals as the storage media, a Ti:sapphire as the recording device, and a phase-contrast microscope configuration for data readout of bits separated by 20 μm. Using this method, Kawata avoided the complication of different recording and read-out laser sources, thereby simplifying the instrumentation. However, in photorefractive material, poor refractive index matching, between the storage medium and the objective, results in aberration and degrades storage densities. Recent advances in objective lens design have attempted to address these limitations. Kawata and Kawata describe many of these optical memory devices in a recent review. A recent publication by Olson *et al.* describes a method for multi-photon data storage in molecular glasses and highly cross-linked polymers. These materials prove to be highly efficient and robust for long-term data storage.

Although the field of optical memory has made great progress since 1989, further advances are required before this field becomes a widely adopted technology. For example, simpler recording and reading techniques are required to insure a cost-effective and reliable data storage technology. Consequently, further progress in the production of compact ultrafast lasers and high-speed scanning instrumentation will be needed before broader acceptance of optical memory storage devices.

Multi-Photon 3D Microfabrication

Another promising emerging application of multi-photon excitation is 3D microfabrication. 3D microfabrication processes can be performed with two-photon absorption. Maruo *et al.* and Sun *et al.* provide examples of microfabricated structures generated with femtosecond pulses to induce photopolymerization. Much like the optical memory techniques, this methodology relies on photo-initiators with large two-photon cross-sections to initiate polymerization of surrounding monomer or polymer molecules. Kawata *et al.* and Sun *et al.* showed that two-photon photopolymerization could be used successfully to create intricate three-dimensional microstructures. These systems offer lower polymerization thresholds, higher polymerization rates, and wider dynamic write ranges such that rapid fabrication and low-power writing are possible. Recently, Cumpston *et al.* described a class of π-conjugated compounds with large two-photon cross-sections, which can be effectively used for two-photon polymerization initiators in three-dimensional optical data storage and microfabrication processes.

As with most of these processes, the techniques have proven to be successful, but the mechanisms behind the multi-photon initiated chemical processes are not completely understood. With further work to optimize the reaction parameters, it is possible to design experiments that will allow new materials to be synthesized or patterned based on processes such as dielectric breakdown, microexplosions, optical damage, and pyrolytic effects.

Conclusion

Relying on femtoliter excitation volumes and large separations between excitation and emission wavelengths, multi-photon microscopy has emerged as a powerful technology that allows for increased resolution and enhanced signal-to-noise ratios. It has also enabled scientists to avoid complications in imaging biological systems due to decreased sample photodamage and in some instances, photobleaching of fluorophores. Advancements in multi-photon imaging applications, such as 4Pi Confocal microscopy and multifoci multi-photon microscopy, have further enhanced the resolution of imaging technology and improved the speed of data acquistion respectively. Furthermore, the application of multi-photon technology in the fields of microfabrication and optical memory promises to address some of the difficulties involved in designing three-dimensional high-density storage devices and microfabricated components. Overall, multi-photon microscopy provides the scientific community with an invaluable tool in the study and design of biological and physical systems.

Interference Microscopy

E Novak, Veeco Instruments, Inc., Tucson, AZ, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Interference microscopy is a powerful noncontact metrology technique for reflection and transmission characterization of samples. The field can be divided roughly into two main categories, polarization-splitting interferometers and amplitude-splitting interferometers. In both cases, the light incident on a test sample is first divided into two beams and later recombined to form an interference pattern. This interference pattern is analyzed by one of a variety of methods to determine the difference in the optical paths the two beams traversed. This optical path difference may be used to quantify surface shape, refractive index variations, or thickness variations of the sample to a very high accuracy. This article describes the background of the two categories of interference microscopy, specifics of their implementations for different types of measurements, current state of the technologies, and examples of different measurements performed using these techniques.

Background

Interference fringes were first observed in a microscope by Robert Hooke in 1665. In the late 1800s, several practical versions of interference microscopes

entered use to examine transparent specimens, though none gained widespread commercial success. Then in the 1950s, differential interference contrast (DIC) microscopy was invented to increase image contrast when examining semi-transparent samples under a microscope, particularly biological specimens. As this technique does not require staining of samples, and avoids the halo effect common in phase contrast microscopy (*see* **Microscopy:** Phase Contrast Microscopy), such systems became widely used in a variety of biological applications. In the early 1960s, Krug, Rienitz and Shulz published a comprehensive book to summarize all of the various interference microscope designs that had been produced thus far, showing the large depth and breath of research to that point.

With the advent of affordable computers and CCD cameras in the 1970s and 1980s, various commercial systems were developed using a variety of interferometric configurations to quantify the measured interference patterns from small samples. Due to their noncontact nature and ability to provide area measurements, as opposed to the two-dimensional traces produced by contact stylus techniques, such systems gained rapid acceptance in a variety of industries. Performance has steadily improved such that vertical resolution is sub-nm and accuracy on the nm-level is readily achievable. Lateral resolution is limited only by the optics of the microscope, with high numerical aperture objectives achieving resolution below 0.5 μm. Today, commercial systems are used in such measurements as index variations of biological samples, roughness of paper, microfluid channel volume, MEMS properties, hard drive head dimensions, drug coating thickness, and machine part characterization.

Polarization-Division Interference Microscopes

While the concepts behind polarization division interference microscopes have been known for well over a century, they did not gain widespread use until after Georges Nomarski invented the DIC microscope, also referred to as a polarization interference contrast microscope, in 1955. A schematic of a transmission-based and reflection-based Nomarski setup is shown in Figure 1, where the displacement of the beams has been greatly exaggerated for clarity.

The illumination in Nomarski systems is generally from an unpolarized broadband source, such as a

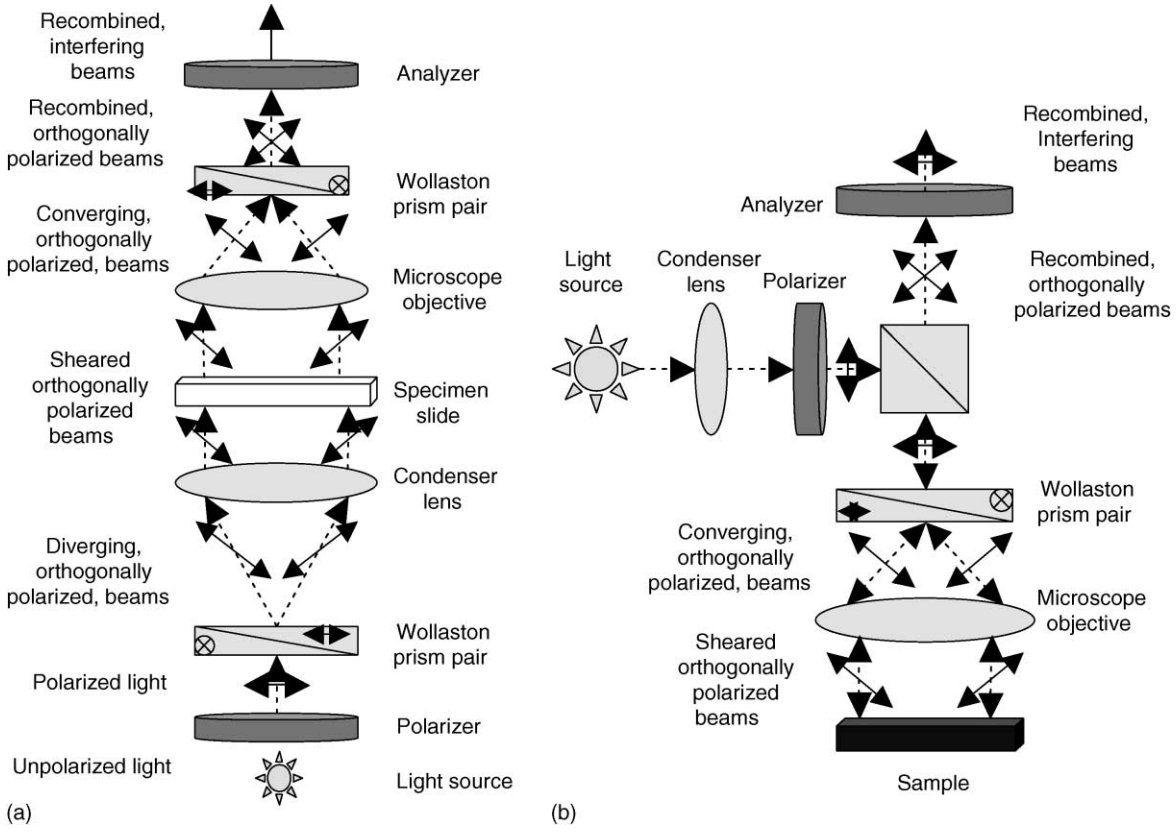

Figure 1 (a) Schematic of transmission-based Nomarski interferometer and (b) reflection-based Nomarski interferometer.

tungsten–halogen bulb. A polarizer in the illumination path is then used to set the polarization state of the light incident on a modified Wollaston prism pair. The modified Wollaston prism consists of two birefringent wedge prisms which divide the beam in two parts, each with orthogonal polarization states. The two beams travel in slightly different directions from one another. The condenser lens brings the light to illuminate the sample, with each of the two orthogonally polarized beams slightly sheared from one another. This shear is typically much less than the resolution limit of the microscope objective, typically from tens of nanometers to several hundred nanometers, such that only one image is seen by the observer. After passing through or reflecting from the sample and the imaging microscope objective, a Wollaston prism pair is used to recombine the two polarized beams. Finally, an analyzer is used to bring both beams to a common polarization state, allowing interference between the two beams.

As the system is very sensitive to the position and optical properties of the prisms, different Wollaston prism pairs are used for each objective, usually rotating into the path automatically on a turret as the objectives are changed. In a reflection system, this prism also recombines the displaced beams after they reflect from the test piece; a transmission system will usually have only one Wollaston prism pair after the sample that can handle all objectives, instead of requiring a different recombining prism for each objective.

The observed interference pattern is an image of the gradient in the sample in the direction of shear created by the Wollaston prism pairs. In order to fully characterize the surface, the sample or optics must be rotated to capture shear images in both orthogonal directions. Essentially the technique acts as a high-pass filter, emphasizing edges and lines on the test piece.

With a white-light source, dispersion effects will cause one side of a feature to appear brighter or in a specific color range whereas the other side appears darker or in different colors. This gradient effect confers a pseudo three-dimensional appearance to the specimen. The images are quite colorful, with different colors shearing differently; by adjusting the Nomarski prisms along the optical axis, one can vary the retardation between the two beams, producing more or less contrast or color variation in the observed images.

The Nomarski system has several appealing qualities for surface and index characterization over other interferometric and polarization-based techniques. First, it is a common-path interferometer; with the exception of the slight shear, both beams pass through exactly the same optics. This means that these interferometers are mostly insensitive to vibration, as both interfering beams will be affected in the same manner. In addition, the common path nature of the system reduces the quality requirements on the optics, improving measurement quality and reducing overall system cost. In addition, Nomarski techniques do not suffer the halos associated with phase contrast imaging techniques (*see* **Microscopy:** Phase Contrast Microscopy) and provide better out of focus rejection and higher light levels since they can use the entire aperture of the microscope objective.

For reflection-based systems, the observed fringes relate to the surface slope along the direction of shear; for transmission systems, index of refraction gradients or thickness variations are observed, producing much higher contrast images of biological samples than conventional bright-field techniques. The good out-of-focus rejection mentioned earlier makes possible more accurate optical sectioning of samples, where each vertical layer of the specimen is in focus while all others are out of focus. These features, combined with the fact that high contrast images can be obtained without chemical staining, have made these systems widely used in biology. In addition, the high sensitivity to slope has made DIC systems commonly used in semiconductor inspection applications and other precision surface characterization and defect inspection applications, where automatic image processing is combined with the highly sensitive measurements to quantify both surface and subsurface defects. For instance, Figure 2 shows a bright-field image of a laser diode facet as

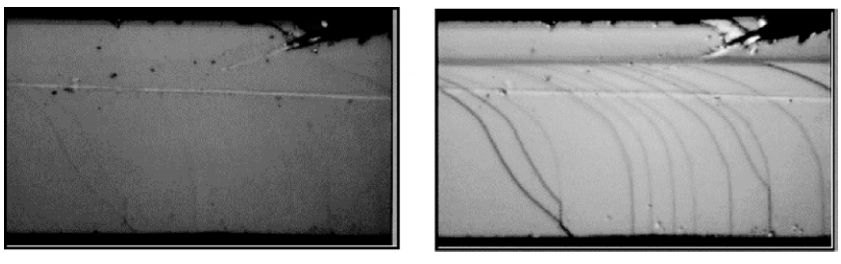

Figure 2 Bright field (left) and Nomarski (right) images of laser diode facet defects. Courtesy of Royce Instruments, Inc., Napa, CA.

well as a Nomarski image, with the facet defects greatly emphasized by the Nomarski optics.

Initial systems using differential interference contrast were strictly qualitative, with the user manually rotating the incoming polarization to produce the best contrast for a given sample and visually evaluating the resulting image. As mentioned above, visual inspection of biological specimens and defect review remain primary applications of these devices, though quantitative. By translating the Wollaston prisms laterally or rotating the analyzer in the system, one can phase shift the interference pattern. Storing multiple phase shifted images on a computer, one can obtain quantitative data about the shear using standard phase shifting interferometry equations. In addition to phase shifting through translation of the prism, quantitative data may be performed through analysis of the colors of the observed fringes or through geometric phase shifting techniques. More details on these methods can be found in the articles on **Interferometry:** Phase Measurement Interferometry; and **Interferometry:** White Light Interferometry.

Once quantitative information about the shear between the beams is obtained, the resulting data may be integrated to get back the original surface or index profile. Performing this operation on data with shear in two orthogonal directions allows the complete surface profile to be obtained. Unfortunately, since Nomarski setups are typically employed as add-on modules to standard microscope platforms rather than custom-designed metrology instrumentation, such quantitative phase shifting capability has not been widely commercialized; only a few custom or laboratory systems are in use when compared with white-light optical profilers described below. However, many research groups report nm-level surface characterization, and have developed a variety of techniques to accurately quantify thickness and index changes. The primary limitation of the quantitative techniques comes from the depth of focus of the microscope objective, which limits the vertical heights, thickness range, and index gradients that can be measured in a single measurement. Phase shifting at multiple vertical locations can be performed, but unless greatly increases the complexity of the measurement and reconstruction algorithms.

Amplitude-Division Interference Microscopes

White Light Optical Profilers

Probably the most common amplitude division interferometric microscopes are white-light interferometers, also often called optical profilers. These systems consist of three main elements: the base microscope, with illuminator and imaging optics; an interferometric element to divide and recombine the wavefront, and a scanning mechanism by which the optical path between the test and reference beams may be varied in a known manner. As the name implies, these systems typically employ spectrally broad sources, generally from a tungsten–halogen bulb. Unlike Nomarski interferometers, white light interferometers are used only in reflection-mode, as their noncommon-path nature and low-coherence source preclude interference from thick samples measured in transmission.

Figure 3 shows a schematic of a typical white light interferometer. Light from the illuminator arm, typically in a Kohler configuration, is coupled into the system with a first beamsplitter and passes through a second beamsplitter which is typically inside the microscope objective. This beamsplitter divides the beam into two parts, one of which travels to the sample and reflects from it, while the other reflects from a very high-quality reference surface. The reflected light is then recombined by the same beamsplitter and the resulting interfering light is imaged onto a camera. The static interferogram thus produced is usually by changing the optical path difference between the test and reference beams through translation of the objective with respect to the sample. The resulting signal is analyzed by one of a variety of methods as described below.

White light interferometers generally have two distinct modes of operation. In the first mode, generally referred to as phase shifting mode, a filter

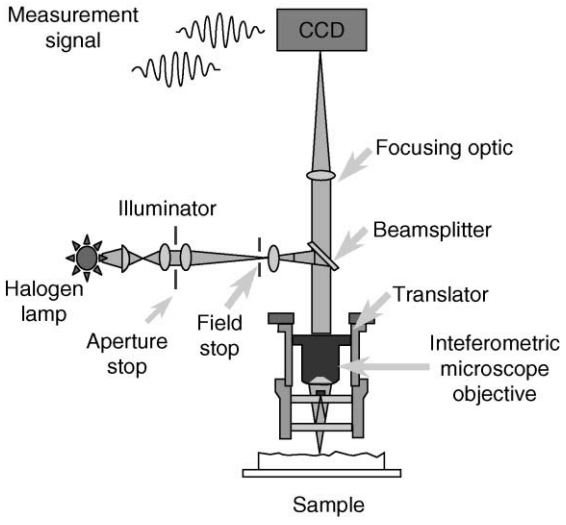

Figure 3 Schematic of white light optical profiler showing the illuminator, and translating interferometric objective.

is used to produce quasi-monochromatic light for the measurement process. This produces a large number of high-contrast interference fringes that obey the classical interference formula:

$$I_i(x, y) = I_t(x, y) + I_r(x, y) + 2\sqrt{I_t I_r}(\cos(\phi(x, y) + \alpha_i) \quad [1]$$

In the above $I_i(x, y)$ is the irradiance observed at any one point of the image, $I_t(x, y)$ and $I_r(x, y)$ are the irradiances of the test and object beams, $\phi(x, y)$ is the optical path difference between the two beams, and α_i is a phase offset introduced by the interferometric instrument. By varying α_i in a known manner and collecting at least three irradiance patterns, any of the three unknowns in the above equation can be determined; specifically, the optical path difference may be solved for every point. Assuming measurements are in a medium of known and constant refractive index, such that the only contributions to the OPD are height variations rather than index variations, surface height at each point is simply:

$$H(x, y) = \frac{\lambda}{4\pi}\phi(x, y) \quad [2]$$

Phase shifting techniques produce sub-nm repeatability and very high accuracy, but suffer from a 2π phase ambiguity from the calculation of phase from irradiance data. Thus, this technique cannot handle surfaces with point-to-point steps greater than one quarter of the wavelength of the light used. Calibration methods and further information may be found in the article on **Interferometry:** Phase Measurement Interferometry.

In order to extend interference microscopy to cover large steps, steep slopes, and vertical ranges greater than the depth-of-focus of the microscope objectives, a second technique of fringe analysis may be employed, that of coherence sensing. In this method an incoherent light source is used, such as a tungsten–halogen bulb. Due to the wide spectral range of the source, as interference patterns from different wavelengths add in the observation plane, the observed interference fringes will rapidly wash out for nonzero optical path difference between the two beams. See the article on **Interferometry:** White Light Interferometry, for further details and illustrations of this effect.

With the localization of fringes only at the point of zero optical path, the instrument scans the interference objective over the desired range and then calculates the position at which maximum fringe contrast occurs for each point. Calculating this position across all points within the field creates a height map of the surface; the interference fringes serve as a tool for depth discrimination in much the same way that the pinhole in a confocal microscope does (*see* **Microscopy:** Confocal Microscopy), another technique finding wide use in surface profiling. No phase unwrapping is required, with each pixel height calculated independently of all others, avoiding ambiguities associated with phase shifting methods. The vertical range is limited only by the scan range of the measurement and the working distance of the microscope objectives; current commercial instruments can achieve vertical ranges of over 8 mm. Figure 4 shows the fringes one would observe at a given scan location during measurement of a test piece with three steps. As the OPD between the test and reference arms varies, the fringes will

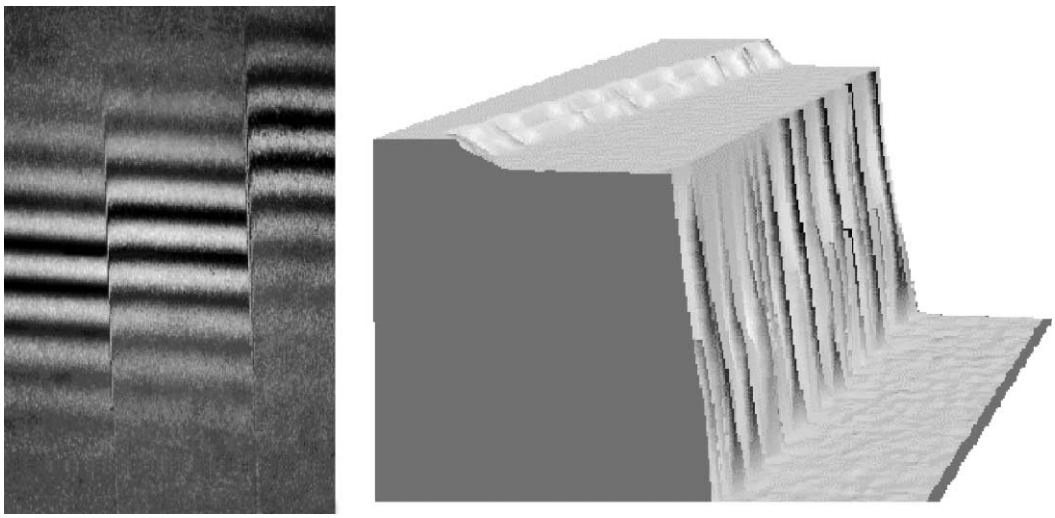

Figure 4 Localized fringes (left) of a 3-tiered surface structure (right). As the OPD is varied, the fringes will scan through the field, with the point of maximum contrast corresponding to the relative surface height of each pixel.

translate across the steps, and the surface plot at the right can be generated by calculating the scanner location of the peak contrast condition for each pixel.

There are a variety of methods for calculating the position of maximum fringe contrast using the coherence-sensing method. These include center-of-mass calculations of the peak fringe position, various frequency-space techniques and correlation of the measured fringe pattern with a theoretical pattern. Calibration of these systems generally involves repeated measurement of a known step height standard and varying the scanner motion until the step height is accurately calculated, though some systems employ separate distance-measuring interferometers to perform on-the-fly calibration for each scan. Generally speaking, coherence sensing techniques have repeatability in the range of a few nm, as opposed to the sub-nm repeatability of phase shifting techniques. This reduced sensitivity is the trade-off for avoiding the height and slope limitations of phase-shifting techniques. More details can again be found in the article on **Interferometry:** White Light Interferometry.

Recent advances in computing power have enabled an additional method of calculating surface height by combining coherence sensing with phase shifting. Coherence sensing methods are used to determine the point of best fringe contrast, and uses this information combined with the phase calculations to overcome ambiguities caused by large steps or steep slopes. Thus, one can obtain the sub-nm repeatability of phase-shifting methods without limitations on the vertical range or slope of the sample to be measured.

New fringe analysis techniques are extending the utility of these systems even further. Strobed sources are now available which effectively freeze the periodic motion for the instrument; this allows dynamic properties of samples to be measured, from surface deformation under motion to resonance frequency and switching time calculations. By analyzing the multiple interference patterns generated by transparent films deposited on a surface, film thickness, homogeneity, and differences between substrate and film surface properties may be determined.

Interferometric Microscope Objectives

One of the most critical elements in white light interferometers is the interferometric objective which splits and recombines the wavefront to form an interference pattern. Three primary interferometric configurations are used to divide and recombine the wavefront: Michelson, Mirau, and Linnik. Each of the three types of objectives is described below.

For low-magnification objectives, typically 5X or below, a Michelson interferometer configuration is typically used. A schematic of such an objective is shown in Figure 4. The illuminating beam passes through the objective and is divided by a beamsplitter placed just underneath the objective. A portion of the light travels to the test sample and the rest to a high-quality reference surface. The light reflected from each beam path is recombined by the beamsplitter and propagates to the observation plane. Note that it is important that the distance between the beamsplitter and reference surface match the distance between the beamsplitter and focus position of the sample. If the reference surface is defocused, fringe contrast will be reduced, aberrations increased, and overall system accuracy and repeatability will suffer.

This objective configuration has several advantages. First, one can add a Michelson housing to almost any standard objective with sufficient working distance for the beamsplitter, making these objectives easy to produce and relatively inexpensive. Second, the reference surface can be easily changed by the user to closely match the reflectivity of the test piece, ensuring maximum fringe contrast in the interfered beam (*see* **Interferometry:** Phase Measurement Interferometry). Third, provided there is distance between the beamsplitter and reference, one can insert a dispersion-compensating plate into the reference arm to allow measurement of parts beneath a cover glass or other dispersive medium; without such compensation, fringe contrast is generally insufficient for accurate measurements for transmissive media beyond a few hundred micrometers thickness.

As one moves towards higher magnifications, however, the working distance of the objective is typically insufficient to accommodate a large beamsplitter and still leave a reasonable distance between the objective and sample. In addition, a large cube beamsplitter will generally introduce unacceptably high aberrations in these higher numerical aperture objectives. For this reason, objectives from 10X magnification to 50X magnification are typically of the Mirau configuration, shown schematically in Figure 5.

Mirau objectives contain two additional plates compared to a standard bright-field objective: one is coated and acts as a beamsplitter, splitting the incident beam, while a second holds a small, high-quality reference surface and acts as a compensating plate so that optical paths in both arms of the interferometer are balanced (Figure 6). Such objectives are more expensive than Michelson designs, but maintain long working distances even at higher magnifications. Thermal stability becomes

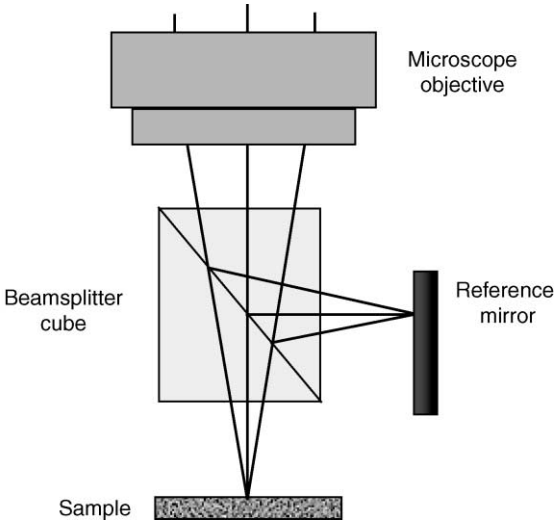

Figure 5 Schematic of a Michelson interference objective used for low-magnification applications.

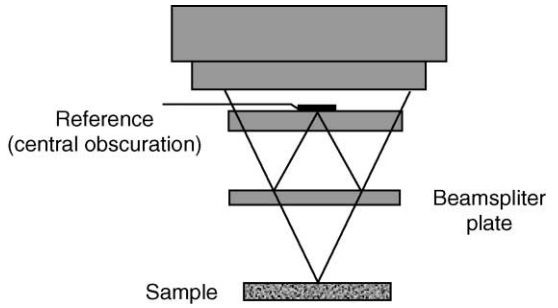

Figure 6 Schematic of a Mirau interference objective used for medium-magnification applications.

very important, as depth of focus is much reduced over lower-magnification objectives and the path from beamsplitter to reference still must be the same as from beamsplitter to in-focus test object, and most Mirau designs are therefore thermally compensated.

As one moves to even higher magnifications and numerical apertures, such as 75X or 100X, the microscope objectives do not have sufficient working distance to allow for any reasonable beamsplitter after the objective unless the numerical aperture is greatly reduced. To maintain high numerical aperture and high lateral resolution, a Linnik configuration must be used. A schematic of this configuration is shown in Figure 5. In this configuration, two separate microscope objectives are used after a beamsplitter, with one beam again reflecting from a high-quality reference and the other from the sample.

A Linnik objective is generally the most difficult to use and expensive interferometric configuration

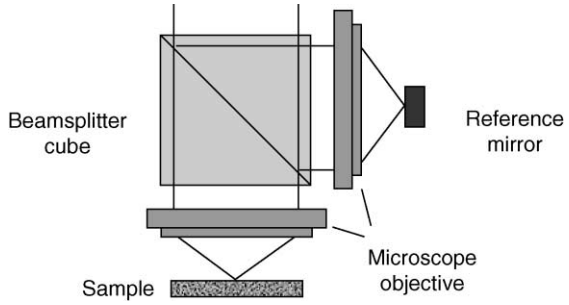

Figure 7 Schematic of a Linnik interference objective used for high-magnification applications.

(Figure 7). High numerical aperture typically limits working distance to a few hundred micrometers. In addition, depth of focus is very small, and thus these objectives must often actively adjust the reference mirror position to maintain focus over long periods of time and environmental conditions. Also, the dispersion and aberrations in the two objectives must be closely matched to ensure good fringe contrast, as there are many noncommon-path optical elements in this design; typically many objectives must be evaluated to find two that suitably match, another contributor to cost. However, these objectives do have the highest lateral resolution, and with an NA of up to 0.95, can measure the steepest slopes due to a large collection angle.

Applications

White-light interferometers are noncontact, and thus will not damage samples under test. They provide true three-dimensional surface characterization with nm-level accuracy and repeatability, and can be employed in production and laboratory environments. The various interferometric objectives allow for lateral resolutions and ranges to meet most needs; fields of view may even be stitched together to create surface maps whose extent is limited only by the range of the translation stage employed. In addition, each scan is typically quite fast, from under one second in phase-shifting mode to vertical scan rates of up to 100 μm/sec in coherence-sensing mode, with no sample preparation time. While the systems must be properly calibrated, vibration minimized, contrast maximized, and potential error sources such as dispersion and phase change on reflection effects must be managed, they remain one of the most accurate surface characterization tools available.

All of the above factors have enabled the use of white light interferometers in a variety of fields. The semiconductor and data storage industries

perform critical dimension and surface characterization of various components using these systems, some of which are configured for full wafer-handling capabilities. Systems are also used to measure precision machine parts, optics, and medical instrumentation and implants. The high sensitivity of the coherence sensing techniques allows surfaces with less than 0.1% reflectivity to be measured, so that characterization of paper, abrasives, and even different foods has been measured with these instruments. With the addition of the advanced technologies mentioned above, these systems are also now doing dynamic measurements of MEMS and thermal response characterization of precision surfaces, and also are measuring thicknesses of adhesives, drug coatings, photoresist, and a variety of other semi-transparent layers in various applications. Figure 8 shows several surface measurements, including human skin, MEMS microgears, a binary optic, and 1 Euro coin.

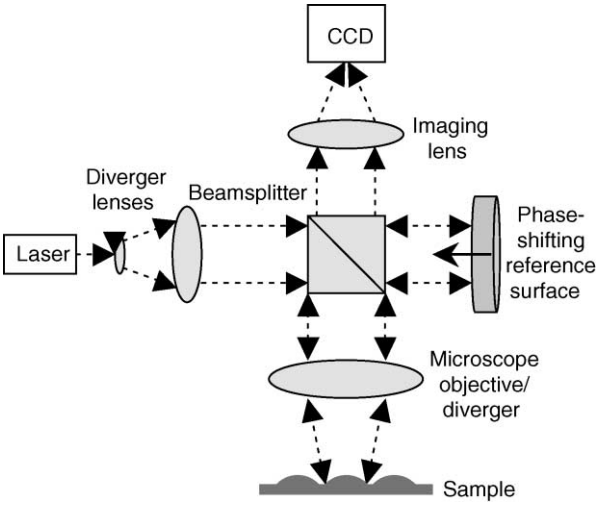

Figure 9 Schematic of a micro-LUPI interferometer operating in reflection mode.

Laser-based Interference Microscopes

Another, less common type of amplitude-division interference microscope has recently been commercialized, primarily for use in examining micro-optics. These laser-based systems employ a Tywman–Green interferometric configuration combined with a microscope, and are generally called micro-LUPI (laser unequal path interferometer) systems. A schematic of a micro-LUPI interferometer is shown in Figure 9. A beamsplitter divides the incident laser beam, half of which travels to a generally flat reference surface, while the other half typically travels through a

microscope objective that acts as a diverger lens and is incident on the test sample.

Due to the long-coherence length of the laser source, the two optical paths do not have to be equal in order to observe interference fringes, and samples may be measured either in reflection or transmission, depending on the desired test result. Collimated, diverging or converging illumination may be brought incident on the sample, depending on the optics in the test beam and their placement. The diverger elements are noncommon-path optics, and reduce the ultimate accuracy of the system to approximately lambda/10, similar to laser-based Fizeau interferometers.

Micro-LUPI-based systems have several advantages for testing small optics over other interference microscopes. First, the ability to measure both transmission and reflection properties of the optics, as well as different incident illumination schemes, means they can test the optics in their use configuration rather than inferring optical properties based solely on surface measurements. They can determine imaging properties, inhomogeneities and thickness variations in addition to characterizing the surfaces under test. Also, the curved test wavefront better matches spherical test surfaces, minimizing the number of observed fringes and making testing of small aspheres easier. Lastly, these systems can have curved reference surfaces as well as flat, and with the proper configuration aberrations in measurements due to the interferometric microscope can be minimized, ensuring high-quality measurements of the optic under test.

These systems have only phase-shifting measurement capability, as the coherence length of the source is too long for white-light interferometric techniques. Transmission tests necessitate a more complex part handling structure, with both the test piece and reflective return optic needing adjustment for tip/tilt and vertical and lateral translation. Therefore, such systems are more costly and not as versatile as a white light optical profiler, but do provide a valuable capability to the micro-optics community.

Nonlinear Microscopy

S Lévêque-Fort and P Georges, Université Paris Sud, Orsay, France

Introduction

Nonlinear microscopy has become an important tool for the investigation of biological applications where high resolution and three-dimensional imaging are essential for understanding the underlying biological function. Two-photon excitation fluorescence (TPEF) microscopy has opened the way to nonlinear techniques and is now widely available. As this new technology enables noninvasive study of biological specimens with high resolution, the number of applications in biology and medicine is still increasing. By exploiting autofluorescence of cells or tissues components, or by coupling with genetically modified fluorescent indicators or small extrinsic probes, high

contrast and localization can be obtained. Different detection techniques (fluorescence lifetime imaging (FLIM), fluorescence correlation spectroscope (FCS), intensity, and spectral imaging) permits the analyze of several fluorescence properties and so obtains complementary informations.

The successful development of two-photon techniques has generated substantial interest in the scientific imaging community in further developing and exploiting optical nonlinearities for generating new image contrast. All these new developments have strongly benefited from the major advances in ultrafast lasers which have become more compact and reliable. Second- and third-harmonic generation (SHG, THG) as well as coherent anti-Stokes Raman scattering microscopy (CARS) have thus benefited from the fact that it is now easier to generate ultrashort pulses at almost any desired wavelengths. Association of these new nonlinear techniques in the same instrument (TPEF-SHG/TPEF-CARS, TPEF/THG) is commonly encountered and provides a powerful instrumental tool for probing biological samples.

Basic Principles of Two-Photon Microscopy (TPM)

Two photon microscopy is preferred over single photon method in many biological applications due to several intrinsic advantages which arise from having a nonlinear intensity depend absorption. In general, the nonlinear polarization for a material can be expressed as

$$P = \chi^{(1)}E^1 + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \cdots \qquad [1]$$

where P is induced polarization, $\chi(n)$ is the nth order nonlinear susceptibility, and E the electric field vector of the incident light. The first term describes normal absorption and reflection of light; the second term describes SHG, hyper-Rayleigh scattering, sum and difference frequency generation, and the third terms covers multiphoton absorption, third-harmonic generation and stimulated Raman processes.

In 1931 Maria Goppert Mayer predicted that photons of lesser energy can together cause an excitation 'usually' produced by the absorption of a single photon of higher energy, in a process call multiphoton excitation. The hypothesis could not be confirmed until the invention of pulsed ruby lasers, in the 1970s, and was first applied to microscopy with the work of Denk *et al*. Two-photon microscopy used the simplest version of her theory: two photons of equal energy (from the same laser) can excite a molecule, and the excitation is similar to that obtained with a single photon possessing twice the energy (Figure 1). Thus, the molecule can emit a fluorescent photon just as if it was excited with a single higher energy photon (Figures 1 and 2). Of course, the absorption of the two photons must occurs nearly simultaneously ($\sim 10^{-16}$ s), resulting in a quadratic dependence on the light intensity rather than the linear dependence of conventional one photon fluorescence.

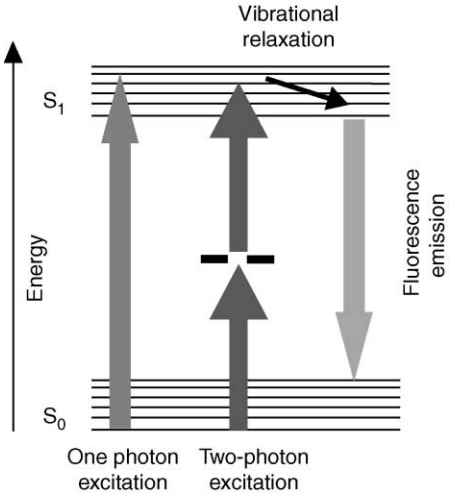

Figure 1 Jablonski diagram for one and two-photon excitation.

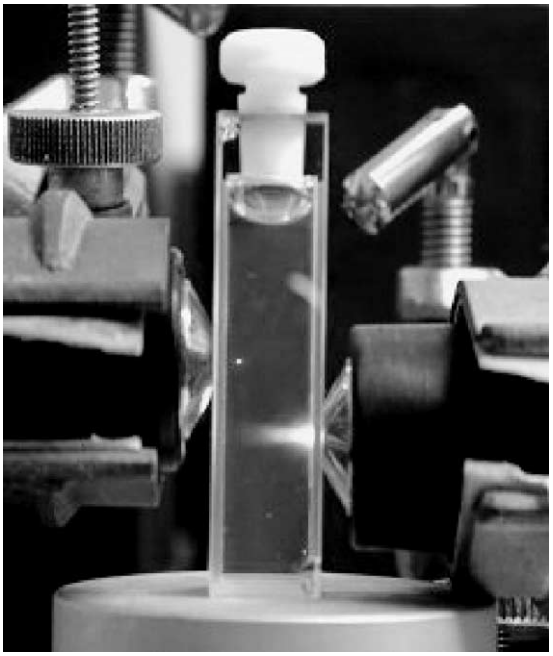

Figure 2 Localization of excitation under two photon excitation (left) compared to one photon excitation (right).

The nonlinear optical absorption property of two-photon excitation, limits the fluorochrome excitation to the point of focus. This localized excitation volume results in greatly improved axial resolution and image contrast compared with conventional microscopy, but also significantly decreases sample photobleaching and photodamage by reducing the region of photointeraction (Figure 2).

Another major advantage of TPEF is its ability to image deeper inside biological samples, owing to the reduced scattering and absorption of near infrared wavelength compared to UV and visible light. Near infrared light (700–1000 nm) is located within the 'therapeutic optical window' where the absorption of the main cells and tissue components is low.

TPEF also permits a high rejection of residual excitation light: in standard one-photon microscopy, the excitation wavelength can be spectrally close to the fluorescence emission band. Filters used to eliminate the leakage of excitation light into the detection channel often cuts off a part of the fluorescence emission. For TPEF excitation and emission band are well separated, and highly efficient filters can remove the residual excitation light without compromising the microscope sensitivity.

Under two-photon excitation, the fluorescence photon flux depends on the square of incident photon flux:

$$F \propto \sigma_{2P} C I^2 \qquad [2]$$

where σ_{2P} is the two-photon cross-section (cm^4 s) with 10^{-50} cm^4 s, called a Goppert–Mayer (GM), C the fluorophore concentration, and I^2 the incident photon flux. The two-photon cross-section is a quantitative measure of the probability of two-photon absorption and as a second-order process is low. As it is difficult to directly measure two-photon cross-sections, we usually use the cross-section of two photon-induced fluorescence (σ_{TPEF}) as the product of two photon absorption cross-section (σ_{2P}) with the fluorescence quantum yield $\phi_F \sigma_{TPEF} = \sigma_{2P} \phi_F$.

Intrinsic fluorophore, such as nicotinamide adenine dinucleotide (NADH), have low cross-sections ($<10^{-4}$ GM), usual fluorescent dye in biology ranging between 1 and 300 GM and quantum dots approaching 50 000 GM. As the probability of two-photon absorption is quiet low, high incident photon flux needs to be delivered to the sample to generate efficient absorption:

$$I \propto E \frac{1}{\Delta\tau \omega^2} \qquad [3]$$

I depends on the energy per impulsion E (mean power/pulse frequency), the pulse duration $\Delta\tau$, and the beam waist ω. The expression of I clearly demonstrates that by using ultrashort pulses and by reducing the beam waist, one can maximize the incident flux. Currently the most commonly used laser source for multiphoton microscopy is the femtosecond titanium-sapphire (Ti:Sa) system. These pulsed femtosecond lasers deliver a 100 fs pulse train at a repetition rate of ~80 MHz with a tuning range from 700 to 1000 nm. The beam waist depends on the objective numerical aperture. If we consider a Gaussian beam profile, with radial and axial parameters of σ_r and σ_z respectively and for a high numerical aperture NA > 0.8:

$$V = \left(\frac{\pi}{2}\right)^{3/2} \sigma_r^2 \sigma_z \qquad [4]$$

with $\sigma_r \approx 0.52\lambda/\sin\alpha$ and $\sigma_z \approx 0.76\lambda/(1-\cos\alpha)$. where λ is the excitation wavelength, α is the one-half of the objective angular aperture ($NA = n \sin\alpha$, n index of the immersion medium). So for a wavelength of 780 nm and an objective working with water immersion with a numerical aperture of 0.9, the excitation volume can be described as an obloidal shape with a radial axis of typically 500 nm and an axial axis of 1.90 μm. It corresponds to an excitation volume of ≈1 fL ou 1 μm^3. Higher resolution can be achieved using an immersion oil objective (NA = 1.3) at the cost of a higher cost and a shorter working distance.

Typical powers used to generate two-photon excitation without damaging the sample are between 1 and 10 mW for the mean incident power. For a laser beam of 1 mW, at a rate of 76 MHz with 100 fs pulse duration, and with an objective leading to a surface in the focal plane of 1 μm^2, the peak power is 0.13×10^9 W/cm^2 at the focal plane of the sample. Of course each samples has its own limits regarding incident intensity, and the key to use TPEF safely is always to reduce the excitation intensity in order to avoid photodamage.

Fluorescent Probes

Biological systems often possess endogenous fluorescent molecules that can be imaged, revealing important sample characteristics without the need of labeling (Figure 3a,b). Cells or tissues can be imaged through their autofluorescent, with the emission of several components, NADH, flavins, collagen fibers, etc. Pharmacology studies also exploit the natural autofluorescence of aromatic drugs, to

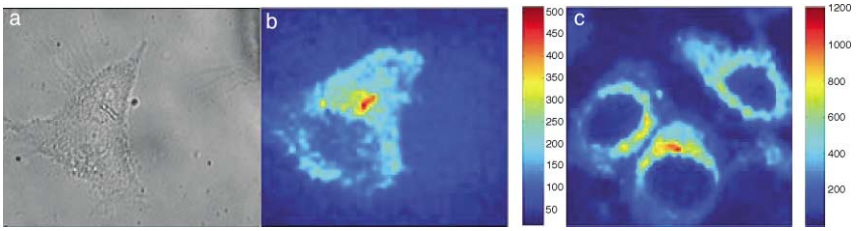

Figure 3 Applications showing various capabilities of TPEF: (a) Hela cells in transmitted image and corresponding autofluorescence image (b) under TPE (780 nm). (c) After adding 40 μM of an anti-HIV drug on similar cells, intrinsic fluorescence of the drug allows us to find its preferable localization inside the cytoplasm.

localize drug inside cells and study their reactivity without any labeling.

However, for some specific applications where the autofluorescence is too low, or if one needs to specifically identify different cells components (Figure 3g), or follow protein mobility, the samples need to be labeled your with extrinsic fluorophores. Extrinsic fluorophores are organic molecules, first developed for one-photon excitation, and are used under two-photon excitation with more or less efficiency as OPE and TPEF have different quantum mechanical selection rules, and the TPE spectrum is not always scaled to the half of OPE spectrum. Current works are focused on the development of specific markers for TPE or SHG to enhance contrast and also reduce incident laser power.

Two new generations of marker have been developed: the development of the green fluorescent protein (GFP) and its mutant introduces a convenient method for monitoring gene expression in cells and tissues; quantum dots are the latest focus in fluorescence labeling. They are promising reporters as their size (1–100 nm) induces a specific narrow emission spectrum in the visible. Absorption can occur over a wide range of short wavelengths because of the existence of multiple electronic states. Time-domain measurement has been performed with CdSe quantum dots which shows multiexponential decay with fluorescence lifetime of 3.4 ns, 16.1 ns, and 35.6 ns, much longer than autofluorescence lifetimes, hence providing greater sensitivity than intensity-based measurement. However, like GFPs, quantum dots display blinking behavior.

Two-photon Applications

Two-photon excitation has become the technique of choice for fluorescence microscopy and is applied to a variety of imaging tasks on samples ranging from single molecules to thick tissues. Owing to the high NIR penetration depth, biopsies and living tissue can be noninvasively investigated by morphological and functional fluorescence imaging of endogenous (Figure 3b) or exogenous fluorophores to depths of more than 300 μm. In genomics, multiphoton multicolour fluorescence *in situ* hybridization (FISH) are used to label various specific regions of DNA, and identified different genes and chromosome regions. In pharmacology, a higher penetration and localization of photodynamic therapy is observed, detection of low drug concentration inside cells facilitates the reactivity comprehension (Figure 3b,c). Neurobiologists investigate calcium dynamics inside brain slices and live animals, or follow neurotransmitter diffusion. Of course, these are only a few examples among the increasing number of applications, and some of them are illustrated in Figure 3.

Two-photon Instrumentation

Two-photon microscopes are now commercially available, however a large number of groups have built their own from separate components or by modifying an existing confocal microscope. Homemade microscopes present a higher configuration flexibility for excitation/detection at a much lower price.

Femtosecond, picosecond, and continuous wave (CW) laser sources have been used for TPM. By using a cw laser sources such as ArKr and NdYag, the average power increases by ~200-fold to achieve the same excitation rate obtained with a femtosecond laser, which is not highly desirable for biological samples. So as previously shown, the TPE efficiency is higher with shorter pulses, so Ti:Sa femtosecond lasers are most commonly used.

One of the drawbacks of TPM is that it is a laser scanning technique. To reconstruct an image you need either to move the sample or the laser beam. Most commonly $x-y$ mirrors driven by a galvanometer scanner are used to scan the laser at the focal plane of the sample. Lenses are used to expand the beam to overfill the objective back aperture and so obtain a diffraction limited focal volume. The excitation light enters the modified inverted epi-fluorescence microscope (Figure 4).

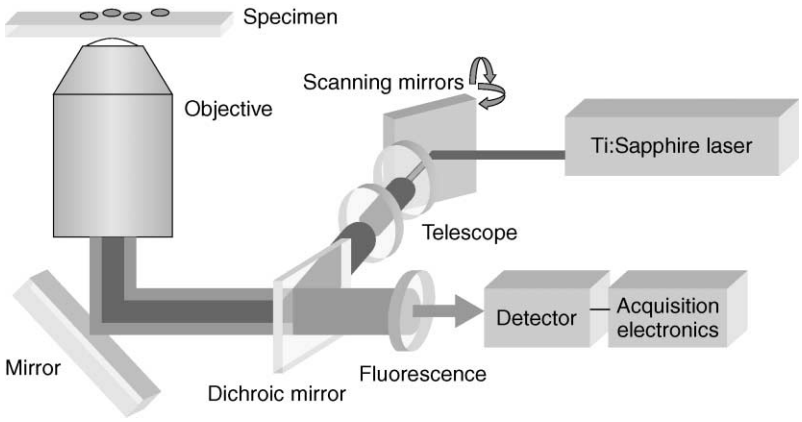

Figure 4 Schematic of a typical two-photon microscope.

A dichroic mirror transmits the excitation light and reflects fluorescence. High numerical aperture objectives are used to provide a high resolution but also maximize fluorescence collection. They are usually mounted on piezo-electric translators to provide a fast Z-scan. The fluorescence is collected by the same objective, reflected by the dichroic to the detector. A filter is placed in front of the detector to remove any residual excitation light. Typical detectors used are the photomultiplier tube (PMT), microchannel plate-PMT (MCP-PMT), avalanche photodiode or charge-coupled device (CCD) cameras. PMTs are the most commonly implemented because they are robust, low-cost, have large, active areas, and good sensitivity.

As TPE is intrinsically confined to the focal volume, two-photon microscopy unlike confocal microscopy, does not need emission pinholes and descanning optics to achieve axial depth discrimination Some authors have, however, added a pinhole to enhance resolution but at the cost of important sign al loss. Concerning the design of the detection pathway, depending on the size of the sample scanned, the objective magnification and the detector area, one may need to use a lens to collect the fluorescence onto the detector.

Fluorescence Detection

Contrast in fluorescence imaging can be provided through several complementary parameters such as steady-state intensity, spectral dependence (at absorption and emission), or fluorescence lifetime.

Intensity Imaging

Intensity images are obtained by summing all the incoming photons during an acquisition time (typically $\sim$1 to 10 ms) which strongly depends on the fluorescence quantum yield of the sample. The whole samples intensity image is obtain by scanning the beam on the focal plane with the $X-Y$ scanner, leading to an acquisition time of 25 s for a 50×50 μm image (1 μm step).

Spectral Imaging

Spectral imaging can be a powerful way to discriminate different molecules, and to identify cellular components or perform co-localization of different proteins. It can be performed by either using an interference filter in front of the detector to extract the contribution in a specific band, or more precisely with a spectrometer. However, autofluorescent spectral bands are usually broad and sometimes it is difficult to separate the different emissions. Extrinsic trackers are thus used to labels specifically, for example, the nucleus, the plasma membrane, and mitochondria, and each tracker usually emits in a specific and well-known spectral band, allowing to easily discriminate and localize the different cellular components. Quantum dots offer narrow emission spectra and allow high spatial resolution, and with the rapid development of their functionalization, they should lead to rapid progress in intracellular imaging.

Fluorescence Lifetime Imaging (FLIM)

Imaging of fluorescence lifetimes is a useful contrast-enhancing method that provides information related to the microenvironment with spatial resolution. The fluorescence lifetime τ corresponds to the average time a fluorophore stays in its excited state is given by $\tau = 1/(k_f + k_{nr})$ with k_f the radiative decay and k_{nr} the nonradiative decay rate.

The radiative decay rate is a characteristic property of a molecule and therefore may be used to contrast different chemical species or fluorophores.

The nonradiative decay rate is a function of the local environment of an excited molecule, and so fluorescence lifetime measurements can provide information about environmental changes (e.g., pH, pO_2, $[Ca^{2+}]$). Furthermore, different cellular probes or tissue components with similar emission spectra but different lifetimes can be distinguished. Another advantage of lifetime measurement is that as a relative measurement of the fluorescence intensity, it does not depend on a non-uniform intensity excitation of the sample, and also does not depend on molecular concentration, allowing one to detect very low quantity of molecules.

Following a delta excitation, the fluorescence intensity de-excitation is given by$I(t) = I_0\, e^{(-t/\tau)}$, with I_0 the initial amplitude. Fluorescence lifetime measurement has been demonstrated either in frequency or time-domains. Time-resolved measurements in the frequency domain are based on the determination of demodulation M and phase shift $\Delta\varphi$ and require modulated light sources (modulation frequency $\omega = 2\pi f$).

The excitation source $I_E(t)$ and induced fluorescence $I_F(t)$ can be written as:

$$\begin{aligned} I_E(t) &= I_{E0} + I_{E\omega}\cos(\omega t + \varphi_E) \\ I_F(t) &= I_{F0} + I_{F\omega}\cos(\omega t + \varphi_F) \end{aligned} \qquad [5]$$

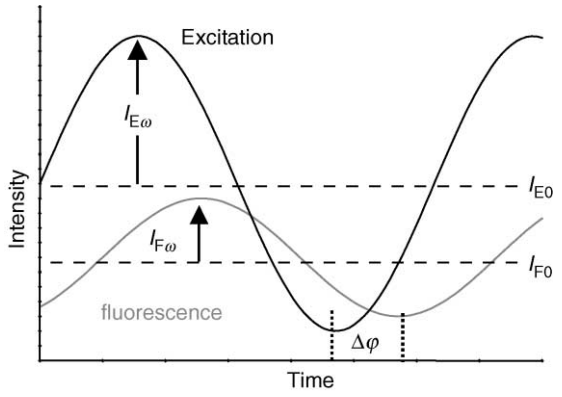

Figure 5 Time course of excitation and emission light in frequency domain fluorescence lifetime measurements techniques.

In the case of fluorescence with mono-exponential decay, the lifetime τ can deduced from the relations (Figure 5):

$$M = \frac{I_{F\omega}/I_{F0}}{I_{E\omega}/I_{E0}}. \qquad \omega\tau = \tan(\Delta\varphi) = \sqrt{\frac{1}{M^2} - 1} \qquad [6]$$

In order to translate the phase and demodulation information from the 80 MHz frequency to a lower kHz frequency, a modulated gain $G(t)$ at the frequency ω' can be applied to the detector (heterodyne detection):

$$G(t) = G_0 + G_{\omega'}\cos(\omega' t + \varphi_G) \qquad [7]$$

The detector response $S(t)$ is thus proportional to the fluorescence intensity:

$$\begin{aligned} S(t) = {} & G_0 I_{F0} + \frac{G\omega' I_{F\omega}}{2}\frac{1}{\sqrt{1+(\omega\tau)^2}} \\ & \times\cos[(\omega - \omega')t + \varphi_G - \varphi_E + \Delta\varphi] \end{aligned} \qquad [8]$$

In the time-domain, the single point detection system is called time-correlated single-photon counting (TCSPC). The principle of the TSCPC system is shown in Figure 6. For each excitation pulse a trigger signal is sent to a time-to-amplitude converter (TAC) within which a capacitor starts charging linearly with time. Upon arrival of each fluorescence photon on the detector a second trigger pulse stops the capacitor charging. The charge is proportional to the delay between the excitation pulse and the fluorescence photon. By repeating the measurement over many thousands of excitation pulse, a histogram of photon arrival can be build up. As each photon must be record individually, the incident power is reduce to avoid the detection of only photons from the beginning of the decay (pile-up) which would lead to shorter lifetimes. To match detector dead-time and TAC counting rate, the TAC is oftenly used in reverse mode: the fluorescence photon starts the TAC and the following pulse stops it.

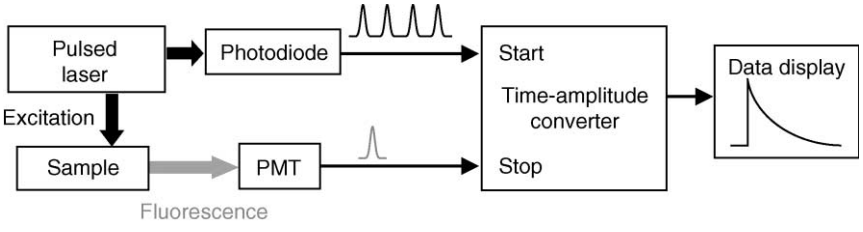

Figure 6 Schematic of time correlated single photon counting system.

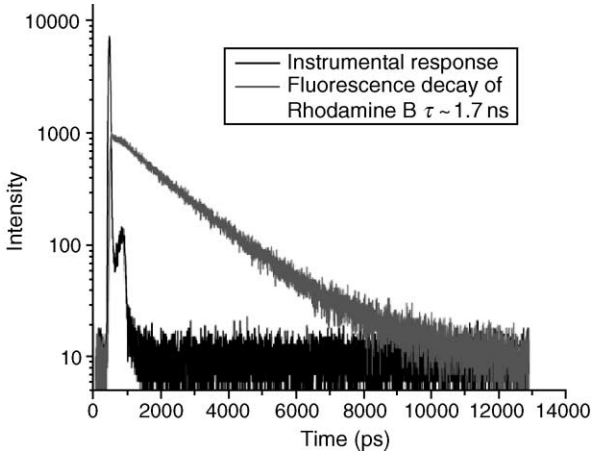

Figure 7 Typical instrumental response of MCP-PMT (black curve), and fluorescence decay curve of rhodamine B (grey curve) with $\tau \sim 1.7$ ns.

Typical detectors used are the photomultiplier tube (PMT), microchannel plate-PMT (MCP-PMT), and avalanche photodiode.

Typical instrumental response of our MCP-PMT is represented in Figure 7 (black curve) leading to a resolution of 30 ps. Depending on the fluorescence quantum yield of the sample, in order to have a good signal to noise ration, acquisition time is ranging between 1 and 30 s per point. Fluorescence decay of rhodamine B with a lifetime $\tau \sim 1.7$ ns is also presented in Figure 7.

For both detection approaches, single point lifetime measurements can be extended to lifetime imaging by synchronizing the sample scanning and the lifetime detection. However, due to the long time acquisition needed, images are only limited to small interesting areas rather than the whole sample. We will see in the recent development section below, new ways to overcome this issue.

Fluorescence Correlation Spectroscopy (FCS)

FCS experiments are performed by recording fluorescence intensity fluctuations (i.e., fluorescence bursts (Figure 8)) from the small focal volume (<1 fl). Applications include diffusion, chemical reactions, molecule concentration, or hydrodynamic flow–FCS under TPE benefits from all the advantages of TPE versus OPE.

Various experimental parameters can be extracted through temporal analysis of fluorescence intensity fluctuations by calculating the autocorrelation or cross-correlation of the fluorescence signal defined as:

$$g(\tau) = \frac{\langle I_F(t) I_F(t+\tau)\rangle}{\langle I_F^2(t)\rangle} = \frac{\int I_F(t) I_F(t+\tau)\mathrm{d}t}{\int I_F^2(t)\mathrm{d}t} \qquad [9]$$

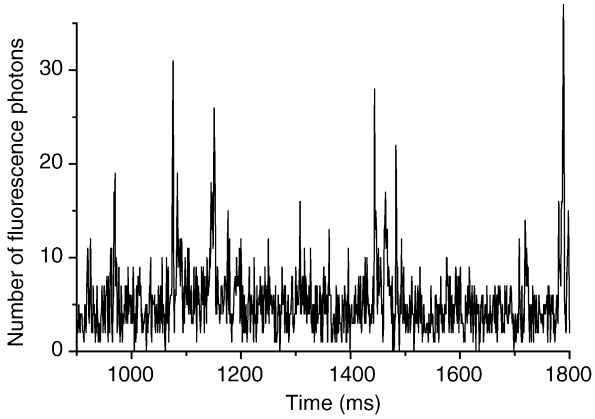

Figure 8 Fluorescence intensity raw data along the time. Bursts are observed when molecules cross the focal volume.

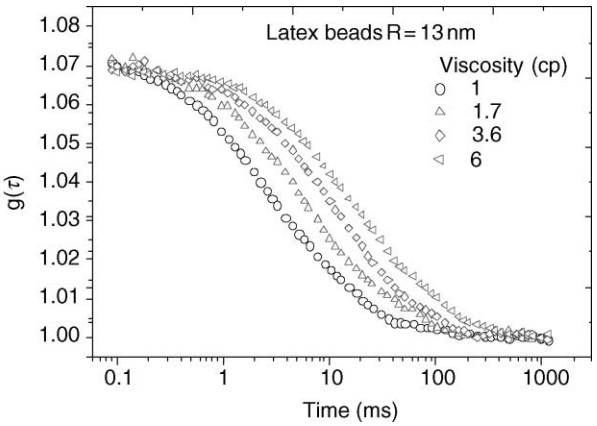

Figure 9 Correlation function observed for microspheres placed in different viscous solution.

where I_F is the time-dependent fluorescence signal. By considering that the fluorescence intensity fluctuates around a mean value:

$$I_F(t) = \langle I_F\rangle + \delta I_F(t) \qquad [10]$$

the autocorrelation function can be written as:

$$g(\tau) = 1 + \frac{\langle \delta I_F(t)\delta I_F(t+\tau)\rangle}{\langle I_F^2\rangle} \qquad [11]$$

FCS have been extensively used to extract diffusion coefficient of small fluorescent latex bead in solution, showing the influence of the bead radius or solvent properties. Figure 9 clearly exhibits the influence of the viscosity of the solvent on the diffusion of microspheres. Single molecule detection has also been reached. FCS as also been extended to biological applications where the low background associated with TPE and the reduced autofluorescence is critical. Diffusion of microbeads inside cells cytoplasm

or bacterial biofilms have been successfully demonstrated.

Recent Developments in Two-Photon Microscopy

Towards video microscopy

All the nonlinear microscopies share an important limitation: the image build up pixel-by-pixel by scanning across the sample, leading to long-time acquisition. Depending on the sample's emission and the area studied, scanning rates between 0.5 Hz and 30 Hz can be reached for intensity images. To speed up this acquisition time, a first approach is based on a line excitation, in combination with widefield CCD detection. This provides real-time image acquisition rates at the expense of a reduced axial resolution (5 μm instead of 1 μm). A more ideal way of spreading the available excitation power over the sample and speed up image buildup, is the simultaneous use of several well separated foci, each of them generating a diffraction limited spot. In combination with whole field detector, as with a CCD camera, image acquisition rates can be strongly enhanced without compromising resolution. The spacing between the foci must be carefully chosen in order to avoid out-of-focus interference. By introducing time-delay between the different foci, larger than the pulse duration, each foci of a microlens array can be position very closed without loss of resolution. An alternative way has been proposed; a special beamsplitter has been developed to create multiple beams with a higher efficiency, furthermore this setup inherently induced time-delay between each foci. Time-domain has been demonstrated in both approach, and FLIM maps on cells imaging have been obtained in only few second with 200 ps time resolution.

Sharpen the focal point

Nonlinear microscopy facilitates 3D-imaging but the resolution is still limited to 180 nm in the focal plane and 500–800 nm along the optical axis. According to the diffraction theory, the resolution of a focusing light microscope is related to the size of its focal point. In the mid-1990s, new concepts appeared to break this diffraction theory and sharpen the focal volume. In 4-pi microscopy the sample is placed between two large NA objective lenses in a single axis at their common focus. Coherent interference of beams passing through the two lenses generate a point spread function whose central maximum is 3–4 times narrower than in the normal confocal case, but which also has side lobes. This last issue can be overcome using two-photon excitation. A two-photon 4-pi microscopy can thus result in a resolution of ~100 nm in all directions, and has been demonstrated successfully on filamentous actin and immunofluorescently labeled microtubules. However, a 4-pi microscopy requires the sample to be thin and mounted between two coverslips, unless one of the lenses is a dipping lens. Recent development on sample chambers allows one to overcome this issue, and results in live mammalian cells have been shown. A compact 4-pi commercial version has recently been proposed (Leica), achieving a seven-fold-improved axial resolution (80 nm) compared to the classical two-photon microscope.

Another technique, also developed by Professor Hell's group, is called stimulated emission depletion (STED) microscopy. The fluorophore in the fluorescent state S1 is stimulated to the ground state S0 with a doughnut-shaped beam. The depletion of the S1 saturates with increased I_{STED} intensity, and therefore establishes a nonlinear relationship between the fluorescence and the intensity applied to the STED. The saturation of S1 depletion is the essential element for breaking the diffraction limit as it confines fluorescence to the center. Spot size is not limited, but in practise depends on the quality and the saturation factor limited depletion. Using STED microscopy with wavelengths of 750–800 nm leads to a lateral resolution of up to 28 nm on single molecules experiments.

STED microscope has been successfully combined to 4-pi microscopy, and lateral resolution of 30–40 nm has been demonstrated.

Others Nonlinear Imaging Techniques

The success of two-photon microscopy has opened the way for other nonlinear microscopy. As opposite to multiphoton fluorescence absorption techniques where the induced signal is incoherent fluorescence, the signal generated by harmonic generation and stimulated Raman scattering is coherent with specific directional and polarization properties, as such fluorescence and harmonic images are derived from fundamentally different contrast mechanisms. However, both techniques share many features like intrinsic three-dimensionality, reduce photobleaching or deep sectioning, and require essentially identical equipment, allowing one to combine these two techniques as discussed further below.

Second-Harmonic Generation Microscopy

SHG is a second-order nonlinear optical process that can only arise from a medium lacking a center of symmetry, for example, an anisotropic crystal or at an

interface of a membrane. SHG can be used to image tissue, muscles, cells membranes, or protein array, and has been recently reported to enhance membrane potential by using voltage sensitive dye.

SHG does not arise from an absorptive process, as the intense laser field induces a nonlinear, second-order, polarization in the assembly of molecules, resulting in the production of a coherent wave at exactly twice the incident frequency (half the wavelength). As represented in Figure 10, for an excitation at 800 nm, the SHG is observed at 400 nm and depending on the fluorescence properties of the molecule, a broadband fluorescent spectra is emitted in the visible.

Contrary to TPEF, where the emission properties depend only on the molecular properties and are independent of the laser source, the spectral and temporal characteristics of SHG are derived from the laser source. The SHG is temporally synchronous with the excitation pulse and its bandwidth is $1/\sqrt{2}$ of the laser's bandwidth. As SHG is an instantaneous process, the signal is only generated during the duration of the laser pulse (Figure 11), in contrary to TPEF where de-excitation of the molecules can occur over several nanoseconds after the pulse excitation.

A major difference between SHG and TPEF is that SHG requires a noncentrosymmetric environment to produce a signal. By examining the second term of eqn [1] $P = \chi^{(2)}E^2$ where the polarization and electric field are vector quantities and $\chi^{(2)}$ is a tensor, this condition is only satisfied for a birefringent crystal, an order array, or an interface. For example, the induced polarization from molecules in a dye cuvette (centrosymmetric sample) would be equal and opposite in all directions, leading to a vector sum zero. The SHG propagation is essentially in the forward direction, and the emission pattern is confined to twin lobes in the case of surface generation, or a cone in the case of volume generation. The off-axis of the two lobes critically depend on the tight focus of the driving field.

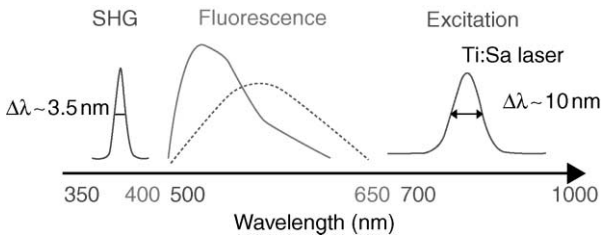

Figure 10 Wavelength domain for two-photon induced fluorescence and second-harmonic generation: excitation meets the same criteria and Ti: Sa are typically used in the range 700–1000 nm. For a typical excitation at 800 nm, fluorescence will be observed over ~450 nm, and SHG, at exactly 400 nm.

The total radiated SHG power can be derived by integrating the radiation profile from all the emission directions: $P_{SHG} = \frac{1}{2}\theta_2 N^2 \sigma_2 I_0^2$ with $\sigma_2 \propto |\chi_2|^2$, I_0 the driving field intensity at the focal center, N the effective number of radiative molecules, and $\theta_2 \approx (0.1\lambda/w_0)^2$.

A schematic of a typical SHG/TPEF microscope is shown in Figure 12. The excitation source is a mode locked Ti:Sa laser which delivers ~120 fs at 76 MHz. The laser light is focused into the sample with a water immersion microscope objective (Olympus, LUM-planFl 60x) and the resultant SHG is collected in a forward direction, while TPEF is collected in the backward direction.

Figure 13 illustrates SHG and TPEF images of Di-6-ASPBS molecules under 880 nm excitation.

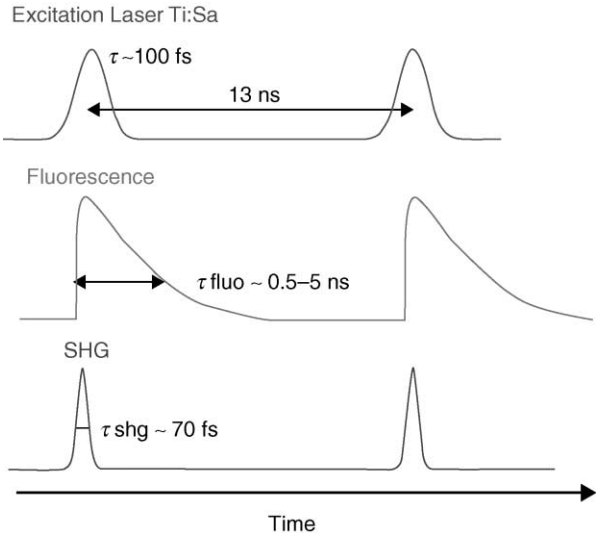

Figure 11 Typical time-response for two-photon induced fluorescence and SHG. SHG signal is an instantaneous process whereas fluorescence emission can occur several nanoseconds after the pulse excitation.

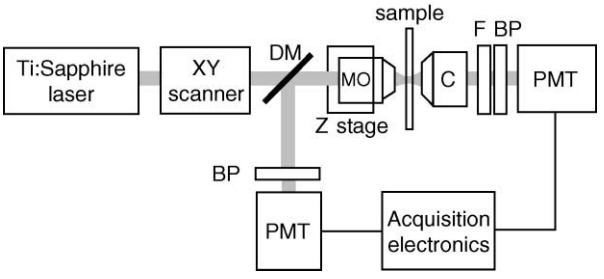

Figure 12 Schematic of SHG setup combined with TPEF extracted from (DM dichroic mirror, MO microscope objective NA 0.9 water immersion, C condenser, F colored glass filter, BP bandpass filter, PMT photomultiplier tube). Reproduced with permission from Moreaux L, Sandre O, Blanchard-Desce M and Mertz J (2000) Membrane imaging by simultaneous second-harmonic generation and two-photon microscopy. *Optics Letters* 25: 320–322, © 2000 Optical Society of America.

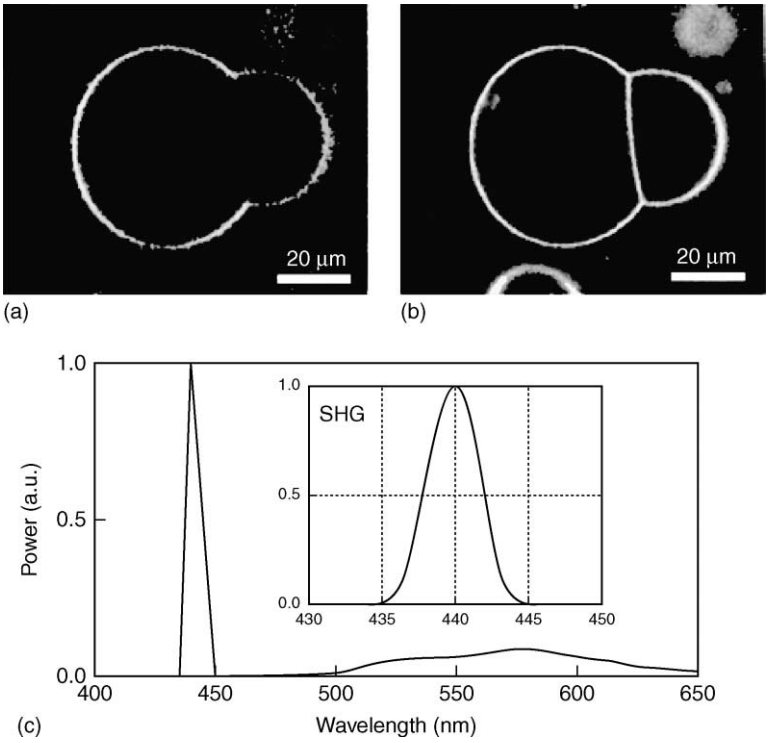

Figure 13 (a) SHG and (b) TPEF of two adhering vesicles labeled with Di-6-ASPBS (equatorial slice) excited at 880 nm. (c) The forward-detected SHG spectra (left peak) and the backward broad band fluorescence spectra (right peak). The Stokes shift in fluorescence leads to an important spectral separation between the two peaks. An expanded view of the SHG peak is presented in the inset. Reproduced with permission from Moreaux L, Sandre O, Blanchard-Desce M and Mertz J (2000) Membrane imaging by simultaneous second-harmonic generation and two-photon microscopy. *Optics Letters* 25: 320–322, © 2000 Optical Society of America.

The total acquisition time for the images was 1.5 s for an excitation power less than 1 mW. The adhesion area where the membranes are fused exhibits a centrosymmetric molecular distribution wherein TPEF is allowed, but not SHG. The corresponding forward-detected emission spectra of SHG (left peak) and TPEF (right peak) is shown in Figure 13c.

Third-Harmonic Generation (THG)

Third harmonic generation takes advantage of the discontinuity of third-order nonlinear susceptibility $\chi^{(3)}$ at material interfaces. At the focus point of an input laser beam with wavelength λ, this discontinuity gives rise to a new wave in the forward direction at the third-harmonic, $\lambda/3$. This signal can be analyzed in the transmission mode either with a single pixel detector or with a CCD camera. As with the other nonlinear techniques, THG offers a high 3D sectioning capability. Since all materials have nonvanishing third-order susceptibilities, THG microscopy can utilized as a general-purpose microscopy technique, with no need for fluorescence labeling or staining. Experimental setup for THG are very closed to SHG microscope. The need for efficient THG in the sample, together with low average laser power to avoid heating, dictates a laser source that operates with femtosecond pulses. The lasers that are often used THG microscopy are a synchronously pumped OPO at the wavelength of 1500 nm, a low repetition-rate OPA at 1200 nm and a Cr:Forsterite laser at 1240 nm. All these lasers are in the infrared above 1200 nm, thus generating THG signals in the visible range. These visible signals are compatible with the collection optics. A infrared laser undergoes low scattering, however absorption in water strongly increases.

THG have been demonstrated from subcellular to millimeter-size organisms with imaging of nerve cells, chloroplasts of a leaf, or Ca^{2+} intracellular dynamics.

Coherent Anti-Raman Stokes (CARS)

Chemical imaging by use of inherent molecular vibration signals avoids the photobleaching problem and perturbations to cell function induced by fluorophore labeling. Confocal Raman microscopy can provide 3D spatial resolution but it requires high average power due to small cross-section of Raman scattering, or long-time exposure which is not desirable in studying dynamic living system.

The above difficulties can be circumvented by multiphoton vibrational microscopy based on coherent anti-stokes Raman scattering (CARS). CARS is a four-wave mixing process in which a pump field $E_p(\omega_p)$, a Stokes field E_S (ω_S), and a probe field $E_{p'}$ $(\omega_{p'})$. Interact with a sample and generate an anti-Stokes field E_{AS}, at the frequency $\omega_{AS} = \omega_p - \omega_S + \omega_{p'}$. In practise, the pump and the probe fields derive from the same laser $\omega_p = \omega_{p'}$ and $\omega_{AS} = 2\omega_p - \omega_S$. The energy diagram of CARS is shown on Figure 14.

The CARS intensity is the square modulus of the induced polarization, $P^3 = \chi^{(3)} E_p^2 E_s$, with $\chi^{(3)}$ the third-order susceptibility.

The application of the CARS process to microscopy opens up a new method for chemical imaging. In CARS microscopy, the signal is also dependent on the square of the pump field intensity, so the temporally and spatially overlapped pump and Stokes laser pulses tightly focused into a sample, generate a signal of a small excitation volume ($<1\ \mu m^3$). As with all other nonlinear imaging techniques, the image is obtained by raster scanning the sample or the laser beams. The vibrational contrast in CARS microscopy arises from signal enhancement when $\omega_p - \omega_s$ is tuned to Raman-active vibrational frequency Ω. CARS signal generation needs to fulfill the phase-matching condition, $l < lc = \pi/|\Delta\mathbf{k}| = \pi/|\mathbf{k}_{as} - (2\mathbf{k}_p - \mathbf{k}_s)|$, where $\mathbf{k}_p$, $\mathbf{k}_s$, and $\mathbf{k}_{as}$ are wavevectors of the pump, Stoke and CARS fields, respectively, and $\Delta\mathbf{k}$ is the wavevector mismatch.

CARS presents several advantages similar to TPEF: high 3D sectioning capabilities, a low scattering and absorption of the excitation beams. CARS signal is higher in frequency than one-photon fluorescence, so it can be detected in the presence of a strong fluorescent background. Vibrational contrast is intrinsic to biological samples. Fluorescent probes are not necessary and photobleaching is thus circumvented. The coherent signal accumulation in the CARS process produces a strong and directional signal, making CARS microscopy much more sensitive than the conventional Raman microscopy. Consequently, CARS microscopy requires only a moderate average power tolerable by biological samples and has a high data acquisition speed. However, CARS microscopy is not without shortcomings. First, the intrinsically weak induced nonlinear polarizability requires sophisticated laser excitation sources with high peak power and moderate average power, and with low jitter. Second, unlike fluorescence imaging, CARS measurement is not background free, and the nonresonant signal limits the image contrast.

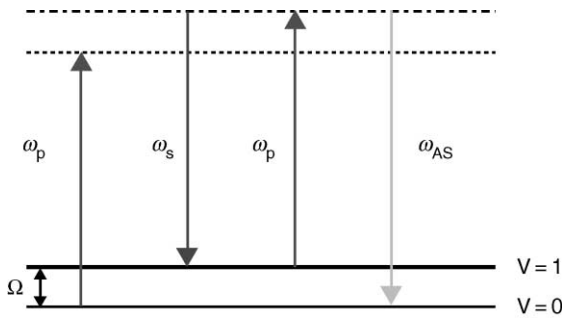

Figure 14 Energy diagram for Coherent anti-Raman spectroscopy (CARS).

The typical setup is very similar equipment compared to TPEF and SHG. The main difference arise from the excitation, two laser beams, the pump, and Stokes laser beams overlapping (in space and time) and are tightly focused into the sample using a high NA objective. The CARS signal can be detected in the forward (F-CARS) and the epi-detection (E-CARS). Unlike fluorescence emission and spontaneous Raman scattering, the radiation pattern of CARS is dependent on both the size and shape of a scatterer. The two detection geometry are thus complementary, the forward detection is suitable for imaging objects of a size comparable to or larger than the excitation wavelength.

For smaller objects, the F-CARS contrast is limited by the large nonresonant background from the solvent. Epi-detected CARS (E-CARS) microscopy provides a sensitive means of imaging objects having an axial length much smaller than the excitation wavelength because it avoids the large background from the solvent.

On the application side, CARS microscopy has been used for mapping the distribution, orientation, and diffusion of specific molecules in dynamic samples, for imaging lipids, proteins, and chromosomes in unstained live cells, and for monitoring cellular processes. CARS is a very promising technique to image small molecules such as lipids, hormones, and drug molecules, for which fluorescence labeling is prone to alter their function in cells and tissues. As for SHG, CARS microscopy is often combined with TPEF in order to obtain simultaneously the complementary contrasts.

Conclusion

Since its introduction more than a decade ago, two-photon fluorescence microscopy has quickly become a standard tool in biophotonic with applications ranging from the study of single molecules to thick tissue imaging. TPEF has opened the way to new coherent nonlinear imaging techniques such as SHG,

THG, or CARS which all shared a high spatial resolution. Based on different contrasts these different approaches are often combined for a more complete diagnosis. With developments of new low cost, compact, and reliable lasers with tuning wavelength covering the spectra of a wide range of endogenous or extrinsic markers, nonlinear imaging will continue its successful implementation outside physics labs. Development of endoscopy systems in which ultrafast pulse duration is preserved, will open a new range of *in vivo* studies. Nonlinear imaging still has more to offer and will definitely be a powerful tool for biomedical applications.

Phase Contrast Microscopy

C J R Sheppard, National University of Singapore, Singapore

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Many biological specimens behave as phase objects, that is, they alter the phase of the light transmitted through them, rather than its intensity. Similarly, reflection from a surface with height variations alters the phase of the reflected light. Observation of phase objects requires special imaging techniques. These include defocusing, dark field, Zernike phase contrast, Schlieren imaging, Hoffmann modulation contrast, differential phase contrast, interference microscopy, shearing interferometry, Nomarski differential interference microscopy, and digital phase retrieval. The imaging performance of these different methods are most easily appreciated and compared by consideration of the transfer function approach. In particular, we can consider weakly scattering objects and slowly varying phase objects as special cases.

When a thin unstained biological specimen is illuminated, in general the transmitted light suffers changes in amplitude, phase, and polarization. The change in polarization is related to the birefringence of the sample, which is neglected in the following. Thus the object (complex) amplitude transmittance can be written:

$$t(x, y) = a(x, y)\mathrm{e}^{\mathrm{i}\phi(x,y)} \qquad [1]$$

where $a(x, y)$ is real and represents the modulus (also called amplitude) of the light wave on exiting from the sample, and $\phi(x, y)$, also real, represents the phase. In a perfect microscope, we observe the

intensity of the transmitted light, so the image is given by

$$I(x, y) = |a(x, y)e^{i\phi(x,y)}|^2 = a^2(x, y) \quad [2]$$

Thus the phase information is invisible in the image. A perfect microscope does not image phase variations in the object, but results in an image that depends on the amplitude of the transmittance, called amplitude contrast. Usually the change in modulus is also small, so that the image will exhibit weak contrast, which may not be discernable. In order to render the phase variations visible it is necessary to modify the microscope in one of a number of different ways.

This conclusion is also relevant in incident light microscopy of surface structures. Then phase changes result from variations in surface height, and can be made visible by phase contrast microscopy. Quantitative measurement of the phase allows quantitative measurement of the surface profile. But care must be taken to avoid errors caused by phase change on reflection from a conducting material, or from effects of the numerical aperture of the optical system. In transmission microscopy quantitative phase measurement can be useful too, for example giving the concentration of a solute.

Some of these phase contrast methods are easily understood using the simple imaging model described above. Others are more easily appreciated by considering imaging in terms of Fourier optics, equivalent to Abbe's theory of microscope imaging. We introduce the angular spectrum of the object amplitude transmittance:

$$T(m, n) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} t(x, y)\exp[-i2\pi(mx + ny)]dx\ dy \quad [3]$$

where m, n are spatial frequencies in the x, y directions. We can write for the object amplitude transmittance:

$$t(x, y) = e^{b(x,y)} \quad [4]$$

where $b(x, y)$ is in general complex. For a weak object we have

$$t(x, y) \approx 1 + b(x, y) \quad [5]$$

and the spectrum is

$$T(m, n) = \delta(m)\delta(n) + B(m, n) \quad [6]$$

where δ is a Dirac delta function and $|B| \ll 1$. The problem with imaging of phase arises because a change in the imaginary part of b produces only a small change in the modulus of t.

For a coherent imaging system, with coherent transfer function $c(m, n)$, the image intensity is

$$I(x, y) = \left|\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} c(m, n)T(m, n) \times \exp\left[\frac{i2\pi}{M}(mx + ny)\right]dm\ dn\right|^2 \quad [7]$$

where M is the magnification. The coherent transfer function $c(m, n)$, is equal to the scaled pupil function $P(\lambda fm, \lambda fn)$, where f is the focal length of the objective. Substituting eqn [6] into eqn [7] and dropping terms of second order we obtain:

$$I(x, y) = |c(0, 0)|^2 + 2\Re\left\{c^*(0, 0)\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \times c(m, n)B(m, n)\exp\left[\frac{i2\pi}{M}(mx + ny)\right]dm\ dn\right\} \quad [8]$$

Normalizing the transfer function to unity at the origin:

$$I(x, y) = 1 + 2\Re\left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} c(m, n)B(m, n) \times \exp\left[\frac{i2\pi}{M}(mx + ny)\right]dm\ dn\right\} \quad [9]$$

For an axially symmetric aberration-free system, the coherent transfer function is real and even, so that a pure phase object is not imaged (only the Hermitian component of B is imaged). Many phase contrast methods in principle rely on appropriate modification of the coherent transfer function, either by making it complex or asymmetric.

However, this theory is an approximation as microscope systems are in practice partially coherent. For a partially coherent system the image intensity is

$$I(x,y)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} C(m,n;p,q)T(m,n) \times T^*(p,q)\exp\left\{\frac{i2\pi}{M}[(m-p)x+(n-q)y]\right\}dm\,dn \quad [10]$$

where $C(m,n;p,q)$ is the partially coherent transfer function, sometimes called the transmission cross-coefficient, which can be calculated as an integral over the objective and condenser pupils. The partially coherent transfer function is nonzero over a finite region of $m,n;p,q$ space, thus limiting the resolution of the system. Then eqn [8] for a weak object

becomes, normalizing so that $C(0,0;0,0)=1$:

$$I(x,y)=1+2\Re\left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}C(m,n;0,0)B(m,n)\times\exp\left[\frac{\mathrm{i}2\pi}{M}(mx+ny)\right]\mathrm{d}m\,\mathrm{d}n\right\} \quad [11]$$

where $C(m,n;0,0)$ is called the weak object transfer function.

For the image of a general object that is not necessarily weak, eqn [10] is often difficult to interpret. We can gain much insight into the imaging process by considering another special form of object, this time a slowly varying object:

$$t(x,y)=a(x,y)\exp\left[\mathrm{i}\left(x\frac{\partial\phi}{\partial x}+y\frac{\partial\phi}{\partial y}\right)\right] \quad [12]$$

where a and ϕ are assumed slowly varying. Thus, the object spectrum, assumed now as slowly spatially varying, is

$$T(m,n)\approx a\delta\left(m-\frac{1}{2\pi}\frac{\partial\phi}{\partial x}\right)\delta\left(n-\frac{1}{2\pi}\frac{\partial\phi}{\partial y}\right) \quad [13]$$

Substituting in eqn [10], we then find:

$$I(x,y)=a^2(x,y)C(m,n;m,n)$$
$$m=\frac{1}{2\pi}\frac{\partial\phi}{\partial x},\ n=\frac{1}{2\pi}\frac{\partial\phi}{\partial y} \quad [14]$$

in which C is called the phase gradient transfer function, and is real. For an ordinary bright field system, C is an even function. Thus a phase gradient results in a change in image intensity, but for an axially symmetric system the sign of the change is independent of the sign of the phase change.

Defocused Imaging

Historically, the oldest method of phase contrast is simply to defocus the object. The transfer function is then complex, and phase detail is imaged. If the system is aberration-free, the contrast of the phase information reverses on the opposite side of focus. The strength of the contrast increases with defocus, until eventually artifacts are introduced when the imaginary part of the transfer function becomes negative. If the relative condenser aperture is too large, contrast is reduced.

Assume a pure weak phase object:

$$t(x,y)=1+\mathrm{i}d\cos(2\pi\nu x) \quad [15]$$

so that

$$T(m,n)=\left[\delta(m)+\mathrm{i}\frac{d}{2}\delta(m-\nu)+\mathrm{i}\frac{d}{2}\delta(m+\nu)\right]\delta(n) \quad [16]$$

Then:

$$I(x,y)=1-dC_{\mathrm{i}}(\nu,0;0,0)\cos\left(\frac{2\pi\nu x}{M}\right) \quad [17]$$

where C_{i} is the imaginary part of C. Thus the phase information is imaged by the imaginary part of the weak object transfer function.

Dark Field Microscopy

Dark field microscopy can be used to visualize weak amplitude and phase information. The constant background in eqn [5] is eliminated, so we obtain an image of b. Note that eqns [8] and [11] are no longer valid because we cannot neglect the second-order term. For a coherent system, the background can be eliminated by use of a central stop to intercept the nondiffracted light. For a partially coherent microscope, an annular condenser aperture (larger in diameter than the objective pupil) is used (Figure 1). In both cases, in practice a range of low spatial frequencies are eliminated, resulting in the appearance of halo artifacts.

For the pure weak phase object of eqn [12], the image in a coherent microscope is

$$I(x,y)=\frac{1}{2}d^2c^2(\nu,0)\left[1+\cos\left(\frac{4\pi\nu x}{M}\right)\right] \quad [18]$$

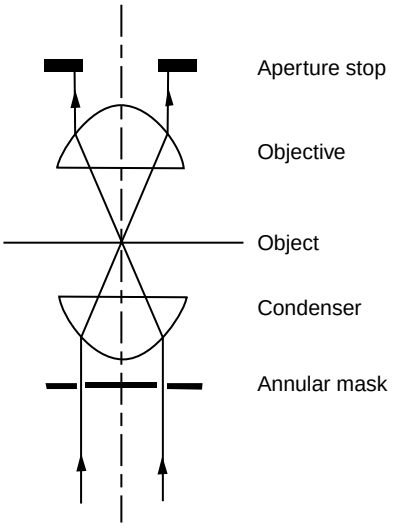

Figure 1 Schematic diagram of dark field microscopy.

so that the spatial frequency is double that in the original object. For the partially coherent microscope, we have

$$I(x,y) = \frac{1}{2}d^2\Big[\, C(\nu,\nu;0,0) + C(\nu,-\nu;0,0)\cos\left(\frac{4\pi\nu x}{M}\right)\Big] \qquad [19]$$

in which the two terms represent difference and sum frequency components. However, it can be shown that for the annular dark field system the transfer function for sum frequencies is zero, so the image intensity is a constant. The system images only difference frequencies of pairs of spatial frequencies, and not sum frequencies.

For a slowly varying phase object, zero intensity results from a region of constant phase, but the intensity rises quickly for small values of phase gradient, thus giving strong contrast. For larger phase gradients, the intensity falls off slowly.

Zernike Phase Contrast

The Zernike phase contrast method is similar to dark field except that the direct (nondiffracted) light has its relative phase changed by 90°, rather being eliminated. In practice this is achieved using an annular condenser aperture and an objective with a phase ring (Figure 2). The phase change can be ±90°, giving positive or negative phase contrast. The phase ring is usually only partially transmitting, which has the effect of enhancing the sensitivity. From eqns [8] or [11], imaging of a weak object is linear in phase. The halo artifact is present, as in dark field microscopy. Weak amplitude information is imaged as in dark field microscopy.

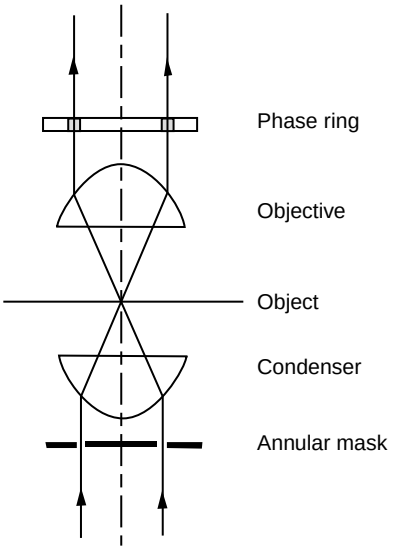

Figure 2 Schematic diagram of Zernike phase contrast microscopy.

For the weak phase object eqn [12], we then have

$$I(x,y) = 1 \pm \frac{2d}{g}C(\nu,0;0,0)\cos\left(\frac{2\pi\nu x}{M}\right) \qquad [20]$$

for positive or negative phase contrast, respectively, where g is the amplitude transmittance of the phase ring. The response of the weak object transfer function is improved as a result of the annular condenser aperture.

Schlieren Imaging, Hoffman Modulation Contrast, and Differential Phase Contrast (DPC)

In Schlieren imaging with coherent illumination, a half plane mask (a Foucault knife edge) is inserted to eliminate say the negative spatial frequencies in x. Taking now $c(0,0) = 1/2$, eqn [8] becomes, after normalization:

$$I(x,y) = 1 + 4\Re\left\{\int_{-\infty}^{\infty}\int_{0}^{\infty} c(m,n)B(m,n) \times \exp\left[\frac{\mathrm{i}2\pi}{M}(mx+ny)\right]\mathrm{d}m\,\mathrm{d}n\right\} \qquad [21]$$

For the weak phase object eqn [15], we then have:

$$I(x,y) = 1 - dc(\nu)\sin\left(\frac{2\pi\nu x}{M}\right) \qquad [22]$$

The image exhibits a variation in phase quadrature to the original phase variation, that is, it is related to the x-derivative of the phase. The effect occurs because the coherent transfer function contains an odd (but real) part.

For a partially coherent microscope a similar effect can be achieved simply by offsetting the illumination system, but now the transfer function is no longer single-sided. It can be resolved into odd and even parts that result in differential phase contrast and amplitude contrast, respectively. The amplitude contrast component merely contributes to the background for a phase-only object, and can be removed simply by contrast enhancement of a digital image. The offset can be introduced in practice by inserting a half-plane mask into the condenser aperture stop. Imaging of a slowly varying object can be explained by eqn [14], in which the transfer function is not symmetrical. The image shows a pseudo-three-dimensional bas relief effect. A commercial implementation of an asymmetric transfer function is Hoffman modulation contrast, which uses offset

illumination together with an amplitude mask in the objective pupil (Figure 3). Advantages of Hoffman contrast are that it uses standard bright-field objectives and avoids problems from birefringent specimens.

A similar method can be used in scanning laser microscopy. In a scanning microscope the effect of the illumination and detection systems are interchanged. Thus DPC can be achieved in a scanning laser microscope by offsetting the detector. In practice this is conveniently done by using a split detector (Figure 4), a detector divided into two semicircular elements. If the signal of one half is subtracted from that of the other, the amplitude contrast component cancels out, so that pure differential phase contrast results. For weak phase gradients, the intensity varies linearly with phase gradient, again showing the bas relief effect. It is thus bi-directional, and the difference signal can become negative. A constant value is, therefore, usually added to it before display. The sum of the two detector elements results in a conventional bright-field image. From eqn [14], both difference and sum signals are proportional to $a^2(x, y)$, so that if the ratio of these two signals is extracted, an image of the phase gradient in the x direction results. The response to either weak phase gradients or fine detail can be enhanced by modifications using annular split detectors. Use of a quadrant detector allows the phase gradients in the x and y directions to be imaged. DPC microscopy has been demonstrated to be sensitive enough to observe monomolecular films and atomic surface steps.

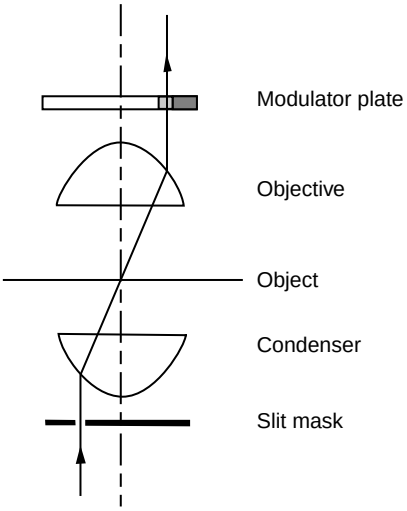

Figure 3 Schematic diagram of Hoffmann modulation contrast microscopy.

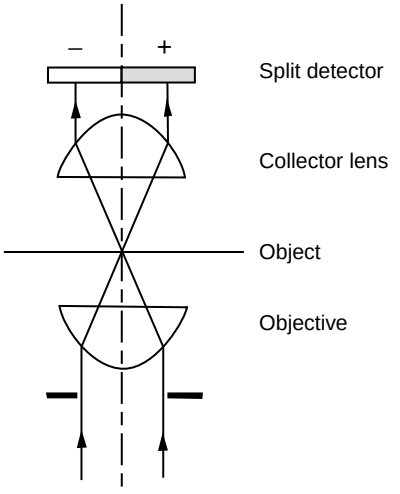

Figure 4 Schematic diagram of differential phase contrast (DPC) microscopy.

Interference Microscopy

Interference microscopy allows quantitative measurement of the object phase by interference of the object beam with a reference beam. In the transmission geometry, a Mach–Zehnder interferometer is used, which is effectively two parallel microscopes, each with matched condenser and objective lenses. In the reflection geometry we can use a Michelson, a Mirau, or a Linnik interferometer. The Michelson interferometer has an inclined beamsplitter and the reference mirror situated between the objective and object, and hence can be used only with low numerical aperture objectives. The Linnik interferometer has matched objectives in the object and reference beam paths. There is no limit to the numerical aperture that can be used, but it is not a common-path interferometer and is hence sensitive to vibrations and air currents. Probably the most practicable system for interference microscopy in the reflection geometry is based on the Mirau interferometer that uses a beamsplitter with its normal parallel to the optic axis. Until recently, interference microscopes used a small condenser aperture giving nearly coherent illumination. The image consists of three components: an object beam term (noninterference image) a reference beam term, and the interference term. The phase (and amplitude) of the object beam can be extracted using phase stepping or heterodyning techniques. The measured phase is wrapped, and requires unwrapping to obtain the absolute phase.

If the condenser aperture is opened up, the behavior is modified. The interference term is

given by

$$I_{\text{int}}(x,y) = 2\Re\left\{ r^* \int\int c_{\text{int}}(m,n)T(m,n) \times \exp\left[\frac{\text{i}2\pi(mx+ny)}{M}\right] \text{d}m\,\text{d}n \right\} \quad [23]$$

where $c_{\text{int}}(m,n)$ is the coherent transfer function for interference imaging, given by a convolution integral of the object path objective pupil with the product of the reference pupil and the source. The first thing to note is that for a high numerical aperture, the spacing of the interference fringes is increased by 20–40%, and depends on defocus, tilt, and central obscuration. Thus accurate measurement of phase requires careful calibration. The objective pupil exhibits a phase variation when defocused that reduces the modulus of the coherent transfer function, resulting in the fringes being modulated by an envelope the width of which becomes smaller as the aperture becomes larger. The envelope is similar to that of the optical sectioning effect in confocal microscopy. This envelope allows the zero-order fringe to be identified, although simulations have suggested that fringe hopping could occur at phase jumps as a result of diffraction effects.

Multiple Beam Interferometry

The topography of a surface can be investigated by using a Fizeau interferometer formed by bringing a coated optical flat near to the surface. Then if the surface and flat have high reflectivity, multiple beam interference occurs and the width of the bright fringes can be much reduced. The system can be used with a tilted flat, to give fringes that are substantially straight, or with an almost parallel flat, so that the entire field of view is occupied by a single fringe. In the latter case, the sensitivity can be in the subnanometer range. Multiple beam interference also enhances the contrast of weak amplitude information.

Shearing Interferometry

In conventional interferometry, the object beam is arranged to interfere with a constant reference beam. In shearing interferometry, on the other hand, it interferes with a shifted version of itself.

Lateral Shearing Interferometry

An approach that is suitable for quantitative optical path measurements is to use an interferometer that shears the microscope image. The Interphako system uses a Mach–Zehnder interferometer that can measure optical path differences as low as ~3 nm in either the reflection or transmission geometry. The interferometer allows the shear distance to be varied.

Differential Interference Microscopy (DIC)

The most common form of shearing interferometry is differential interference microscopy, usually associated with the name of Nomarski. DIC microscopy can be performed in either the transmission or the reflection geometry. A plane polarized illumination beam is split into two orthogonally polarized beams traveling at slightly differing angles by a Wollaston prism in the front focal plane of the condenser lens (Figure 5). The beams are thus sheared laterally in the object plane. The light from the sample travels through the objective and a second Wollaston prism, which recombines the two beams into one. In the reflection geometry, a single lens and Wollaston prism are used. An analyzer set at 45° allows the two beams to interfere. The shear is arranged to be smaller than the width of the point spread function. Different prisms are supplied for use with different magnification objectives. The system results in

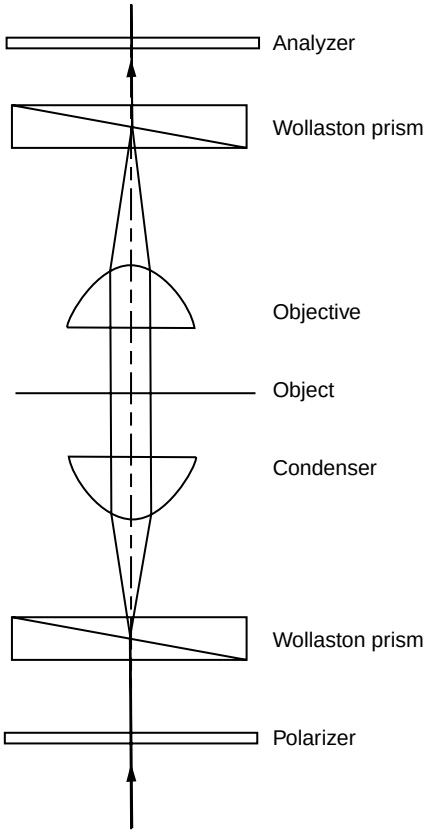

Figure 5 Nomarski differential interference contrast (DIC) microscopy.

differential phase contrast, but there are differences as compared with the DPC microscope described above.

There are two different implementations of DIC in use. In one implementation, the illumination polarizer and analyzer are crossed. The relative phase difference between the two beams (the bias retardation) is adjusted by moving the Wollaston prism laterally. It is claimed that rotation of the analyzer can be useful when observing mixed phase/amplitude objects. In the second arrangement (the Sénarmont compensator) the position of the Wollaston prism is fixed, and the analyzer rotated to change the relative phase.

A recent variation of DIC uses circularly polarized illumination. The Wollaston prism still produces two plane polarized components, but with an additional phase difference of $\pi/2$. The advantage of using circular polarization is that the prism can then be rotated to change the direction of shear.

If the shear is 2Δ, and the phase difference is $\pi - 2\phi_0$ (i.e., if $\phi_0 = 0$ then the two beams are in anti-phase), then the effective object spectrum is:

$$T_{\text{eff}}(m,n) = -2\sin(2\pi m\Delta - \phi_0)T(m,n) \qquad [24]$$

Thus the effective transfer function can be written:

$$\begin{aligned} C_{\text{eff}}(m,n;p,q) &= 4\sin(2\pi m\Delta - \phi_0)\sin(2\pi p\Delta - \phi_0) \\ &\quad \times C(m,n;p,q) \\ &= 2\{\cos[2\pi(m-p)\Delta] \\ &\quad - \cos 2\phi_0 \cos[2\pi(m+p)\Delta] \\ &\quad - \sin 2\phi_0 \sin[2\pi(m+p)\Delta]\} \\ &\quad \times C(m,n;p,q) \end{aligned} \qquad [25]$$

It is the final term of the three in braces that, because it is an odd function, results in differential phase contrast. We can now examine imaging of special forms of object. For a weak object, putting $p = 0$ as in eqn [11]:

$$\begin{aligned} C_{\text{eff}}(m,n;0,0) &= 2\{(1 - \cos 2\phi_0)\cos[2\pi m\Delta] \\ &\quad - \sin 2\phi_0 \sin[2\pi m\Delta]\}C(m,n;0,0) \end{aligned} \qquad [26]$$

The first term in braces corresponds to an amplitude contrast background component because it is real and even. The second term results in DPC, because it is real and odd. For zero bias retardation, dark-field imaging results. As the bias retardation is increased from zero, the strength of both the amplitude contrast and the DPC components increase, but that of the DPC component increases more rapidly. For visual observation we require good contrast, and hence we choose a small value of bias retardation, just large enough so that the background is large enough to avoid artifacts in the DPC image. In digital microscopy, contrast is not so important as it can be enhanced digitally, and hence we can increase ϕ_0 to a value of $\pi/4$, which maximizes the strength of the DPC component. Further increase in bias retardation decreases the DPC signal, until for $\pi/2$ pure amplitude contrast results. The actual form of the weak object transfer function depends on the magnitude of the shear. The condition $m_0\Delta = 1/4$, where m_0 is the cut-off in spatial frequency, gives optimum performance for the imaging of weak objects.

The phase gradient transfer function is:

$$C_{\text{eff}}(m,n;m,n) = 4\sin^2(2\pi m\Delta - \phi_0)C(m,n;m,n) \qquad [27]$$

For the bright-field microscope the phase gradient transfer function falls off symmetrically from its value at zero phase gradient. The effect of the pre-multiplying factor in eqn [27] is to increase the fall-off for positive phase gradients and reduce it for negative ones. A bas-relief effect occurs, with highlighting for negative phase gradients for some values of the parameters. Increasing the value of the shear increases the highlighting effect, but, unlike in DPC, the behavior is not anti-symmetric.

Because interference is dependent on the wavelength of the light, useful and beautiful effects can be seen with DIC microscopy using white light. Usually it is regarded as a qualitative, rather than a quantitative, imaging method. However, as from eqn [14], the intensity can be written:

$$I(x,y) = 2a^2(x,y)[1 - \cos(2\pi m\Delta - \phi_0)]C(m,n;m,n) \qquad [28]$$

By recording images at different bias retardations, conventional phase stepping methods can be used to extract the phase gradient $2\pi m = \partial\phi/\partial x$.

Axial Shearing Interferometry

Instead of shearing in the transverse direction, a shear in the axial direction can be used. In the reflection geometry, the complex amplitude from the point of observation is compared with the average over a defocused spot. This method has proved to be extremely sensitive, and can detect height changes smaller than 0.1 nm.

Phase Retrieval

Digital Phase Retrieval

The phase of a single two-dimensional (2D) measurement of intensity can be retrieved by an iterative

procedure, if constraints such as nonnegativity and band-limitedness can be assumed. If the modulus of both an object and its Fourier transform are known, then the phases can also be recovered. In this case, the two 2D real data sets have information content sufficient to reconstruct the 2D complex object. This approach has been extended to the case of measurement of two defocused images, using the method of phase diversity.

Imaging Using the Transport of Intensity Equation

The transport equation of intensity can be used to recover the phase of a partially coherent wavefield directly (i.e., noniteratively) from two 2D intensity measurements. If the wavefield is represented in terms of its intensity I and phase ϕ in a plane, the transport equation can be written in the paraxial approximation and in the absence of phase singularities:

$$-k\frac{\partial I}{\partial z} = \nabla_T \cdot [I\nabla_T \phi] \qquad [29]$$

where ∇_T is a 2D operator acting in the plane. This expression can be inverted to give ϕ quantitatively, if I and $\partial I/\partial z$ are known. However, it gives the phase of the image field, rather than the phase of the object, so that obtaining quantitative values for a strong object may be difficult. The transport of intensity method is valid with partially coherent illumination: if the relative condenser aperture is too great then contrast becomes weak. Further, an effect similar to the variation in fringe spacing with aperture in interference microscopy is introduced because oblique illuminating rays traverse the sample at an angle to the axis. In practice, a series of three images are usually taken at different focus positions. Then, from the quantitative phase data, various different contrast mechanisms such as DIC, Zernike phase contrast, and so on, can be simulated.

Surface Profiling Methods: Triangulation and Coherence Domain Methods

Although strictly they are not phase imaging methods, other surface profiling methods can be used to measure optical path. These could also be adapted to measure optical path in transmission. It is important also to be aware of these methods, as they could affect measurements made using other phase contrast techniques.

Apart from the phase measurement techniques described above, surface profiling methods fall into one of two categories: triangulation and coherence domain methods. An example of a technique that relies on triangulation is confocal microscopy. Confocal microscopy exhibits an optical sectioning effect similar to that described for interference microscopy. The effect is stronger for higher numerical aperture. As a reflector is scanned through focus the intensity goes through a maximum. By locating the position of the maximum, the local surface height can be obtained. In a similar way, in a confocal transmission system, introduction of an object with some optical thickness has the effect of altering the axial position of the confocal pinhole, with a resultant drop in intensity. This effect can be used to image the optical thickness of the sample.

Coherence domain methods rely on the finite coherence length of the light. In an interferometer, this results in an envelope that multiplies that arising from the nonzero relative condenser aperture. Measurement of the peak of the envelope allows local surface height to be measured. Unlike the confocal approach, the width of this coherence envelope is independent of the numerical aperture of the system.

In reflection, both the confocal and the coherence domain methods have the advantage over direct phase imaging techniques that they allow measurement of surface height changes without errors caused by the phase change on reflection from a conducting medium.

Acousto-optics deals with the interaction of light waves with sound waves and has given rise to a large number of devices related to various laser systems for display, information handling, optical signal processing, and numerous other applications requiring the spatial or temporal modulation of coherent light. The basic principles and phenomena controlling these interactions were largely understood by the mid-1930s, but had little practical significance because very high acoustic power levels were required to attain good optical efficiency and there were few good sources of well-collimated monochromatic light. During the period from 1960 to the present, several key technologies were developing rapidly, at the same time that many applications of the laser were being suggested which require high-speed, high-resolution scanning methods. These new technologies gave rise to high-efficiency, wideband acoustic transducers capable of operation to several gigahertz, high-power wideband solid-state amplifiers to drive such transducers, and the development of a number of new, synthetic acousto-optic crystals with low-drive-power requirements and low acoustic losses at high frequencies. This combination of properties makes acousto-optics feasible for many systems, and for several is the method of choice to satisfy demanding requirements. This chapter will summarize the basic features of acousto-optic interactions and the operating principles of the most common acousto-optic devices.

The Photo-Elastic Effect

The change induced in the refractive index of a transparent material by the pressure change produced by an acoustic disturbance is the underlying mechanism of all acousto-optic interactions. An acoustic wave produces periodic regions of compression and rarefaction in the material, which modulates the density. The Lorentz–Lorenz relation relates the refractive index to the density, for the simplest case of an ideal gas

$$\frac{(n^2-1)}{(n^2+2)} \propto \rho \qquad [1]$$

where n is the refractive index and ρ is the density. This relation is followed to a good approximation for most simple solid materials as well. The elastooptic coefficient is

$$\frac{\rho\, \mathrm{d}n}{\mathrm{d}\rho} = \frac{(n^2-1)/(n^2+2)}{6n} = p \qquad [2]$$

The fundamental quantity given by eqn [2], also known as the photo-elastic constant p, is related to the pressure applied by

$$p = \frac{1}{\beta}\left(\frac{\mathrm{d}n}{\mathrm{d}p}\right) \qquad [3]$$

where P is the applied pressure and β is the compressibility of the material. The photo-elastic

constant of an ideal material with refractive index of 1.5 is 0.59. The photo-elastic constants of a wide variety of materials lie in the range from about 0.1 to 0.6.

The relation in eqn [3] follows from the usual definition of the photo-elastic constant:

$$\Delta(1/\varepsilon) = \Delta(1/n^2) = pe \qquad [4]$$

where ε is the dielectric constant, $\varepsilon = n^2$, and e is the acoustic strain amplitude. The induced change in refractive index, Δn, is

$$\Delta n = -n^3 pe \qquad [5]$$

Strain amplitudes typically lie in the range of 10^{-8} to 10^{-5}, with Δn in the range of about 10^{-8} to 10^{-5} (for $n = 1.5$). Devices based upon such a small change in refractive index are capable of generating large effects because these devices are configured in a way that can produce large phase changes at optical wavelengths.

The more complete relation defining the photo-elastic interaction is more complex than the simple scalar eqn [5] in which the photoelastic constant is independent of the directional properties of the material. In fact, even for an isotropic material such as glass, longitudinal acoustic waves and transverse (shear) acoustic waves cause the photoelastic interaction to assume different parameters. A tensor relation between the dielectric properties, the elastic strain, and the photo-elastic coefficient describes the interaction, particularly for anisotropic materials. The tensor equation is

$$\Delta(1/n^2) = \sum_{kl} p_{ijkl}\, e_{kl} = \Delta(1/\varepsilon)_{ij} \qquad [6]$$

where $(1/\varepsilon)_{ij}$ is a component of the optical index ellipsoid, e_{kl} are the Cartesian strain components, and p_{ijkl} are the components of the photo-elastic tensor. The crystal symmetry of the photoelastic material places limits on the possible configurations of interaction geometry.

Diffraction by Acoustic Waves

For typical acousto-optic devices the acoustic wave acts as a diffraction grating, made up of periodic changes in optical phase, moving at sound velocity. These features determine the properties of acousto-optic diffraction. Using a quantum-based model, the light and sound may be thought of as particles, photons and phonons, undergoing collisions in which energy and momentum are conserved. Either of these descriptions may be used to obtain all the important diffraction effects, but some are more easily understood on the basis of one or the other. A description of both is given here. Consider Figure 1 in which the light wave, of frequency ω and wavelength λ, is incident into the material with an acoustic wave of frequency f and wavelength Λ. If the refractive index of the medium is $n + \Delta n$ in the presence of the acoustic wave, the phase of the optical wave will be changed by an amount

$$\Delta\phi = 2\pi(L/\lambda)\Delta n \qquad [7]$$

where L is the length of the interaction region. Some typical values of $\Delta\phi$ can be obtained by assuming $L = 2.5$ cm and $\lambda = 0.5$ μm, with Δn reaching a peak value of 10^{-5}. This yields a phase change of π rad, which is, of course, quite large. It is large because L/λ, the number of optical wavelengths, is 50 000, so that a very small Δn can still produce a sizable $\Delta\phi$. If the electric field incident on the delay line is represented by

$$E = E_0\, e^{i\omega t} \qquad [8]$$

then the field of the phase-modulated emerging light will be

$$E = E_0\, e^{(i\omega t + \Delta\phi)} = e^{i\omega t}\, e^{2\pi i(L/\lambda)\sin(ft)} \qquad [9]$$

where f is the acoustic frequency.

A detailed derivation of the resulting temporal and spatial distribution of the light field is mathematically complex, but, analogy with radio-wave modulation can be used to arrive at the resultant fields. The spectrum of a phase-modulated carrier of frequency ω consists of components separated by multiples of the modulation frequency f, as shown in Figure 2. Sidebands are produced about the carrier frequency, such that the frequency of the mth sideband is

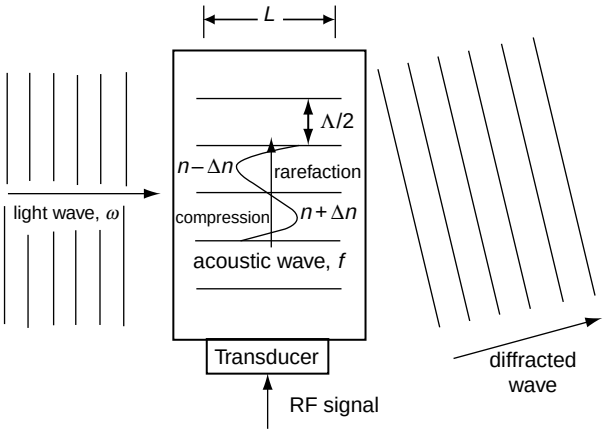

Figure 1 Interaction of light waves with acoustic waves.

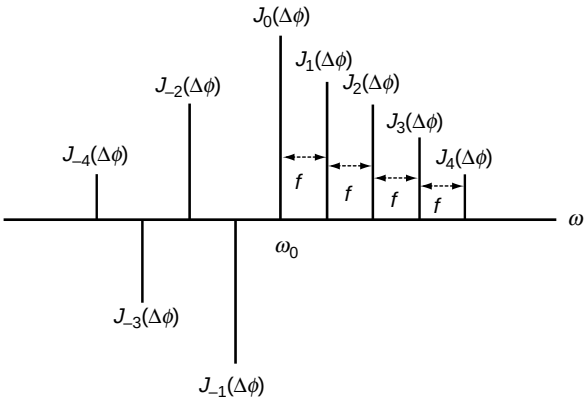

Figure 2 Spectrum of a phase-modulated wave of carrier frequency ω_0, and modulation index $\Delta\phi$.

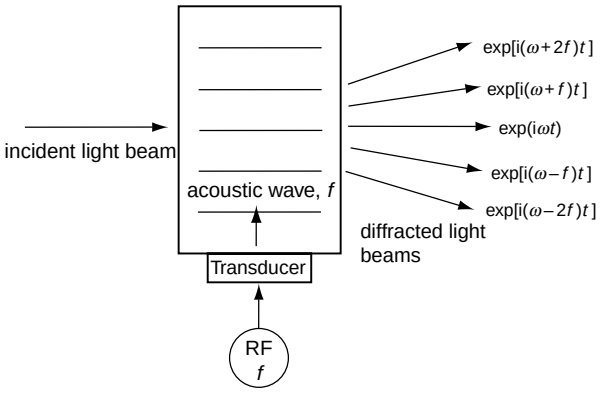

Figure 3 Diffraction of light in the Raman–Nath limit.

$\omega + mf$, where m may be positive or negative. The amplitude of each of the sidebands is proportional to the Bessel function of order equal to the sideband number, and whose argument is the modulation index $\Delta\phi$. The odd-numbered negative orders are 180° out of phase with the even-numbered ones, a feature that may be useful for certain signal processing applications. The light emerging from the delay line is composed of a number of light waves whose frequencies have been shifted by mf from the frequency ω of the incident light. The relative amplitudes will be determined by the peak change in the refractive index. The two extremes of the diffraction process are simplified in the 'thin grating' and the 'thick grating' models. The ratio of the interaction length, L, to the acoustic wavelength, Λ, will determine the character of the diffraction process. The plane wave approximation in which the acoustic energy propagates as a plane wave is valid when this ratio is very large. However, when this ratio is small, the acoustic propagation can be described in terms of a sum of plane waves, the angular spectrum of which increases as the ratio decreases. In this phenomenological model the partial wave which is propagating at an angle λ/Λ to the forward direction may diffract the light second time into an angle $2\theta = 2\lambda/\Lambda$, and the frequency of this light will once again be up-shifted, for a total frequency shift of $2f$. If the spectrum of acoustic waves contains sufficient power of still higher orders, then this rediffraction process can be repeated, so that light will be multiply diffracted m times into higher-order angles, $m\theta = m\lambda/\Lambda$ each with a frequency shift mf. A similar argument holds for the negative orders, so that a complete set of diffracted light beams will appear as shown in Figure 3, where the deflection angle corresponding to the mth order is given by $\sin\theta_m = m\lambda/\Lambda$ and the frequency of the light deflected into the mth order is $\omega_m = \omega + mf$. The intensity of the carrier wave, or zero order, will be zero when the modulation index $\Delta\phi$ is equal to 2.4. The first order will be a maximum for $\Delta\phi = 1.8$, corresponding to the maximum of the first-order Bessel function B_1, and decreasing for larger modulation indices. These phenomena were described by Debye and Sears and so are often referred to as Debye–Sears diffraction. An extensive theoretical analysis of the effect was given by Raman and Nath and is alternatively referred to as Raman–Nath diffraction. As the interaction length is increased the Raman–Nath diffraction gradually weakens. The weakening begins around an interaction length $L \sim \Lambda^2/4\lambda$. This value of L is expressed in the Q parameter

$$Q = 4L\lambda/\Lambda^2 \qquad [10]$$

which is known as the Raman–Nath parameter. A different regime of diffraction takes effect for values of the interaction length $Q \gg 1$.

The phenomena in this regime can be more easily understood in terms of the quantum description of the light and sound waves as collisions between photons and phonons. In this model, the dynamics of the collisions of the light and sound are governed by the laws of conservation of energy and momentum. The momentum vectors magnitudes of the light and sound, $\mathbf{k}$ and $\mathbf{K}$, are given by the well-known expressions

$$|\mathbf{k}| = 2\pi n/\lambda \text{ and } |\mathbf{K}| = 2\pi/\Lambda \qquad [11]$$

where the acoustic wavelength, Λ, is related to the acoustic velocity, V, by $\Lambda = V/f$.

Conservation of momentum is expressed by the vector relation

$$\mathbf{k}_\mathrm{i} + \mathbf{K} = \mathbf{k}_\mathrm{d} \qquad [12]$$

the diagram for which is shown in Figure 3, where $\mathbf{k}_i$, and $\mathbf{k}_d$ represent the momentum of the incident photon and the diffracted photon, respectively. In this notation

$$\mathbf{k}_i = 2\pi n_i/\lambda, \qquad [13a]$$

and

$$\mathbf{k}_d = 2\pi n_d/\lambda \qquad [13b]$$

If the material is anisotropic (birefringent), n_i and n_d may be different.

Conservation of energy requires that

$$h\omega_d = h\omega_i + hf \qquad [14]$$

in which h is Planck's constant. Since ω_i lies in the optical frequency range, $\sim 10^{13}$ Hz, and f lies in the RF or microwave range, 10^6–10^9 Hz, then $\omega_d \sim \omega_i$. This results, for isotropic materials, in the magnitudes of $\mathbf{k}_i$ and $\mathbf{k}_d$ being equal and resulting in the isosceles momentum triangle of Figure 4. The angles of incidence and diffraction (with respect to the planar acoustic wavefronts), called the Bragg angles, are equal for this case, and are

$$\theta_B = (1/2)\lambda/\Lambda \qquad [15]$$

A schematic diagram for this process is shown in Figure 5. The interaction will be large only if the light is well-collimated, and incident at this angle. Unlike the Debye–Sears regime, there is only a single diffracted beam. The energy of the phonon may either be added to that of the incident photon, increasing its frequency to $\omega_d = \omega_i + f$, or the reverse, resulting in $\omega_d = \omega_i - f$. The sense of the momentum vectors determines which of these occurs. The Debye–Sears

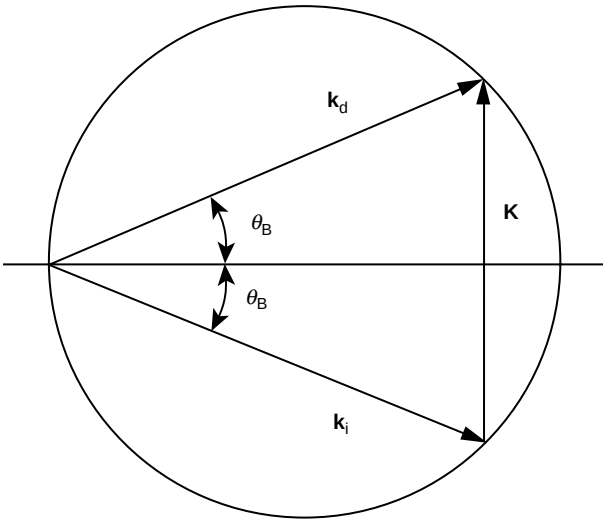

Figure 4 Momentum diagram for diffraction of light.

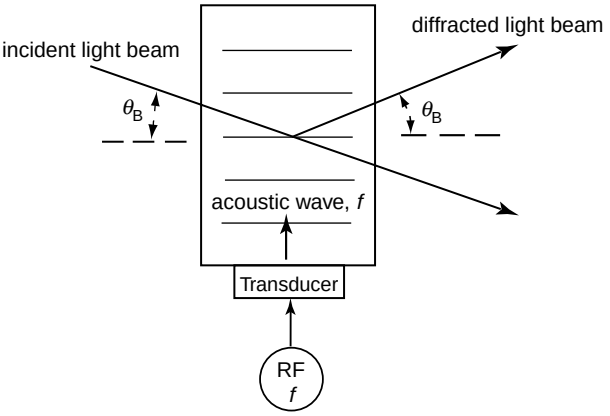

Figure 5 Acousto-optic diffraction cell.

effect and Bragg diffraction are not different phenomena, but are the limits of the same mechanism. The Raman–Nath parameter Q determines which is the appropriate limit for a given set of values λ, Λ, and L.

Anisotropic Bragg Diffraction

In optically anisotropic materials, acousto-optic Bragg diffraction can occur between an ordinary and extraordinary optical beam, and vice versa. This is generally referred to as birefringent diffraction, and it offers additional design capabilities compared to the isotropic case, such as enhancing the angular aperture, and extending the aperture–bandwidth product.

The theory of diffraction of light so far described has assumed that the optical medium is isotropic. A number of important acousto-optic devices make use of the properties of birefringent materials. It is different from diffraction in isotropic media in that the magnitude of the momentum vector of the light will in general be different for different light polarization directions. Thus, the vector diagram representing conservation of momentum will no longer be the simple isosceles triangle of Figure 4. The momentum vector for ordinary polarized light will, in general, be different from the momentum vector for light that is extraordinary polarized. To understand the effect of anisotropy on diffraction, it is necessary to mention another phenomenon which occurs when light interacts with shear acoustic waves, i.e., waves in which the displacement of matter is perpendicular to the direction of propagation of the acoustic wave. A shear acoustic wave may cause the direction of polarization of the diffracted light to be rotated by 90°. The underlying reason for this is that the shear

disturbance induces a birefringence which causes the plane of polarization to be rotated. The acousto-optic tunable filter (AOTF) is a particularly interesting birefringent device. It was first developed for the case of collinear optical and acoustic beams, and was used for wavelength selection in a dye laser.

Diffraction Efficiency

The acoustic power required to diffract light will be determined by the geometric parameters as well as by the properties of the medium. A simplified calculation leads to results that are useful. Referring to the spectrum of a phase-modulated wave shown in Figure 2, we can see that the ratio of the intensity in the first order to that in the zero order is

$$I_1/I_0 = \left[B_1(\Delta\phi)/B_0(\Delta\phi)\right]^2 \qquad [16]$$

By analogy this same result comes about for acousto-optically diffracted light. The acoustic power flow is given by

$$P_a = \frac{1}{2} cVe^2 \qquad [17]$$

where c is the elastic stiffness constant. The elastic stiffness constant is related to the bulk modulus β, the density ρ, and acoustic velocity v through the expression

$$c = \frac{1}{\beta} = \rho V^2 \qquad [18]$$

and the acoustic power density is

$$P_a = \frac{1}{2}\rho V^3 e^2 \qquad [19]$$

The optical phase modulation of the medium resulting from the change in refractive index, Δn, is

$$\Delta\phi = 2\pi(L/\lambda)\Delta n \qquad [20]$$

Using eqn [5] for Δn, the phase modulation is related to the acoustic power density by

$$\Delta\phi = -\pi(L/\lambda)\, n^3 p\, (2P_a/\rho V^3)^{1/2} \qquad [21]$$

The diffraction efficiency can now be calculated by using this value for the optical phase change in eqn [16]. The first- and second-order Bessel functions can be approximated for small modulation index by

$$\begin{aligned} &B_0(\Delta\phi) \sim \cos(\Delta\phi) \sim 1 - (\Delta\phi)^2, \quad \text{and} \\ &B_1(\Delta\phi) \sim \sin(\Delta\phi) \sim \Delta\phi \end{aligned} \qquad [22]$$

The small signal approximation to the diffraction efficiency is then

$$I_1/I_0 \sim (\Delta\phi)^2 = \left(\pi^2 L^2/2\lambda^2\right)\left(n^6 p^2/\rho V^3\right) P_a \qquad [23]$$

The expression $n^6 p^2/\rho V^3$ is known as the figure of merit of the material, and is designated as M_2; it is comprised entirely of intrinsic material properties.

Acousto-optic Materials

Acousto-optic device technology has matured to the point that performance is chiefly limited by material parameters, particularly the figure of merit and acoustic attenuation. Nature has arranged that materials with high figures of merit usually have high attenuation and vice versa. The widely used acousto-optic materials are fused quartz, tellurium dioxide, and lithium niobate. Development work on new infrared materials has been reported recently. A list of commonly used acousto-optic materials is given in Table 1. For materials with a low figure of merit, a higher drive power can be used to obtain the required efficiency.

Experience has indicated that the upper limit for very small devices (active area $\sim 0.1\ \text{mm}^2$) is a drive power density of 100–500 mW/mm^2, provided there is proper heat sinking to transfer the heat energy. For larger devices, sizes greater than $\sim 1\ \text{cm}^2$, the limit is closer to a few W/cm^2. At the high drive power levels, the acoustic attenuation may cause significant optical distortion.

AO Devices

Resolution, bandwidth, and speed are the important characteristics of acousto-optic scanners, shared by all types of scanning devices. Depending upon the application, only one, or all, of these characteristics may have to be optimized. Consider the acousto-optic scanner in Figure 6 with a collimated incident beam of width D, diffracted to an angle θ_B at its RF bandcenter, and whose bandwidth is Δf. If the diffracted beam is focused onto a plane by a lens, or lens combination, at the scanner, the diffraction spread of the optical beam will be

$$\Delta x = F\Delta\phi \sim F - \lambda/D \qquad [24]$$

[a]Longitudinal acoustic waves propagating along the [100] crystallographic direction.
[b]Shear acoustic waves propagating along the [001] crystallographic direction.
[c]Attenuation constant at 1 GHz; the frequency dependence of the attenuation for most crystals is quadratic.

where F is the focal length of the lens. The light intensity will be distributed in the focal plane with a sinc^2 distribution by aperture diffraction. The number of resolvable spots, N, will be the angular scan range divided by the angular diffraction spread,

$$N = \frac{\Delta\theta}{\Delta\phi} \qquad [25]$$

where $\Delta\theta$ is the range of the angular scan. Differentiating the Bragg angle formula yields

$$\Delta\theta = (\lambda/V \cos\theta_0)\Delta f \qquad [26]$$

and

$$N = \Delta f(D/V \cos\theta_0) = \Delta f \tau \qquad [27]$$

where θ_0 is the Bragg angle at band center, and τ is the time that it takes the acoustic wave to cross the optical aperture. The resulting expression is the time–bandwidth product of the acousto-optic scanner, a concept applied to a variety of electronic devices as a measure of information handling capacity. The time–bandwidth product of an acousto-optic Bragg cell is equivalent to the number of bits of information which may be instantaneously processed by the system. In order to maximize the number of resolution elements, it is desirable to have as large a bandwidth as possible (i.e., large frequency range) and also as large an aperture delay time as possible. There are two factors limiting the bandwidth of an acousto-optic device: the bandwidth of the transducer structure (discussed later), and acoustic absorption in the delay medium. The acoustic absorption increases with increasing frequency; for high-purity single crystals the increase generally goes with the square of the frequency. For glassy materials, on the other hand, the attenuation will increase more slowly with frequency, often approaching a linear function. The maximum frequency is generally taken as that for which the attenuation of the acoustic wave across the optical aperture is equal to

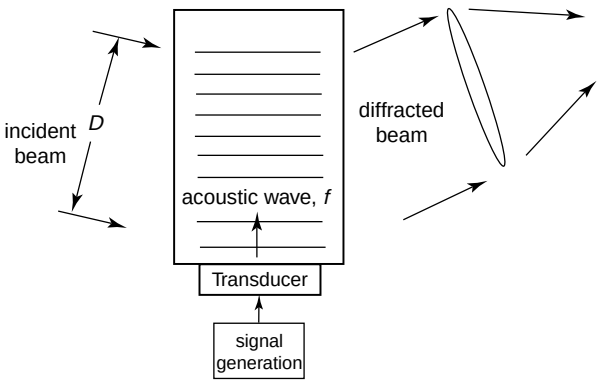

Figure 6 Acousto-optic scanner.

3 dB. A reasonable approximation of the maximum attainable bandwidth is

$$\Delta f = 0.7 f_{\max} \qquad [28]$$

Birefringent Scanners

The birefringent scanner is a significant use for anisotropic Bragg diffraction. There are a number of advantages with the birefringent scanner over the anisotropic scanner, such as a larger angular scan range along with lower frequencies. There are also disadvantages, such as lower speed due to generally lower shear wave velocities, and the particular application will dictate whether an isotropic or birefringent scanner is better. Scanners represent a fairly important aspect of acousto-optic devices due to the widespread commercial use of laser beam deflectors for displays and laser printers. For applications where the required speed is beyond that of mechanical scanners, the acousto-optic scanner is an ideal candidate. However, unlike mirrors, acousto-optic deflectors are wavelength sensitive, and can only be used with single-wavelength laser beams.

The birefringent scanner can be described with the wavevector diagram, as shown in Figure 7 for a positive uniaxial crystal where the extraordinary index of refraction is larger than the ordinary. The acoustic wavevector is tangent to the diffracted surface, which produces the largest scan angle for a given acoustic bandwidth. This is also the degenerate case, where only a single diffracted beam results, whereas two beams at two different acoustic frequencies will generally result from arbitrary input and acoustic propagation directions. The azimuthal acceptance angles (angles normal to the plane of incidence) of the acoustic and optical wavevectors can be different, although propagation and polarization directions must be selected that will produce high efficiency.

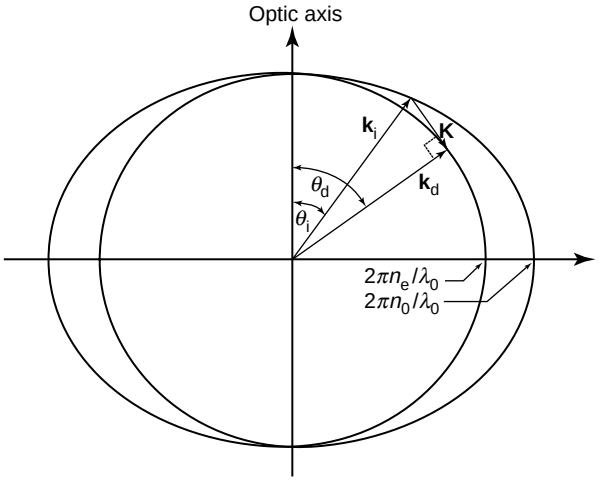

Figure 7 Wavevector diagram for birefringent scanner using a positive uniaxial crystal.

For the positive uniaxial case, the acoustic and diffracted wavevectors will be perpendicular at the design point, which allows the center frequency to be calculated from geometry as

$$f_0 = (V/\lambda)(n_i^2 - n_0^2)^{1/2} \qquad [29]$$

where n_i is the index of refraction at the incidence angle. Due to the typically low velocity of shear waves, this frequency can be much lower than an isotropic scanner, and the incidence angle can also be chosen to adjust the frequency. It is also possible to use the optical activity of certain materials such as TeO_2, along with circularly polarized light to further reduce the acoustic frequency. It is important to maintain as low a frequency as possible due to acoustic attenuation, which is especially high with the soft materials typically used for birefringent applications.

The bandwidth over which the scanner can efficiently operate is fairly large due to having the acoustic and diffracted wavevectors perpendicular, and is approximately $\Delta f = 2f_0$, assuming an octave of bandwidth for the isotropic scanner. This will produce a larger scan angle than an isotropic scanner, and more spots of resolution. The number of resolution spots is determined through diffraction by the aperture size and diffraction, along with the scan angle. Since a larger aperture requires a longer time for the acoustic waves to propagate across the aperture, the response time τ to access the scanner will increase, and the product of τ and f is related to the number of spots by eqn [27]. The advantage of the birefringent scanner is that it can operate at a lower frequency f_0 with better performance. However, since other factors such as acoustic attenuation are important in designing a scanner, for some applications it might be better to operate an isotropic scanner at a higher frequency.

AOTFs

With anisotropic Bragg diffraction, the magnitude of the diffracted wavevector $\mathbf{k}_d$ will differ from the incident wavevector $\mathbf{k}_i$, which cannot occur for the isotropic case. This is illustrated in Figure 8 for an AOTF utilizing a negative uniaxial crystal where an extraordinary input wave propagating at an incident angle θ_i relative to the crystal axis is diffracted into an ordinary output wave at an angle θ_d. This occurs through an acoustic wave propagating at an angle θ_a

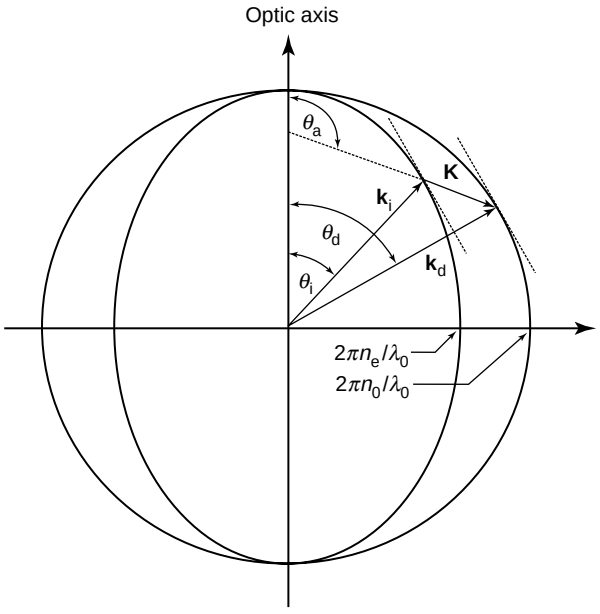

Figure 8 Wavevector diagram for an AOTF using a negative uniaxial crystal.

with wavevector $\mathbf{K}_a$, where all the wavevectors lie in a plane through the optic axis of the crystal. This diagram is identical to the index ellipsoid for the crystal, scaled by $2\pi/\lambda$, where λ is the vacuum wavelength. The acoustic wavevector is shown as adding to the incident wavevector, which increases the frequency of the optical wave by the acoustic frequency. It can also be represented in the reverse direction, which would reduce the optical frequency by the same amount.

An AOTF spectrally filters the optical input, and maintains its spectral purity over a large angular aperture. These conditions are maximized when the power flow or ray directions of the input and output beams are collinear. This produces a parallel-tangents condition, where lines drawn tangent to the wavevector surfaces and connecting the input and diffracted wavevectors are parallel. For beams at 90° to the optical axis, it is referred to as the collinear case, whereas all other parallel-tangents conditions are noncollinear. The diffracted beam is rotated by 90° during anisotropic Bragg interaction, so that crossed polarizers can be used to separate the input and diffracted beams. For the collinear case polarization separation must be used, whereas angular separation can also be used for the noncollinear case.

The AOTF design equations can be derived from the geometrical conditions imposed by the wavevector matching condition

$$\mathbf{k}_d = \mathbf{k}_i + \mathbf{K} \qquad [30]$$

along with decomposing the acoustic wave into its Fourier components which result from the finite interaction length produced by the transducer. These components allow for phase matching over a range of input angles, and they also allow for a spectral spread of the interaction. The full width half maximum (FWHM) resolution is given by

$$\Delta\lambda = \frac{1.8\lambda^2}{bL \sin 2\theta_i} \qquad [31]$$

where λ is the vacuum wavelength, b is the dispersion term (essentially $2\pi\Delta n$, where the birefringence Δn is the difference between the ordinary index n_0 and extraordinary index n_e of refraction), L is the interaction length of the input beam defined geometrically by the acoustic beam, and θ_i refers to the angle of the central or cardinal ray of the input beam, and the AOTF is designed around this angle. It is therefore a sensitive function of the incidence design angle, with the highest resolution occurring for the collinear case. The resolution is also narrower for larger birefringence.

The geometry of a noncollinear AOTF is shown schematically in Figure 9. The acoustic waves propagate in the correct direction and are generated by a transducer of length L_t, which is related geometrically to the interaction length. These waves are generally absorbed at the other side of the AOTF to prevent interfering reflections, and the sides may also be wedged to eliminate reflections into the interaction region. The optical beam enters the AOTF at the correct angle to the crystal optic axis, and either diffracts or passes through as the zero order. The input beam will have an angular spread, producing an acceptance angle that is a function of the interaction length, wavelength, and crystal parameters, and the external solid angular aperture

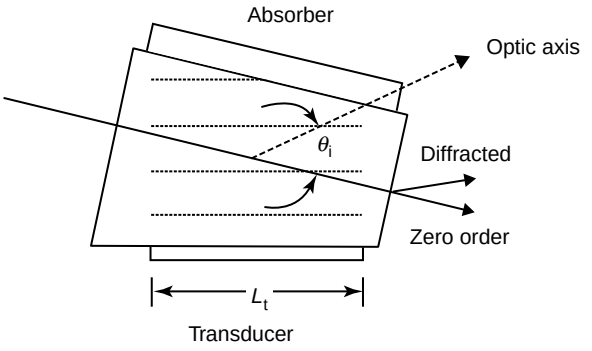

Figure 9 Noncollinear AOTF orientation of optical and acoustic beams.

is roughly given by

$$\Delta\Omega = \frac{\pi n^2 \lambda}{\Delta n L} \qquad [32]$$

where n refers to the diffracted beam index of refraction, which can be either n_0 or n_e depending upon the design. The resolution and solid angle are therefore related through the transducer length, and the product of the resolving power times the solid angle is given by

$$(\lambda/\Delta\lambda)(\Delta\Omega) = 2\pi n^2 \sin^2\theta_i / |F_\theta F_\varphi|^{1/2} \qquad [33]$$

where

$$F_\theta = 2\cos^2\theta_i - \sin^2\theta_i \qquad [34a]$$

$$F_\varphi = 2\cos^2\theta_i + \sin^2\theta_i \qquad [34b]$$

are form factors for the polar and azimuthal components of the optical field. Since all the wavectors lie in a plane containing the optic axis, the azimuthal components of the incident, diffracted, and acoustic wavevectors must always be identical under the parallel-tangents condition.

The product $(\lambda/\Delta\lambda)(\Delta\Omega)$ forms a figure of merit for spectrometers, and for the collinear case, the product is identical to a Fabry–Perot etalon having an index of n, and at other angles it is more complicated due to the angular dependence. The angular field is also symmetrical for the collinear AOTF, but nowhere else other than along the optic axis, where the resolving power becomes zero.

The great advantage of the AOTF designed under the parallel-tangents condition is the large angular aperture compared to the general case. Under this condition, the dependence of the angular aperture on resolving power is second order rather than first order, and the angular aperture can be tens of degrees for a typical resolution, which is useful for imaging applications. At the special angle of 54.7°, the second-order dependence is also zero, and the aperture can be extremely large relative to the resolving power, although this requires a high-resolution device with a corresponding narrow field, since the condition would soon be violated at larger field angles.

The efficiency of the AOTF under phase matching is given by

$$\eta = \sin^2[\pi^2 M_2 P_a L^2/(2\lambda^2)]^{1/2} \qquad [35]$$

which depends on θ_i and various material properties. Since the interaction is anisotropic, M_2 must be taken as a tensor quantity, in which both the polarization and propagation directions of the acoustic and optical waves must be accounted for. For acoustic waves, the polarization direction is the particle motion, which is perpendicular to the propagation direction for shear waves. In general, M_2 is much larger for a specific configuration of a particular material, and AOTFs are designed around this condition. The range of useful design angles is also usually limited since M_2 is generally a sensitive function of θ_i. The angular dependence on M_2 is important in designing an efficient device since it can be near zero at specific design angles for some materials, such as with TeO_2 for the collinear case.

The AOTF must be designed to optimize performance. The resolution is generally given as a system requirement, and the design angle along with the transducer length must be adjusted to optimize the throughput, or total optical power through the AOTF. This requires maximizing the efficiency, angular aperture, and aperture dimension. The maximum crystal size that can be grown ultimately limits these parameters, both in the interaction length and in the aperture size.

AOTFs have been used for a wide range of spectral filtering applications for spectroscopy and laser applications. Both collinear and noncollinear devices have electronically tuned a variety of lasers, including dye, semiconductor, and Ti:sapphire lasers. The AOTF is placed within the laser cavity, which requires high transmission on the laser line, with enough resolution to separate nearby laser transitions. A related application is the multiplexing of optical communications systems, where the AOTF is used to separate the various laser diode wavelengths. Perhaps the most widely used application is spectroscopy, and single-point detection systems have been used for a variety of biological and chemical applications in the visible and infrared. These techniques have been extended to spectral imaging, again in the visible and the infrared. Due to a variety of AOTF aberrations the image quality will be somewhat degraded. Since the AOTF is electronically tunable, it can be rapidly modulated both in amplitude and wavelength, which allows for modulation spectroscopy to detect small signals in a large background. By applying multiple frequencies, the AOTF has also been used as a rejection filter, in which all wavelengths other than that selected are allowed to pass.

Modulators

Acousto-optic modulators are used to vary and control laser beam intensity. A Bragg configuration gives a single first-order output beam, where intensity is directly linked to the power of RF control signal. The rise time of the modulator is the time required for

the acoustic wave to traverse the laser beam. For minimum rise time the laser beam will be focused down, forming a beam waist as it passes through the modulator.

A Bragg configuration gives a single first-order output beam, the intensity of which is controlled by the RF signal power, and diffaction angle controlled by the drive frequency. Two deflectors can be used in series and at right angles to each other to give full two-dimensional scanning.

One requirement in the design of acousto-optic modulators is that the diffracted beam and undiffracted beam must be well separated. For an adequate extinction ratio, the Bragg angle should be at least as large as the divergence of the optical beam. This condition puts a minimum value on the center frequency. Equating the Bragg angle

$$\theta_B = \frac{\lambda f_0}{2nV} \qquad [36]$$

and the diffraction angle of the Gaussian beam

$$\delta\theta_0 = \frac{4\lambda}{\pi(nd)} \qquad [37]$$

where d is the beam diameter at the minimum, it follows that the lower limit of the acoustic frequency is given by

$$f_0 = \frac{8}{\pi\tau} \qquad [38]$$

We may combine these expressions to determine a limit of modulator bandwidth of acousto-optic modulators, with the result

$$\Delta f \sim \frac{1}{4} f_m \qquad [39]$$

i.e., the modulation bandwidth is approximately equal to 25% of the midband acoustic frequency, f_m. In view of the present status of transducer technology, the modulation bandwidth of acousto-optic modulators is limited to several hundred MHz.

A frequency shifter uses the shift inherent in the acousto-optic interaction to up- or down-shift a laser's frequency. Two kinds of shifters can be distinguished: the fixed frequency shifter, and the variable frequency shifter. The frequency shift is equal to the signal frequency applied to the transducer. Various device configurations can be used to shift the laser beam, such as multiple travels inside the shifter to double or triple the frequency shift, or a combination of two frequency shifters in series. Acousto-optic frequency shifters can be used, for example, in optical heterodyning and interferometry, or in laser Doppler velocimetry for particle velocity analysis.

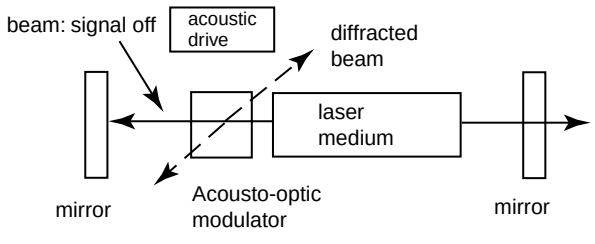

Figure 10 An acousto-optic Q-switch in a laser cavity.

Q-Switches

A Q-switch is a special modulator which introduces high repetition rate losses inside a laser cavity (typically 1 to 100 KHz). They are designed for minimum insertion loss and to be able to withstand very high laser powers. In normal use an RF signal is applied to diffract a portion of the laser cavity flux out of the cavity. This increases the cavity losses and prevents oscillation. When the RF signal is switched off, the cavity losses decrease rapidly and an intense laser pulse evolves. A diagram of a typical acousto-optic Q-switched laser cavity is shown in Figure 10. Q-switches are the preferred method of intracavity modulation where high speed, high stability, and modest cost are important design factors.

List of Units and Nomenclature

b	dispersion constant	–
c	elastic stiffness	dynes cm^{-2}
D, d	optical beam diameters	cm
e	elastic strain	–
f	acoustic frequency	hertz
F	optical focal length	cm
F_ϕ, F_θ	angular form factors	–
$\mathbf{k}$	optical momentum wavevector	cm^{-1}
$\mathbf{K}$	acoustic momentum wavevector	cm^{-1}
M_2	acousto-optic figure of merit	$sec^3\,gram^{-1}$
n	refractive index	
p	photo-elastic constant	–
P	pressure	dynes cm^{-2}
P_a	acoustic power	watts cm^{-2}
V	acoustic velocity	cm sec^{-1}
β	compressibility	$cm^2\,dyne^{-1}$
η	diffraction efficiency	–
ε	dielectric constant	–
ω	optical frequency	hertz
Ω	solid angle	steradians
ρ	density	grams cm^{-3}
θ	Bragg angles	radians
τ	acoustic wave travel time	sec

The electro-optic (EO) effect can be described as any one of a number of phenomena that occur when an electromagnetic wave in the optical spectrum (e.g., characterized by wavelengths in the range 200 to 2000 nm) interacts with an electric field, or with matter under the influence of an electric field. Two of the most important electro-optic phenomena are the Kerr effect (discovered by John Kerr in 1875) and the Pockels effect (discovered by Friedrich Pockels in 1893), in which birefringence is induced or modified in a liquid (the Kerr effect) or a solid (the Pockels effect). Birefringence is the difference in refractive indices for light of orthogonal line polarizations, one of which is parallel to the induced optical axis. The Kerr effect involves creation of birefringence in a liquid that is otherwise not birefringent. The degree of birefringence is quadratically proportional to the applied electric field strength. Hence, the Kerr effect is frequently referred to as the quadratic electro-optic effect while the Pockels effect involves a linear dependence on the applied electric field and is referred to as the linear electro-optic effect. In considering practical applications of the electro-optic effect, a commonly encountered term is that of 'electro-optic modulator', which can be described as a device wherein a signal control element is used to modulate a beam of light. The control element is typically an electric field with frequency components in the zero (DC) to hundreds of gigahertz (1 GHz = 10^9 Hz) range (or even tens of terahertz (1 THz = 10^{12} Hz). The modulation may be imposed on the phase, frequency, amplitude, or direction of the modulated optical beam.

Electro-optic effects are one class of second-order nonlinear optical phenomena. Other important second-order nonlinear optical phenomena include sum (e.g., second-harmonic) and difference frequency generation. Such phenomena derive from the second-order term in the power series expansion of macroscopic (material) polarization, P, in terms of applied electric fields:

$$P_i = \chi_{ij}^{(1)} E_j + \chi_{ijk}^{(2)} E_j E_k + \chi_{ijkl}^{(3)} E_j E_k E_l + \cdots \quad [1]$$

where $\chi_{ij}^{(1)}$, $\chi_{ijk}^{(2)}$, and $\chi_{ijkl}^{(3)}$ are the linear, second-, and third-order optical susceptibilities, respectively. Second-harmonic generation (SHG) or frequency doubling (2ω) effects, where a beam at twice the frequency of the input beam is generated, can be seen by substituting a sinusoidal field, $E_\omega \cos(\omega t - kz)$; for E_j and E_k. After using a well-known trigonometric identity, the equation for macroscopic polarization becomes (through second-order and dropping the subscript i):

$$P = \chi^{(1)} E_\omega \cos(\omega t - kz) + (1/2)\chi^{(2)} E_\omega^2 \times [1 + \cos(2\omega t - 2kz)] + \cdots \quad [2]$$

The electro-optic effect can be appreciated by considering interaction of the medium with an optical field $E_\omega \cos(\omega t - kz)$ and a low-frequency field E_0. Note that although we have used the symbol zero to

denote the frequency of the low-frequency electrical field, actual frequencies can extend to hundreds of gigahertz or even tens of terahertz. Again substituting (and now keeping terms to third order), the equation for polarization can be written as:

$$\begin{aligned} P &= \chi^{(1)}E_\omega\cos(\omega t-kz)+2\chi^{(2)}E_0E_\omega\cos(\omega t-kz) \\ &\quad +3\chi^{(3)}E_0^2E_\omega\cos(\omega t-kz)+(3/4)\chi^{(3)}E_\omega^3\cos(\omega t-kz) \\ &= \chi_{\text{eff}}E_\omega\cos(\omega t-kz) \end{aligned} \quad [3]$$

The equation for the nonlinear index of refraction, n, can be expressed as

$$\begin{aligned} n^2 &= 1+4\pi\chi_{\text{eff}} \\ &= 1+4\pi[\chi^{(1)}+2\chi^{(2)}E_0+3\chi^{(3)}E_0^2+(3/4)\chi^{(3)}E_\omega^2] \end{aligned} \quad [4]$$

Denoting the linear index of refraction as n_0, the above equation can be rewritten as

$$n^2-n_0^2=8\pi\chi^{(2)}E_0+12\pi\chi^{(3)}E_0^2+3\pi\chi^{(3)}E_\omega^2 \quad [5]$$

which in turn leads to

$$\begin{aligned} n &= n_0+(4\pi/n_0)\chi^{(2)}E_0+(6\pi/n_0)\chi^{(3)}E_0^2 \\ &\quad +(3\pi/2n_0)\chi^{(3)}E_\omega^2 \end{aligned} \quad [6]$$

The definition of light intensity in cgs units is $E_\omega^2=(8\pi/cn_0)I(\omega)$, which when substituted into the above equation gives

$$\begin{aligned} n &= n_0+(4\pi/n_0)\chi^{(2)}E_0+(6\pi/n_0)\chi^{(3)}E_0^2 \\ &\quad +(12\pi/cn_0^2)\chi^{(3)}I(\omega) \end{aligned} \quad [7]$$

The index of refraction can now be written as

$$n(\omega)=n_0(\omega)+n_1(\omega)E_0+n_2(0)E_0^2+n_3(\omega)I(\omega) \quad [8]$$

where the terms $n_1(\omega)$, $n_2(0)$, $n_3(\omega)$ correspond to the linear electro-optic effect, the quadratic electro-optic effect, and the optical Kerr effect, respectively. The above equation can also be expressed as

$$n=n_0-(1/2)n^3rE_0-(1/2)n^3sE_0^2-\cdots \quad [9]$$

where r and s are the linear and quadratic electro-optic coefficients, respectively.

Unfortunately, a great deal of confusion exists concerning the use of the terms electro-optic effect and electro-optic modulator. First of all, the terms 'electro-optic' and 'opto-electronic' are frequently confused and used interchangeably. Opto-electronic devices function as electrical-to-optical or optical-to-electrical signal transducers. Examples of commonly used opto-electronic devices include light-emitting diodes (LEDs), photodiodes (PDs), injection laser diodes (ILDs), and integrated optical circuit (IOC) elements. An electro-optic device can also function as an electrical-to-optical signal transducer (e.g., a Mach–Zehnder interferometer or a birefringent modulator employing polarizers at the input and the output); however, the mode of operation is entirely different for electro-optic and opto-electronic devices. For example, with LEDs or modulated lasers, the applied electric field produces modulation of transmission of light by altering the excited state population of the light emitting (lasing) state of the material. With electro-optic materials, no actual excited state population is generated. Electro-optic devices typically operate in regions of the optical spectrum removed from resonant transitions, i.e., regions of relatively high transparency. The applied electric field acts only to perturb the charge distribution of the material (the spatial positions of the electrons and nuclei). The altered charge distribution interacts with the optical beam transmitting the material with the result that the speed of light in the material (i.e., the index of refraction or birefringence) is altered. The response times of opto-electronic and electro-optic phenomena (and hence bandwidths of devices exploiting these phenomena) are quite different. In the former case, response will be limited by the lifetime of the relevant (emitting) excited state while in the latter case, response will be defined by the relaxation time of the material (e.g., reorientation time of a liquid or lattice relaxation time of a solid) following removal of the perturbing electric field.

An even greater confusion can arise due to the jargon used in particular technologies, such as telecommunications. A telecommunications engineer frequently refers to 'electro-optic switching' when describing opto-electronic transduction of an optical signal to an electrical signal, followed by re-routing in the electrical domain, and finally opto-electronic transduction of the electrical signal back to the optical domain. Electro-optic switching (in the sense used in this article) involves quite a different operation and would be described by that same telecommunications engineer as 'all-optical switching' – a term reserved by physicists for the optical Kerr effect (control of one light beam by another light beam).

A second point of confusion involves distinguishing between the terms 'electro-optic' and 'electro-absorptive' modulation. Again, the terms are frequently used interchangeably. However, they involve quite different physical mechanisms. An electro-absorptive

modulator is, like a modulated laser or LED, a 'resonant' device. In a device such as a gallium arsenide (GaAs) or indium phosphide (InP) quantum dot electro-absorptive modulator, the position and width of an optical absorption (resonant transition) are defined by the physical dimensions of the quantum dot. Application of an electric field shifts the spectral wavelength of the quantum dot absorption. This phenomenon can be used to dramatically change optical transmission through (or equivalently, absorption by) the material by choosing the wavelength of the propagating beam of light to be near the resonant absorption. With the electric field off, the material is reasonably transparent but becomes strongly absorbing when the electric field is applied, shifting the resonant absorption to the wavelength of the propagating beam. Obviously, the voltage required to achieve a desired change in optical transmission will depend on control of quantum dot dimensions in fabrication, which has been and continues to be a topic of research focus for electro-absorptive materials. Likewise, control of insertion losses of such devices is a concern as the wavelength used for the transmissive state of the device must be sufficiently close to the optical resonance to achieve the desired attenuation with application of a modest control voltage. Another issue to be faced with electro-absorptive devices is that of 'chirp' (optical signal distortion arising from the fact that both absorption and index of refraction – the imaginary and real parts of the optical susceptibility – change with application of the electric control field). On the positive side, electro-absorptive modulators are 'polarization-insensitive' modulators and are thus conveniently used with multimode (as well as single mode) optical transmission.

Further confusion exists because widely different types of materials can be used in electro-optic and electro-absorptive devices. As these materials are frequently competing for the same applications (signal transduction, optical switching, etc.), the advantages and disadvantages of different materials are often compared without maintaining the context that quite different phenomena are involved. Even restricting our discussion to electro-optic materials, we note that materials can range from organic liquid crystalline materials (nematic, smetic, ferroelectric, etc.) to organic electro-optic materials (both crystalline and 'macromolecular') to inorganic crystalline materials (lithium niobate, $LiNbO_3$; barium titanate, $BaTiO_3$; barium borate, BBO; potassium dihydrogen phosphate, KDP; lithium tantalate, $LiTaO_3$; zinc telluride, ZnTe, etc.). The response times of these materials to transient application of an applied electric field will be quite different, reflecting the different types of lattice motion involved. With liquid crystalline materials, particularly nematic materials, considerable molecular reorientation is involved and due to the mass that must be moved, response times are quite slow although the index change will be relatively large. With use of liquid crystalline materials, device bandwidths will typically be limited to tens of megahertz (MHz) or less. In contrast, conjugated π-electron organic materials typically exhibit response times of tens to hundreds of femtoseconds, which translates to potential device bandwidths of tens of terahertz (actual device bandwidths may be less due to factors other than material response). For conjugated π-electron organics, the response time is the phase relaxation time of the π-electron system. Because only a slight change in bond length alternation of the conjugated π-electron system occurs with application of an applied electric field and because strong electron–phonon coupling and resonance stabilization of the π-electron system act to reduce the barrier to lattice relaxation, the response times of π-electron organic materials are among the fastest observed in nature. With crystalline inorganic materials, the ionic constituents move to new locations with application of an electric field with the exact movement determined by the field strength, the charge on the ions, and the restoring force. Unequal restoring forces along the three mutually orthogonal (perpendicular) axes of the crystal lead to anisotropy in the optical properties of the material. The applied electric field will induce a change in the anisotropy (the principal refractive indices). The symmetry of the electro-optic tensor will be closely related to the symmetry of the piezoelectric tensor. The linear electro-optic effect requires that the crystal exhibit noncentrosymmetric (acentric or ferroelectric) symmetry. A centrosymmetric crystal possesses a center of symmetry defined by identical particles existing in the lattice at vectors $\mathbf{r}$ and $-\mathbf{r}$, where $\mathbf{r}$ is a position vector measured from an arbitrary origin. A centrosymmetric crystal, like an isotropic liquid or gas, can exhibit a quadratic electro-optic effect.

For the sake of completeness, it can also be noted that index of refraction changes can be induced by acoustic waves (acousto-optic modulation) and by heating (thermo-optic modulation). Also, elasto-optic and photo-elastic effects can produce index of refraction changes.

To keep this article to a manageable length, discussion is limited to solid-state electro-optic materials. Design principles being used to produce new organic electro-optic materials will be

illustrated. Since inorganic materials exist as crystals, limited chemical modification of such materials is possible, although processing techniques for fabricating thin films of such crystalline materials have been developed in a number of cases. For organic macromolecular materials, development of new materials is an on-going activity. Several representative devices being fabricated, using electro-optic materials, will be discussed. Four of the most commonly encountered types of EO devices include: (i) stripline devices; (ii) prism, cascaded prism, and superprism devices; (iii) resonated devices, such as ring microresonator and photonic bandgap devices, and (iv) waveplates. Of course, devices such as stripline devices can be configured in a variety of ways to produce polarization-sensitive and polarization-insensitive electrical-to-optical signal transducers, optical switches either using simple 1×2 or 2×2 switch architectures or multimode interference (MMI) switches, optical gyroscopes, photonically controlled phased array radar systems, spectrum analyzers, optical digital signal processors, analog-to-digital (A/D) and digital-to-analog (D/A) signal converters, electromagnetic (radiofrequency to millimeter wave) signal generators, voltage sensors, etc. Prism-type devices are typically used for spatial light modulation or laser beam deflection. Ring microresonator devices afford a rich array of applications ranging from active wavelength division multiplexing (WDM) to active optical interconnect reconfiguration, to voltage-controlled wavelength tuning of laser outputs.

Basic Relationships

The effect of the applied field is to deform the index of refraction ellipsoid, which can be represented as

$$\left(\frac{1}{n^2}\right)_1 X^2 + \left(\frac{1}{n^2}\right)_2 Y^2 + \left(\frac{1}{n^2}\right)_3 Z^2 + 2\left(\frac{1}{n^2}\right)_4 YZ + 2\left(\frac{1}{n^2}\right)_5 XZ + 2\left(\frac{1}{n^2}\right)_6 XY = 1 \qquad [10]$$

leading to the corrections

$$\Delta\left(\frac{1}{n^2}\right)_i = \sum_{j=1}^{3} r_{ij} E_{0j} \qquad [11]$$

where the electro-optic tensor components are related to the tensor components of the second-order nonlinear optical susceptibility by $r_{ij} = -(8\pi/n_{0i}^2 n_{0j}^2)\chi_{ji}^{(2)}$. The full tensorial equation for change of the 'indicatrix' (index of refraction ellipsoid) can be expressed as

$$\begin{pmatrix} \Delta\left(\frac{1}{n^2}\right)_1 \\ \Delta\left(\frac{1}{n^2}\right)_2 \\ \Delta\left(\frac{1}{n^2}\right)_3 \\ \Delta\left(\frac{1}{n^2}\right)_4 \\ \Delta\left(\frac{1}{n^2}\right)_5 \\ \Delta\left(\frac{1}{n^2}\right)_6 \end{pmatrix} = \begin{pmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \\ r_{41} & r_{42} & r_{43} \\ r_{51} & r_{52} & r_{53} \\ r_{61} & r_{62} & r_{63} \end{pmatrix} \begin{pmatrix} E_{0X} \\ E_{0Y} \\ E_{0Z} \end{pmatrix} \qquad [12]$$

The electro-optic tensor reduces considerably for specific materials reflecting the symmetry of the particular material. For inorganic crystalline materials, the electro-optic tensor can be reasonably complex (containing many nonzero elements). It is also helpful to note that for crystalline inorganic materials, the electric-field-induced change in crystal shape leads to strain and the orientation of the indicatrix is altered, leading to an additional contribution to the change in index coefficients:

$$\Delta(1/n^2)_i = \sum_k p_{ik} S_k + \sum_j r_{ij} E_j \qquad [13]$$

where S_k is a component of the strain and p_{ik} is the elasto-optic tensor. At high frequencies, the inertia of the crystal prevents macroscopic straining so that the first term of the above equation vanishes. At low frequencies, elasto-optic effects cannot be ignored. Because the deformation leading to strain is generally caused by the inverse piezoelectric effect, it is linearly related to the applied electric field (the same dependence as the linear electro-optic effect). This can lead to a frequency dependence of the 'effective' electro-optic coefficient for crystalline materials.

A brief comment on the photo-elastic effect (the change in index coefficients produced directly by applied stress) is warranted. This effect has the form:

$$\Delta(1/n^2)_i = \sum_l \pi_{il} \sigma_1 \qquad [14]$$

where σ_l are the components of the stress and π_{il} are the piezo-optical coefficients. Note that this effect is independent of the applied electric field.

For axially symmetric 'charge-transfer type' organic chromophores prepared by deposition or

electric field poling, only two unique tensor elements, r_{33} and r_{13}, survive:

$$\tilde{r} = \begin{pmatrix} 0 & 0 & r_{13} \\ 0 & 0 & r_{13} \\ 0 & 0 & r_{33} \\ 0 & r_{13} & 0 \\ r_{13} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \qquad [15]$$

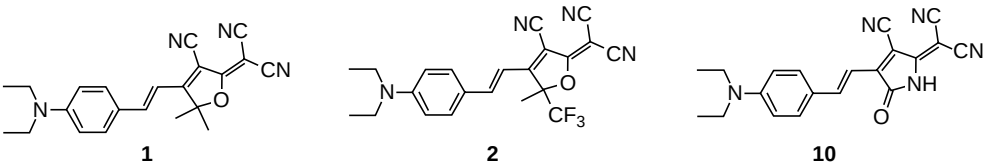
The electro-optic effect for organic macromolecular materials derives from molecules with conjugated π-electrons confined within molecules (chromophores). The electro-optic tensor elements can be related to molecular first hyperpolarizability, β, and the chromophore number density, N (molecules/cm^3), by

$$\begin{aligned} r_{33} &= -2Nf(0)\beta\langle\cos^3\theta\rangle/n_0e^4 \\ r_{13} &= -Nf(0)\beta\langle\sin^2\theta\cos\theta\rangle/n_{0o}^2n_{0e}^2 \end{aligned} \qquad [16]$$

The expressions in brackets are 'order parameters' describing the degree of noncentrosymmetric order. $\langle\cos^3\theta\rangle = 1$ corresponds to all 'dipolar' (charge transfer type) molecules pointing in the same direction (perfect noncentrosymmetric or ferroelectric order) while $\langle\cos^3\theta\rangle = 0$ corresponds to complete disorder and no electro-optic effect. The reason that three angles appear in the order parameter is that an angle is required to represent the principal symmetry axis for the chromophore, the principal symmetry axis of the optical field, and the principal symmetry axis of the electric control field. Thus, averaging (denoted by brackets) must be carried out over each of these three angles. The tensor element r_{33} corresponds to the electric control field applied along the principal axis of the ordered chromophores and the principal axis of the optical field vector, transverse magnetic (TM) polarized light. The tensor element r_{13} corresponds to the control electric field applied along the principal axis of the optical field, transverse electric (TE) polarized light, and orthogonal to the principal chromophore axis. The notation r_{33} is contracted notation for r_{333}. The factor $f(0)$ takes into account the dielectric nature of the medium into which the chromophores (molecules with large first hyperpolarizability) are embedded.

For organic electro-optic materials, elasto-optic effects do not appear to make significant contributions. Moreover, electro-optic activity can be systematically improved by improving β and by optimizing the product of chromophore number density and order parameter. Due to the presence of intermolecular electrostatic interactions, W, among chromophores, order parameters and number density are not independent, e.g., for materials that are prepared by electric field poling the order parameter relevant to the principal component of the electro-optic tensor can be expressed approximately as

$$\langle\cos^3\theta\rangle = L_3(\mu f(0)E_p/kT)[1 - L_1(W/kT)^2] \qquad [17]$$



where L_3, and L_1 are Langevin functions, μ is the chromophore dipole moment, E_p is the strength of the electric poling field, k is the Boltzmann constant, and T is the Kelvin poling temperature. W is a quadratic function of chromophore number density, N. The above equation indicates that a maximum will be observed in the graph of r_{33} versus N.

Materials

With inorganic and organic crystalline materials, very little can be done to optimize electro-optic activity other than discovering new EO crystalline materials or employing isotopic (e.g., deuterium for hydrogen) or ion substitution with existing materials.

As with organic liquid crystalline materials, the electro-optic activity of macromolecular organic second-order nonlinear materials can be systematically improved by molecular modification. As shown in **Figure 1**, quantum mechanical calculations can provide useful guidance as to which structural modifications will lead to improvements in molecular (first) hyperpolarizability and ultimately electro-optic activity. The molecular hyperpolarizability (long wavelength limit) can be increased by a factor of two by simple variation of the acceptor structure. The calculated values of wavelengths for the interband charge transfer transitions are 390 nm, 403 nm, and 430 nm. Since dipole moments do not change significantly with structure, intermolecular electrostatic interactions should be similar for these three chromophores and the improvement in β should translate to an improvement in electro-optic activity. This theoretical prediction has been experimentally verified. This is just one example of use of quantum mechanics to guide the improvement of electro-optic activity for organic materials. This figure also illustrates the typical structure of an organic electro-optic chromophore, which consists of an electron donor region (an amine donor in the example shown), a connective

conjugated π-electron bridge, and an electron deficient electron acceptor region. The theoretically predicted (by density functional theory, DFT, calculations) variation of molecular first hyperpolarizability with molecular structure has been verified for the structures shown. However, the critical point is that electro-optic activity of organic materials (currently exhibiting a maximum value of 182 pm/V at 1.3 microns wavelength) is likely to be improved for some time to come. This value is to be compared to a value of 32 pm/V for lithium niobate. Another factor influencing the value of macroscopic electro-optic activity realized for electrically poled organic materials is the effect of intermolecular electrostatic interactions on optimization of $N\langle\cos^3\theta\rangle$. Statistical mechanical calculations can provide guidance as to how this is achieved (see **Figure 2** where the role of chromophore shape is illustrated). Approximating the chromophore shape by a rigid prolate ellipsoid with embedded dipole moment yields nearly quantitative reproduction of the experimental data. If the π-electron structure (dipole moment) is left unchanged but the shape of the chromophore is altered to a spherical shape, a significant improvement in electro-optic activity is predicted. The shape effect arises because there are two components to the electronic dipole–dipole intermolecular electrostatic potential function describing the many body interaction of chromophores.

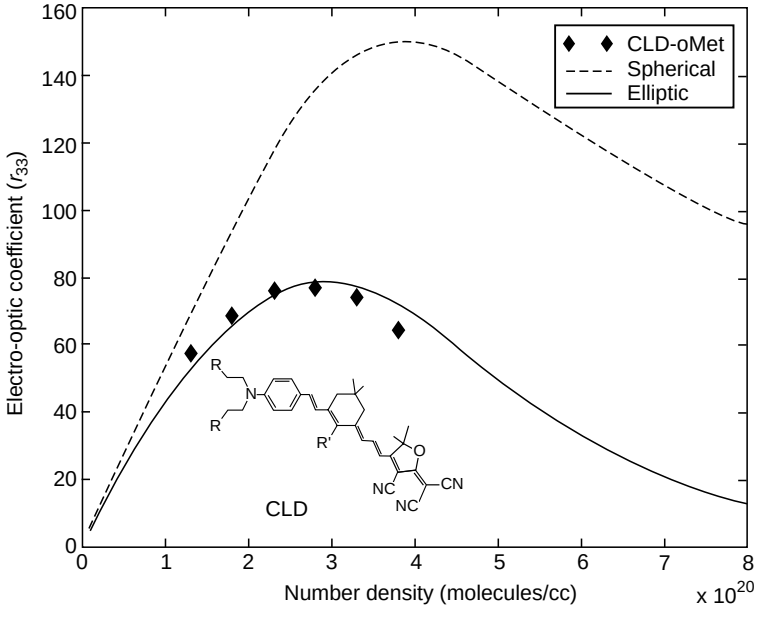

Figure 2 Two theoretical (statistical mechanical) simulations of the variation of electro-optic activity with chromophore number density are shown and compared with experimentally observed results for the CLD chromophore (structure shown) dissolved in an amorphous polycarbonate host polymer.

One component favors centrosymmetric ordering while the second component favors noncentrosymmetric ordering. Their relative weighting in defining macroscopic order depends on chromophore shape. Theoretical calculations have also shown that embedding chromophores in nanoscopic macromolecular objects (such as dendrimers and dendronized polymers) can dramatically enhance electro-optic activity. This type of engineering can also be used to control auxiliary properties such as optical loss and stability. The exceptional processability of organic electro-optic materials has permitted conformal and flexible devices to be fabricated and has permitted electro-optic circuitry to be integrated vertically on top of semiconductor VLSI (very large-scale integration) electronics. Mach–Zehnder modulators, with 3 dB operational bandwidths of 200 GHz, have been fabricated from organic electro-optic materials as have Mach–Zehnder devices with operational drive voltages of less than one volt. The major advantage that crystalline inorganic materials possess, relative to macromolecular organic EO materials, is superior thermal and photostability. A comparison of lithium niobate and the best organic EO materials, is given in Table 1. Cost is a significant factor if electro-optic materials are to compete with modulated lasers and other opto-electronic devices for applications in communications, computing, transportation, and defense. Currently, manufacturing costs for both crystalline and macromolecular materials are very high (several thousand dollars per modulator). Recently, it has been demonstrated that organic macromolecular materials can be used with soft lithography techniques to mass-produce electro-optic circuitry. This could conceivably dramatically reduce manufacturing costs. Also, the fact that organic macromolecular materials can be directly integrated with silicon photonics and VLSI semiconductor electronics, may influence future commercial utilization of electro-optic materials, which is currently dominated by lithium niobate.

Optical loss, dB/cm	0.2	0.2–1.0
Processing temperature (°C)	1000	<200
Multiple layers possible	No	Yes

Devices

Representative simple device structures are shown in Figure 3. For a simple stripline phase (birefringence) modulator (Figure 3, upper left), the phase retardation produced by application of an electric field is given by

$$\Delta\phi = 2\pi\Delta nL/\lambda = \pi n^3 rEL/\lambda = \pi n^3 rVL/\lambda d \qquad [18]$$

where L is the electrode length (the distance over which the electrical and optical fields co-propagate),

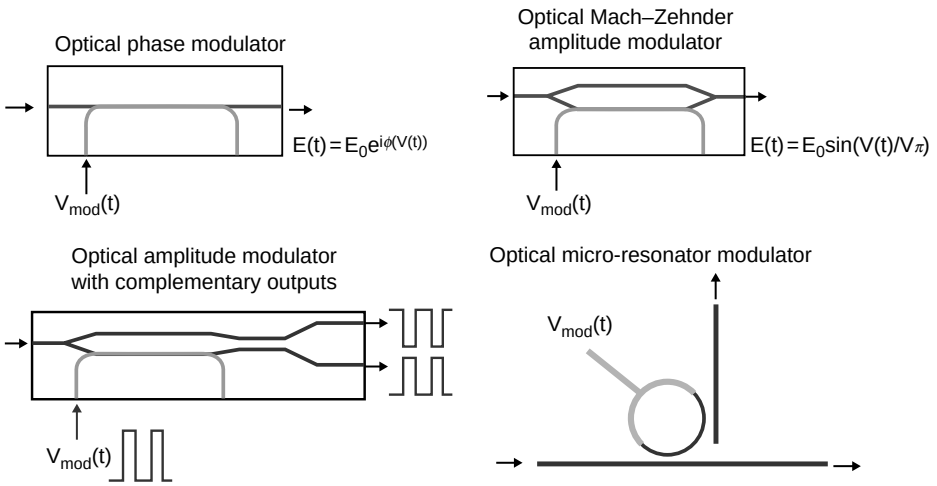

Figure 3 Schematic representation of simple electro-optic device structures are shown: Upper left (birefringent modulator), upper right (Mach–Zehnder interferometer), lower left (1 × 2 optical switch), lower right (ring microresonator).

λ is the optical wavelength, $V = E/d$ is the electric field felt by the material, and d is the electrode spacing. Electro-optic device performance is frequently characterized by the voltage, V_π, required to produce a phase shift of π radians. For a TM polarized light propagating through a birefringent modulator:

$$V_\pi = \lambda d/(n_{0e}^3 r_{33} L\Gamma) \qquad [19]$$

where Γ characterizes the overlap of the optical and electrical waves.

A simple Mach–Zehnder interferometer (electro-to-optical signal transducer) is shown in the upper right of Figure 3. When such a device is constructed from electrically poled organic electro-optic chromophores and a voltage is applied to one arm, a retardation of light propagating in that arm will be effected. This, in turn, will result in a change in the constructive/destructive interference of the beams at the output of the device. The consequence of applying an electrical signal to one arm of a Mach–Zehnder interferometer is that the applied voltage is transduced onto the optical output beam as an amplitude modulation of that beam. The voltage required to achieve full wave modulation for an optical beam of TM polarization is

$$V_\pi = \lambda d/(n_{0e}^3 r_{33} L\Gamma) \qquad [20]$$

Amplitude modulation can also be achieved using a birefringent modulator by placing polarizers at the input and output of the device. If an input polarizer is used to launch TM and TE modes, the birefringent modulator functions to produce a rotation of light, which is turned into an amplitude modulation by inserting a polarizer at the output. For such a device, V_π depends upon the difference in r_{33} and r_{13}. Note that for poled organic chromophores, $r_{33} \approx 3r_{13}$, $(V_\pi)_{\mathrm{BRM}} \approx 1.5(V_\pi)_{\mathrm{MZM}}$. For the above devices, it is clear that V_π will depend on the length over which the electrical and optical fields co-propagate in phase. For low electrical field frequencies, L will be the electrode length. The electrode spacing d, that can be used, will depend on the index of refraction difference between the core (electro-optic material) and a cladding material used to prevent the optical field experiencing the metal electrodes (an event that would dramatically increase propagation loss). For poled organic macromolecular materials and standard commercial claddings, d is typically in the order of 10 microns. Electrode lengths usually range from 1 to 3 cm. Two factors limit bandwidth in stripline devices: (i) velocity mismatch between the electrical and optical waves (which relates to the difference between n_0^2 and ε, where ε is the dielectric permittivity of the material – see Table 1); and (ii) microwave and millimeter wave loss in the metal electrodes. For organic electro-optic materials, the latter defines operational 3 dB bandwidth of devices.

Optical routing switches (see Figure 3, lower left) are more complicated to understand and typically require somewhat larger V_π voltages to effect a switching operation (e.g., $(V_\pi)_{\mathrm{simple2\times2crossbar}} \approx 1.7(V_\pi)_{\mathrm{MZM}}$).

Two conditions must be satisfied for light to be coupled into a ring microresonator device (see Figure 3, lower right): (i) the circumference of the ring must be a multiple of the wavelength of light, and (ii) the velocity of light in the ring must equal the velocity of light at the input. If a ring microresonator is fabricated from an electro-optic material, then an applied electrical voltage can be used to control coupling of light into and out of the ring microresonator. The same electrode structure, that is used to achieve voltage-controlled wavelength selective filtering, can also be used to transduce electrical information onto the optical beam while it is in the ring resonator. The quality (Q) factor of a ring microresonator defines both the wavelength selectivity and the bandwidth of the device. Ring microresonator devices also have the advantage of permitting a long interaction length to be achieved in a very compact device structure. The dimensions (radii) of ring microresonator structures are defined by bending loss and thus by the difference between core and cladding materials. Typical radii can range from hundreds of nanometers to hundreds of microns. With ring microresonators, a reduction in drive voltage requirements can be achieved by trading off bandwidth. Another price paid in the use of ring microresonator device structures is that of bending loss, which is not present in the other device structure shown. Ring microresonators can be used for active wavelength division multiplexing (WDM), voltage-controlled optical signal routing, and wavelength tuning of optical sources.

The interaction length of a prism optical beam deflector can be increased by cascading prisms together. For such a device structure, the angle of deflection becomes

$$\theta = n_0^3 r_{33}(V/d)(L/h) \qquad [21]$$

where h is the height of an individual prism and L is the length of the prism array. For currently available electro-optic materials only small deflection angles (a few degrees or less) can be achieved with practical

voltage levels. Superprism structures may permit large deflection angles to be achieved but such devices have yet to be demonstrated in a convincing manner.

Modulation and Demodulation of Optical Signals

R A Minasian, University of Sydney, Sydney, NSW, Australia

Introduction

Since earliest times, light has been used for communication purposes. In order to convey information, a physical variable of light, such as the optical intensity or field amplitude, must be modulated to encode a signal onto the optical carrier, and it must be demodulated or decoded after transmission. Laser sources provide the capability of extremely high modulation speeds, which result in high information-carrying capacity in optical communication systems. After transmission, semiconductor photodetectors demodulate the optical signals to recover the original information (*see* **Optical Communication Systems:** Basic Concepts).

The modulation of optical signals can be classified into two types: field modulation and intensity modulation, which is illustrated in Figure 1. In field modulation, the physical variable that is modulated is the frequency, phase, or amplitude of the optical field. These three techniques are sometimes referred to as frequency shift keying (FSK), phase shift keying (PSK) and amplitude shift keying (ASK). Figure 1b shows an example of frequency modulation of light. Field modulation requires keeping track of the phase of the carrier, which imposes strict requirements on the optical coherence (*see* **Coherent Lightwave Systems**). Because the optical carrier is at an extremely high frequency of around 2×10^{14} Hz at fiber-optic communication wavelengths of 1.5 μm, the required optical coherence is very difficult to realize, and moreover the receiver requires complex optical heterodyne methods to detect the phase of the optical field.

In intensity modulation, the physical variable that is modulated is the optical power. Figure 1c shows that it is the envelope of the light power that contains the information. The optical field oscillations at 10^{14}–10^{16} Hz in this case are not related to the

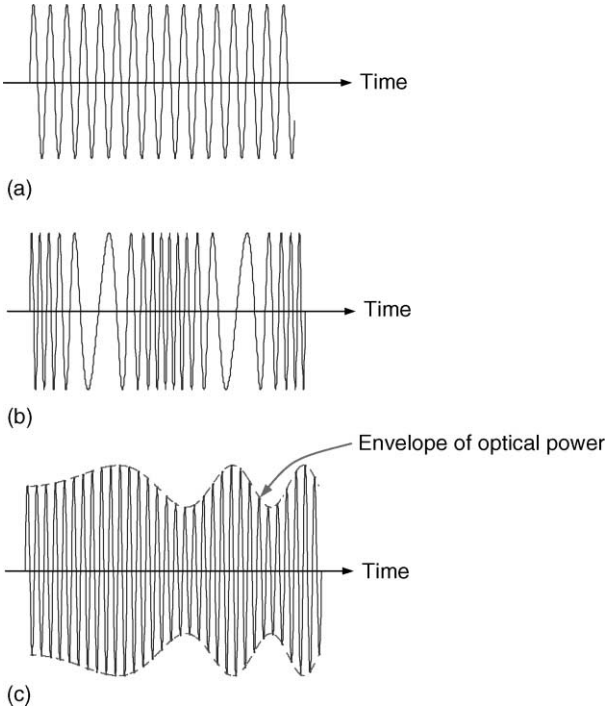

Figure 1 Types of modulation of optical signals. (a) unmodulated optical field; (b) frequency-modulated field; (c) intensity or envelope modulation of the optical power.

modulation and demodulation process, and only the optical power variation is important. This is a key advantage, and as a result intensity modulation systems are prevalent for optical communications. Here, we discuss how varying the injected current in a semiconductor laser or light emitting diode, or by operating the source with constant output and introducing an external modulator, can realize modulation of the optical power of the source. The process by which the optical power variations can be detected at the receiver with semiconductor photodiodes are also discussed, including detection noise characteristics and means of enhancing the responsivity by introducing internal gain mechanisms or wavelength selectivity. The speed capabilities of optical modulation and demodulation in semiconductor lasers and photodetectors are discussed, based on the rate equations for carrier and photon dynamics.

The Modulation of Semiconductor Lasers

Townes, Basov and Prokhorov, who shared the Nobel Prize in 1964, developed the principle of lasers. Semiconductor lasers emit light through a stimulated emission mechanism. The required optical gain for

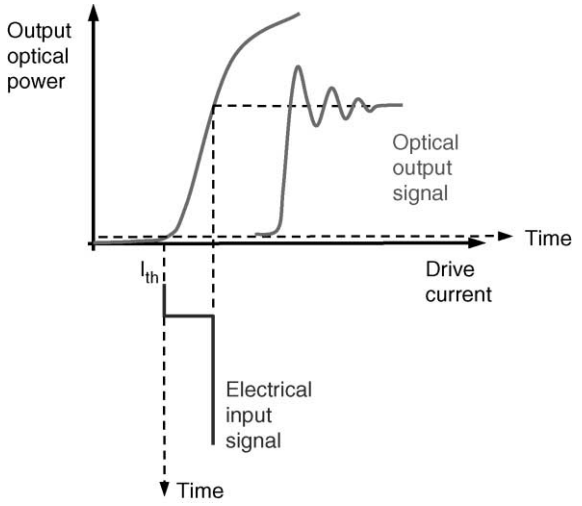

Figure 2 Light-current properties and the dynamic modulation characteristics of semiconductor lasers.

the lasing action is obtained by injecting a forward bias current into a heavily doped p-n junction, thereby injecting carriers into the active junction layer and creating a population inversion. Here we limit our discussion to the optical modulation characteristics of the laser in response to changes in the injection current.

Figure 2 shows the typical light-current characteristics of semiconductor lasers. For drive currents above the threshold value I_{th}, the emitted optical power is predominantly by stimulated emission and it increases linearly with the drive current up to moderate currents. The differential responsivity of the laser, defined by the ratio of optical power increase to electric current increase above threshold, is typically around 0.5 mW/mA. At high current levels, the light output deviates from a proportional dependence on the current because of saturation effects and the differential responsivity decreases.

The dynamic response of the semiconductor laser to modulation of the injection drive current is governed by the rate equations for the carrier density and the photon density in the active junction region. Figure 3 shows the active layer under consideration (*see* **Lasers:** Edge Emitters). The electron concentration in the active layer is denoted N and the photon concentration in the active layer is denoted S. The dynamic behavior of the electron concentration and photon density is governed by the following rate equations:

$$\frac{\partial N(x)}{\partial t} = \frac{I(x)}{q\nu_a} + D_n \frac{\partial^2 N(x)}{\partial x^2} - \frac{N(x)}{\tau_{ns}} - G(x)\cdot S(x) \qquad [1]$$

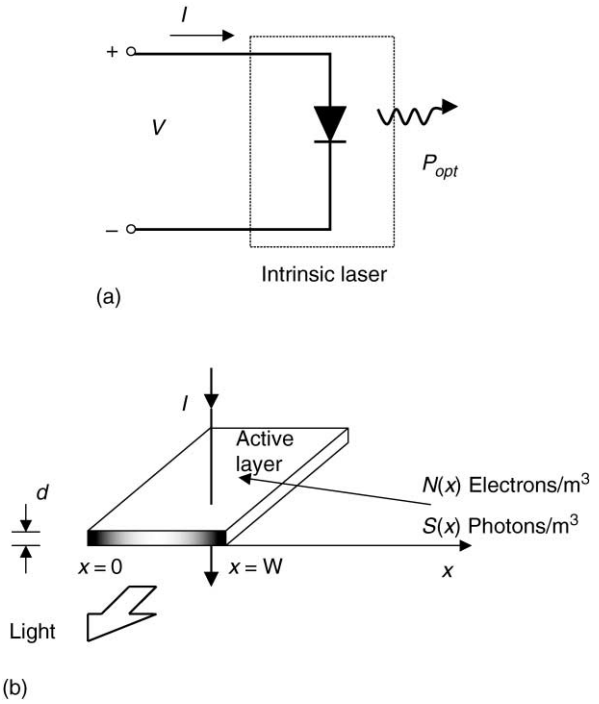

Figure 3 Semiconductor laser. (a) intrinsic device; (b) active region with injected current I, electron concentration N, and photon concentration S.

$$\frac{\partial S(x)}{\partial t} = \Gamma \cdot \beta \frac{N(x)}{\tau_{ns}} + \Gamma \cdot G(x) \cdot S(x) - \frac{S(x)}{\tau_p} \qquad [2]$$

where I is the injected current, q is the electronic charge, ν_a is the volume of the active layer, D_n is the diffusion constant, τ_{ns} is the carrier lifetime, Γ is the confinement factor (defined as the fraction of the optical power in the active region), β is the fraction of the spontaneous emission power coupled into the lasing mode, τ_p is the cavity or photon lifetime, and

$$G(x) = \gamma[N(x) - N_t] \qquad [3]$$

where G is the net rate of stimulated emission, and N_t is the electron concentration at transparency.

Equations [1] and [2] are statements of the fundamental continuity equations for electrons and photons in the active layer. Hence, eqn [1] expresses the fact that the rate of increase of electron concentration in the active layer is given by the rate of increase of electron concentration due to injected current, the rate of increase of electron concentration due to diffusion current, the rate of decrease of electron concentration due to spontaneous recombination, and the rate of decrease in electron concentration due to stimulated photon emission. Equation [2] expresses the fact that the rate of increase of photon density in the active layer is given by the rate of increase in photon density due to spontaneous emission coupled into the lasing mode, the rate of increase of photon density due to stimulated emission coupled into the active layer, and the rate of decrease of photon density due to cavity loss mechanisms.

The actual electron and photon distribution varies across the active layer. However, for simplicity, it is convenient to use average values of N and S, and the simplified rate equations in terms of position independent variables are given by:

$$\frac{dN}{dt} = \frac{I_i}{q\nu_a} - \frac{N}{\tau_{ns}} - G(1 - \varepsilon S)S \qquad [4]$$

$$\frac{dS}{dt} = \Gamma \cdot \beta \frac{N}{\tau_{ns}} + \Gamma \cdot G(1 - \varepsilon S)S - \frac{S}{\tau_p} \qquad [5]$$

where the scaling factor $(1 - \varepsilon S)$ accounts for gain saturation arising from several phenomena such as spatial hole burning, spectral hole burning, carrier heating and two-photon absorption, and ε is a nonlinear gain parameter.

The modulation response of the laser is obtained by solving the rate eqns [4] and [5] for a time dependent input current of the form

$$I(t) = I_b + I_m x(t) \qquad [6]$$

where I_b is the steady-state bias current, I_m is the modulation current amplitude and $x(t)$ represents the normalized shape of the modulation waveform.

The small-signal modulation bandwidth of the laser is obtained by considering the response to small amplitude sinusoidal current modulation at frequency ω, so that $x(t) = \sin(\omega t)$, around a steady-state bias current above lasing threshold. Under the small signal condition, the rate equations can be linearized and combined to result in a second order differential equation. The solution for the photon output exhibits a damped resonant type response. Hence the modulation response displays some peaking at the relaxation oscillation resonance frequency ω_r, and is flat for frequencies much lower than ω_r. The resonance frequency $\omega_r \propto \sqrt{S_o}$, where S_o is the photon density at the laser bias level, so the bandwidth can be increased by biasing the laser further above its threshold current. Semiconductor laser bandwidth to 30 GHz has been observed; however, it is often limited to around 10 GHz due to electrical parasitics in the current drive circuit and interface.

The large-signal modulation response of the laser is obtained by solving the differential eqns [4] and [5]. The response of the carrier-photon coupled system to

a step change of drive current has the potential for damped oscillation. This is caused by a resonant type of behavior in which, for example, an increase in photon density causes a depletion in population inversion which leads to a decrease in photon density enabling the carrier density to recover, thus producing a time lag between cause and effect resulting in damped oscillations before settling to the steady state value. These dynamic characteristics are illustrated in Figure 2. For a step modulation of the laser drive current, the optical output response exhibits a delay time, a risetime, an overshoot, and damped oscillations. The risetime of the laser output is typically in the range of 100–300 ps. The turn-on time of the laser and the overshoot are improved by ensuring that the minimum drive current does not fall below threshold. The damped oscillations in the optical output occur at the relaxation oscillation frequency of the laser.

These laser pulse waveform imperfections cause deteriorations in the eye diagram of the laser transmitter that is modulated by very high speed digital bit streams (*see* **Optical Communication Systems:** Lightwave Transmitters). Figure 4 shows the eye diagram for the optical output of a semiconductor laser directly modulated by a 5 Gbit/s pseudo-random bit stream of length $2^{15}-1$. The output waveform imperfections cause a partial closure of the eye, which ultimately limits the modulation speed that can be obtained by directly modulating the laser drive current. Although the semiconductor laser optical output does not exactly replicate the applied electrical drive waveform, the deviations are small enough so that these lasers can be used for data transmission up to around 10 Gbit/s.

Another inherent consequence of direct modulation of semiconductor lasers is the production of laser frequency chirp. This arises from the fact that modulation induced changes in the carrier density in the active region of the laser cavity cause a change in the refractive index of the active layer, which results in a chirping in the output wavelength during modulation. Hence amplitude modulation of semiconductor lasers is fundamentally accompanied by phase modulation from the basic physical mechanism of carrier induced changes in the refractive index. The resulting transient changes in the output wavelength of the laser causes a chirping phenomenon as it is being modulated. The order of chirp magnitude is about 0.1–1 GHz/mA of drive current change. During digital pulse modulation, the laser wavelength shifts to the blue side near the leading edge and towards the red side near the trailing edge of the pulse. Chirp results in a broadening of the laser linewidth. This wavelength change effect in combination with the dispersion characteristics of optical fiber (*see* **Fiber and Guided Wave Optics:** Dispersion; Light Propagation) causes an important limitation to the transmission capacity of fiber optic communication systems. The chirp in semiconductor lasers can be reduced, but not entirely eliminated, by using modulation-doped strained multiquantum-well lasers, which reduce the linewidth enhancement factor.

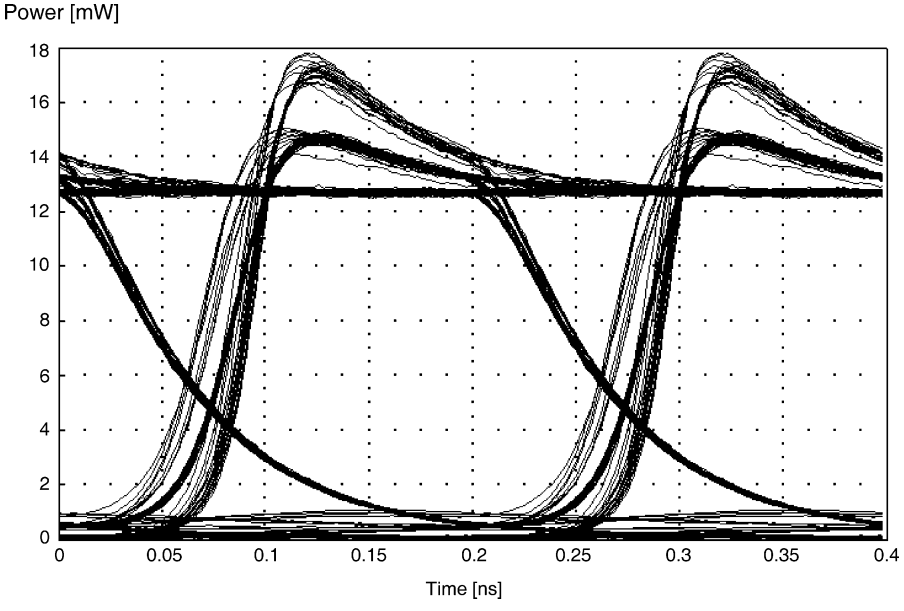

Figure 4 Eye diagram for the optical output of a semiconductor laser directly modulated by a 5 Gbit/s pseudo-random bit stream.

The Modulation of Light Emitting Diodes

The light emitting diode (LED) generates light through spontaneous emission. A semiconductor p-n junction is pumped with a forward current, so that electrons are provided in the upper energy state that can recombine radiatively to produce incoherent light by a spontaneous emission mechanism. The rate of photon generation is directly proportional to the carrier injection rate, and hence the modulating drive current.

Figure 5 shows the typical light-current properties and the modulation characteristics of a LED. The responsivity of the LED, defined as the ratio of the emitted optical power to the injected current, is typically in the range of 10 to 50 μW/mA. The optical output power generated is linearly related to the injection (drive) current up to moderate currents, and is given by

$$P = \eta \cdot h\nu \cdot \frac{I}{q} \qquad [7]$$

where η is the emission quantum efficiency (defined as the ratio of the radiative recombination rate to the total recombination rate), h is Planck's constant, ν is the optical frequency, I is the injected current, and q is the electronic charge. For larger currents, the light output deviates from a proportional dependence on the current because of saturation effects and the responsivity decreases.

The modulation response of the LED is governed by the rate equation for the carrier density N

$$\frac{dN}{dt} = \frac{I}{qv_a} - \frac{N}{\tau_c} \qquad [8]$$

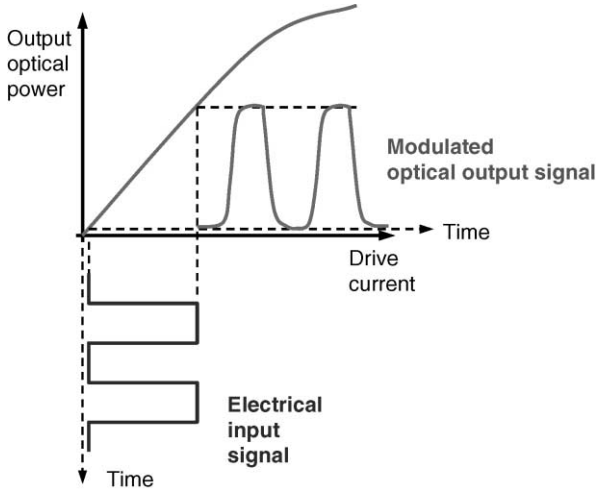

Figure 5 Light-current properties and the modulation characteristics of light emitting diodes.

where I is the injected current, q is the electronic charge, v_a is the volume of the active region, and τ_c is the carrier lifetime. Equation [8] expresses the fact that the rate of increase of carrier concentration is given by the rate of increase of carriers through current injection and the rate of carrier loss through radiative and nonradiative recombination. The small signal response arising from this first order differential equation, exhibits a simple single pole response and the resulting modulation bandwidth of the LED is given by

$$B = 1/(2\pi\tau_c) \qquad [9]$$

The pulse modulation response of the LED is shown in Figure 5. The output modulated optical waveform is not square but exhibits risetimes and falltimes determined by the carrier lifetime τ_c. This sets a limit to the maximum modulation rate that the LED can achieve. The bandwidth can be increased by decreasing the radiative lifetime, which can be controlled to a limited extent by the choice of doping level. Typical lifetimes for InGaAsP LEDs are in the range of 1–5 ns, which corresponds to attainable modulation data rates of several hundred Mbit/s.

The External Modulation of Lasers

Modulation of lasers realized by changing the injection current, as described above, is classed as direct modulation. This is the simplest method of modulation; however, it is limited by several physical phenomena. These include bandwidth limitations due to carrier dynamics in the laser active region, waveform limitations due to relaxation oscillations and overshoot effects, and chirping which causes transmission limitations in optical fibers arising from dispersion effects.

A superior modulation technique, classed as external modulation, operates the laser with continuous wave (CW) output and impresses the modulation by means of a device external to the laser. Although more complex, this approach has many modulation performance advantages. Because the laser is operated CW, this technique removes chirping effects and also enables higher power lasers to be used. Moreover, it is capable of much higher modulation bandwidths, larger on–off extinction ratios, and superior modulation spectral purity.

Electro-optic Modulation of Light

The linear electro-optic effect in materials was first described by Friedrich Pockels in 1893. The Pockels effect is the change in refractive index of the material

resulting from the application of an electric field, and is given by

$$n(E) = n - \frac{1}{2} r n^3 E \qquad [10]$$

where n is the refractive index, E is the applied electric field, and r is the electro-optic coefficient. Typical values of r lie in the range 10^{-12} to 10^{-10} m/V, and the most common electro-optic materials used include $LiNbO_3$, GaAs, InP, InGaAsP, and synthetic polymers such as polymethylmethacrylate (*see* **Modulators:** Electro-optics).

If light traverses an optical waveguide of length L, to which an electric field E is applied, it undergoes a phase shift given by

$$\Delta\phi = -\frac{\pi r n^3 E L}{\lambda} \qquad [11]$$

The electric field can be produced by applying a voltage V across the waveguide of width d, hence $E = V/d$. It is therefore possible to modulate the phase of the light by varying the voltage V that is applied to the material through which the light passes. The voltage required to produce a phase shift of π is given by

$$V_\pi = \frac{\lambda d}{n^3 r L} \qquad [12]$$

The parameter V_π, known as the half-wave voltage, is an important characteristic that expresses the applied voltage required to give a phase shift of π.

Intensity modulation of light can be obtained by placing the phase modulator in one arm of an optical interferometer. The structure, known as a Mach-Zehnder modulator, is shown in Figure 6a. The optical output is the phasor sum of two lightwaves that travel through the two arms, resulting in constructive or destructive interference depending on the optical phase difference. The electric field is applied to the optical waveguide in a direction perpendicular to the direction of light propagation using the metal electrodes, see Figure 6a. Hence the refractive index of the waveguide and thus the phase of the light can be modulated by varying the voltage V. When no voltage is applied, the optical fields in the two arms of the interferometer experience identical phase shifts, and hence interfere constructively at the output. When a voltage is applied, the waveguide index changes, and the light in that arm experiences a phase shift with respect to the light in the other arm. This destroys the constructive nature of the interference at the output, and reduces the transmitted light emitted at the output. The extreme

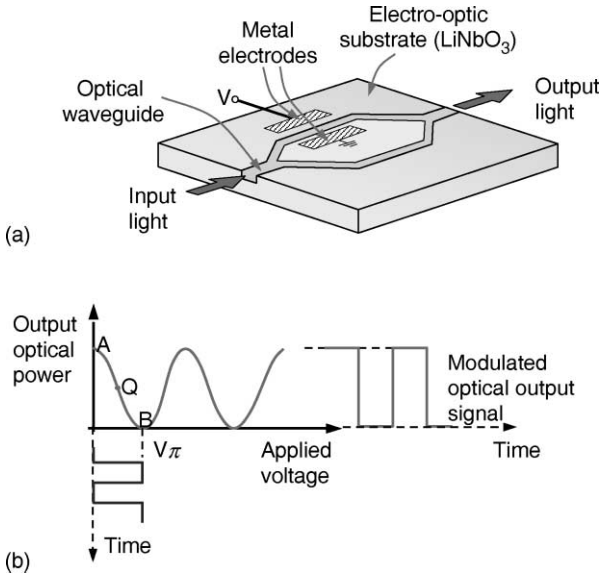

Figure 6 Mach-Zehnder electro-optic intensity modulator. (a) Structure; (b) transfer function and modulation characteristics.

case is when the phase difference between the two arms equals π, which causes complete destructive interference resulting in no light transmission.

The modulation transfer function is given by

$$P_{out} = \frac{1}{2} P_{in}[1 + \cos(\Delta\phi)] \qquad [13]$$

where $\Delta\phi$ is the phase difference encountered by light as it travels through the two arms. In terms of the applied voltage, the optical power transmitted through the modulator is given by

$$P_{out} = \frac{1}{2} P_{in}\left[1 + \cos\left(\pi \frac{V}{V_\pi}\right)\right] \qquad [14]$$

This transfer characteristic is shown in Figure 6b. The modulator may be operated as an analog optical modulator by operating in the nearly linear region around point Q. Alternately, it may be operated as a digital modulator by operating between points A and B, thus switching the light on and off as V is switched between 0 and V_π.

Improved efficiency of modulation, and hence a reduction in the value of V_π (typically a few volts) can be obtained by placing a second electrode on the other arm of the interferometer, and using a push-pull configuration to drive the interferometer. Hence the phase modulators in both arms are driven with modulating voltages of opposite polarities so the phase is advanced in one arm and is retarded in the other arm. This produces a net phase difference, which is double that produced in either arm.

The Pockels effect is an extremely fast physical mechanism, hence in principle external modulation is capable of achieving extremely high speeds. In practice, the modulation speed of an electro-optic modulator is limited by the capacitive effects at the electrodes and by the transit time of the light through the material. If the electric field varies significantly within the time it takes for light to transit through the waveguide, then the travelling optical wave will be subjected to different electric fields as it traverses the waveguide, and this results in a transit time limitation to the modulation bandwidth. A technique to avoid this limitation is to apply the voltage at one end of the waveguide and to design the electrodes to form a transmission line. By this means it is possible to make the velocity of the electrical wave match that of the optical wave to essentially eliminate the transit time effects. These external modulators have demonstrated speeds well in excess of 100 GHz.

Electro-absorption Modulation of Light

Electro-absorption external modulators are based on the principle of semiconductor bandgap decrease that occurs upon application of an electric field (the Franz-Keldysh and Stark effect). With no applied voltage, the semiconductor waveguide is transparent to light having a photon energy smaller than the bandgap, and such wavelengths are transmitted with very little attenuation. When a voltage is applied, the bandgap of the semiconductor decreases and the material absorbs the light once the photon energy exceeds the bandgap energy, and this produces optical attenuation. Hence by applying a modulation voltage to the semiconductor waveguide, the absorption property of the waveguide and hence the output light intensity can be modulated.

Improved modulation efficiency, and hence a reduction in the voltage required to decrease the bandgap energy, is obtained by using multiquantum-well semiconductor structures, which exhibit enhanced electro-absorption effects arising from the quantum confined Stark effect. The conventional technique of applying a transverse field across a multiquantum-well is to apply a reverse voltage across it. Modulator drive voltages of a few volts can be obtained. The on/off extinction ratio of modulation depends on the value of the field-dependent absorption coefficient at the operating voltage, and typical on/off extinction ratios are 10–15 dB.

The modulation bandwidth is determined by intrinsic factors related to carrier dynamics, such as exciton formation and dissociation times and the time taken to remove electrons and holes from the wells by thermionic emission and tunelling. It is also determined by extrinsic factors related to the capacitance of the junction diode. These modulators can have bandwidths of around 50 GHz. They also enable low chirp modulation to be obtained. The optical power handling capability of electro-absorption modulators is lower than for electro-optic modulators. However, a principal advantage of the electro-absorption modulator is that the semiconductor waveguide can be fabricated onto one substrate with the semiconductor laser, enabling the realization of monolithic integration on the same chip.

The Demodulation of Optical Signals

The process of demodulation converts the modulated intensity of an optical wave into an electrical signal to recover the information content. Semiconductor photodetectors are based on the principle of absorption of photons to generate mobile electron-hole pairs, and the transport of these mobile carriers via an applied electric field to create a flow of current.

Demodulation using PIN Photodiodes

The PIN photodiode comprises a P-doped/intrinsic/N-doped semiconductor structure. An applied reverse voltage bias creates a depletion region with a high electric field in the intrinsic layer. When the intrinsic layer is illuminated with light, photons are absorbed and electron-hole pairs are created, which are swept by the built-in electric field. The resulting flow of current is proportional to the incident optical power.

The quantum efficiency of the photodetector is defined as the ratio of electron generation rate to the photon incidence rate, and is given by

$$\eta = \frac{h\nu}{q} \cdot \frac{I_p}{P} \qquad [15]$$

where I_p is the photocurrent, P is the incident optical power, ν is the optical frequency, h is Planck's constant and q is the electron charge. If the width of the absorbing intrinsic region is large enough to capture all the light, quantum efficiency values approaching 100% can be achieved.

The current-voltage characteristics of the photodiode under optical illumination are shown in Figure 7a. The dark current I_d, which is the current generated in the photodetector in the absence of light originates from thermally generated electron-hole pairs, and is typically extremely small (<5 nA). Figure 7b shows the transfer characteristic of the

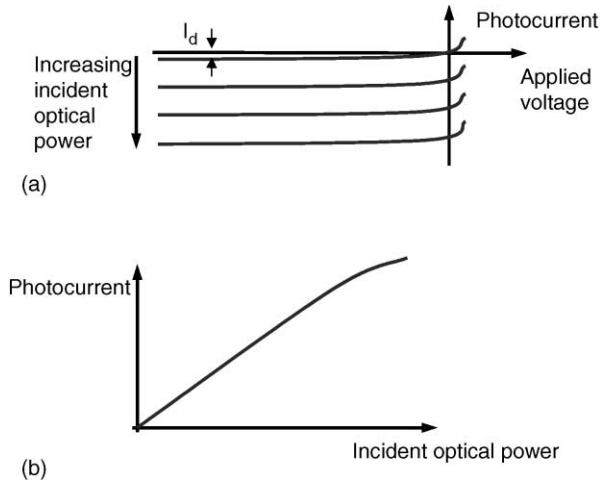

Figure 7 Semiconductor photodiode. (a) Current-light characteristics under optical illumination; (b) transfer function and demodulation photocurrent versus incident optical power.

photodetector. The current is linearly proportional to the optical power up to moderate power levels, when saturation mechanisms occur. The responsivity of the photodiode $\Re$, defined as the ratio of the generated electric current to the incident optical power, is given by

$$\Re = \frac{\eta q}{h\nu} \qquad [16]$$

The responsivity is an important parameter, and provides a measure of the photodetection efficiency of the device for demodulating optical signals. Typical responsivity values for PIN photodiodes are around 1 A/W.

The bandwidth B of demodulation of the photodetector is determined by the speed with which it responds to variations in the incident optical power. This is limited by the transit time τ_{tr} and the RC time constant τ_{RC} and is given by

$$B = \frac{2\pi}{\tau_{tr} + \tau_{\mathrm{RC}}} \qquad [17]$$

The transit time limitation arises because of the time it takes for the generated carriers to traverse the absorption region and be collected. To maximize the bandwidth, the transit time needs to be reduced, which can be achieved by decreasing the width of the absorption region. However, this requires a trade-off with the responsivity, which drops because a smaller fraction of the light can be absorbed under these conditions. The capacitance C and the resistance R of the photodetector and its circuitry form the RC time constant. To maximize the bandwidth, the photodiode capacitance needs to be reduced by decreasing the area of the photodiode. The demodulation bandwidth of PIN photodiodes can exceed 100 GHz.

Photodetection shot noise is a fundamental noise mechanism that introduces noise in the demodulation process of optical signals. This leads to fluctuations in the photocurrent, even for a constant incident optical power, because the photocurrent actually consists of a stream of electrons that are generated at random times. The photodiode current generated by a constant incident optical power is given by

$$I(t) = I_{\mathrm{avg}} + i_{\mathrm{shot}}(t) \qquad [18]$$

where I_{avg} is the average photocurrent generated, and $i_{\mathrm{shot}}(t)$ is the current fluctuation due to shot noise and which is described by a stationary random process with Poisson statistics. The mean-square noise current is given by

$$< i^2_{\mathrm{shot}}(t) >= 2qI_{\mathrm{avg}}\Delta f \qquad [19]$$

where Δf is the effective noise bandwidth of the receiver. The shot noise degrades the signal to noise ratio of the demodulated signal, and causes a fundamental limit to the sensitivity of the PIN photodetection.

Demodulation using Avalanche Photodiodes

Demodulation using avalanche photodiodes detectors (APD) has the advantage of significantly increased responsivity. This is achieved by providing an internal current gain mechanism within the device. The APD operates by generating more than one electron-hole pair per absorbed photon. This is achieved by strongly reverse biasing the diode to create a large junction electric field, so photoelectrons accelerate and acquire enough energy to produce new carriers by the process of impact ionization. These devices incorporate a modification to the PIN structure, by including an additional doped layer known as the multiplication layer, which under reverse bias provides a region of very high electric field that can produce avalanche breakdown. Hence a single primary electron generated through absorption of a photon, generates many secondary electrons and holes in the avalanche multiplication layer, and all these secondary carriers contribute to the photocurrent. As a result of this current gain mechanism, the responsivity of the APD is increased by a multiplication factor M, and is given by

$$\Re_{ADP} = \frac{M\eta q}{h\nu} \qquad [20]$$

where M can range between 5–50 depending on the bias voltage.

The bandwidth of the APD depends on the multiplication factor M. This is because the avalanche process takes additional time. The frequency response can be written

$$M(\omega) = \frac{M_0}{[1 + (\omega\tau_e M_0)^2]^{\frac{1}{2}}} \qquad [21]$$

where M_0 is the low frequency gain and τ_e is the effective transit time that depends on the ionization coefficient. The intrinsic APD bandwidth (assuming no RC limitations) is approximately given by

$$B_{\text{APD}} = \frac{1}{2\pi\tau_e M_0} \qquad [22]$$

Hence the bandwidth decreases as the multiplication factor increases, and there exists a trade-off between the bandwidth and the responsivity. The demodulation characteristics of the avalanche photodiode can be expressed by means of a gain-bandwidth product $B_{\text{APD}} \cdot M_0$, and this can exceed 150 GHz.

Photodetection noise in APDs has an additional contribution because the avalanche gain itself is a random variable. Hence the secondary electron-hole pairs are generated at random times and this adds a noise component to the basic shot noise associated with the generation of primary electro-hole pairs. The total shot noise is given by

$$< i^2_{\text{shot,APD}}(t) >= 2qM^2F(M)I_{\text{avg}}\Delta f \qquad [23]$$

where $I_{\text{avg}} = \Re P$, and F is the excess noise factor expressed by

$$F = \frac{< M^2 >}{< M >^2} \qquad [24]$$

and is approximately given by $F \approx M^x$, where $0.2 < x < 1$. Hence the excess noise increases with the multiplication ratio, so there exists an optimum avalanche photodiode gain that maximizes the signal to noise ratio of the demodulated signal. Despite the fact that additional noise is introduced, because of the higher responsivity, APDs can provide higher sensitivity in demodulating optical signals than PIN photodiodes.

Demodulation using Metal-Semiconductor-Metal (MSM) Photodiodes

Demodulation using MSM photodiodes enables extremely high bandwidths to be achieved. The MSM photodiode comprises two reverse-biased metal-to-semiconductor Schottky contacts formed on a semiconductor layer that prevents flow of electrons from metal to semiconductor. Photons incident between the contacts create electron-hole pairs that are collected by the electric field to generate a photocurrent proportional to the incident optical power. The metal contacts are usually fabricated on the same side of the semiconductor to create a planar structure, which is suitable for monolithic integration. However, a drawback of the MSM device is that the electrodes block some of the light from reaching the absorption region, which results in a reduced responsivity.

The bandwidth of demodulation of the MSM photodiode is determined by the transit time of the photogenerated carriers and the RC time constant. Since the electrode spacing can be around 1 μm, the transit time is extremely small. Moreover, since in the planar structure the parasitic capacitance is inherently low, the RC time constant is also extremely small. This results in demodulation bandwidths of up to 300 GHz.

Wavelength Selective Demodulation

A technique to obtain both wavelength selective demodulation and high-speed, high-responsivity demodulation involves the use of microcavity resonant photodetectors. This is useful for very high-speed detection in wavelength multiplexed systems.

The microcavity photodiode comprises a Fabry-Perot cavity placed around the photodetector absorption region, to enhance the responsivity. The mirrors are typically formed using Bragg reflectors or dielectric mirrors implemented in the semiconductor. A resonance is built up in the cavity at the wavelengths of incoming light for which the round-trip phase shift is 2π, which corresponds to constructive interference. Hence at the resonant wavelength, the incoming light is reflected at the two mirrors and permits the absorbing layer to be reused many times by effectively recirculating the optical signal, thus enhancing the absorption and the responsivity. However, the transit length can remain extremely small, because the photogenerated carriers only have to traverse the thickness of the absorption region to be collected. This solves the problem of the fundamental responsivity-bandwidth trade-off in normal photodetectors, in which increasing the absorption layer width to increase responsivity increases the transit time thus reducing the bandwidth. Microcavity resonant photodiodes enable the simultaneous achievement of large bandwidth and high responsivity possible. Also, the resonant

behavior leads to wavelength selectivity, which can be used to advantage in some wavelength division multiplexed WDM applications (*see* **Optical Communication Systems**: Wavelength Division Multiplexing). This approach can provide demodulation of optical signals with quantum efficiencies close to 100% and with bandwidths in excess of 100 GHz.

Optical Receivers – Preamplification and Clock Recovery

The front end of an optical receiver comprises the photodiode and a preamplifier to amplify the electrical signal for further processing. In order to obtain a high demodulation bandwidth, it is important to minimize the photodetector capacitance and to minimize the input resistance of the preamplifier that acts as the load resistance. However, because the thermal noise current is inversely proportional to the load resistance, minimizing the load resistance causes excessive noise and degraded demodulation sensitivity. An alternative approach is to use a high-impedance preamplifier. This reduces the noise at the price of a lower bandwidth. Thus there is a trade-off between the bandwidth and sensitivity. The trans-impedance front-end, in which the load resistor is connected as a feedback resistor around an inverting amplifier, is often used as an optimum compromise that combines high sensitivity together with large bandwidth. This enables the use of a large resistance, which minimizes noise, but at the same time the effect of negative feedback reduces the input impedance by a factor equal to the amplifier gain, thus increasing the bandwidth.

In digital optical transmission systems the data recovery section of the optical receiver comprises a clock recovery circuit and a decision circuit. Accurate timing (clock) information about the bit slot, in order to synchronize the decision process, is obtained from the amplified front-end waveform using a timing extraction circuit (*see* **All-Optical Signal Regeneration**). Typical clock recovery circuits comprise a high-Q resonant circuit which rings at the bit rate frequency or a phase locked loop. This enables precise data time sampling in the following decision circuit within the bit intervals of the original pulse train.

NONCLASSICAL LIGHT

Introduction

The pioneering experiments by Hanbury-Brown and Twiss, and the subsequent development of the quantum theory of electromagnetic radiation by Glauber and Sudarshan, raised the interest in the question of photon statistics. It followed from their theories that states of the electromagnetic field which can only exist in a quantum treatment. These nonclassical states show up in photon statistics through the phenomenon of antibunching. Later, further nonclassical states of the radiation field were found in the so-called squeezed fields, which are fields with phase-sensitive quantum fluctuations being at certain phase angles smaller than those of a perfect classical coherent field. In order to achieve squeezing of laser radiation, various forms of nonlinear optical interactions can be used.

Classical Versus Quantum Waves

In classical electrodynamics, a monochromatic wave (e.g., an extended light beam) is often described using the complex representation:

$$E(r,t) = E^{-}(r,t) + E^{+}(r,t) = \frac{1}{2}[\varepsilon(r,t)\mathrm{e}^{-\mathrm{i}\omega t} + \varepsilon^{*}(r,t)\mathrm{e}^{\mathrm{i}\omega t}] \qquad [1]$$

In classical theory, this complex description is merely a tool for the simplification of some calculations. However, there is some physical significance when using the quantum description, where ε and ε^{*} lead to the lowering and raising operators of the field. The above field can also be represented in the following way:

$$E(r,t) = \frac{\varepsilon + \varepsilon^{*}}{2}\cos\omega t + \frac{\varepsilon - \varepsilon^{*}}{2}\sin\omega t \qquad [2]$$

with real coefficients $\varepsilon_1 = (\varepsilon + \varepsilon^{*})/2$ and $\varepsilon_2 = (\varepsilon - \varepsilon^{*})/2\mathrm{i}$. This description gives the state of the field in a two-dimensional phase diagram where the sin-component is plotted versus the cos-component. In this plot, the wave above is represented by one point giving phase and amplitude of the field. These phase diagrams will play an important role in characterizing the nonclassical fields in a quantum phase diagram, as discussed below.

The properties of a field are described by the first- and second-order correlation functions. The first-order correlation function is given by

$$G^{(1)}(r_1,t_1,r_2,t_2) = \langle \varepsilon^{*}(r_1,t_1)\varepsilon(r_2,t_2)\rangle \qquad [3]$$

It is obtained by multiplying the electric field amplitudes at two spacetime points and taking the ensemble average. For $r_1 = r_2$ and $t_1 = t_2$, $G^{(1)}$ is proportional to the intensity at this point and is, therefore, called the first-order in intensity. The first-order correlation function is connected to the spectrum $I(\omega)$ of the field through its Fourier transform.

The second-order correlation function is necessary to characterize the radiation field completely. It describes the intensity fluctuations, being the classical equivalent to photon statistics, and is given in the general form:

$$G^{(2)}(r_1,t_1,r_2,t_2,r_3,t_3,r_4,t_4) = \langle \varepsilon^{*}(r_1,t_1)\varepsilon^{*}(r_2,t_2)\varepsilon(r_3,t_3)\varepsilon(r_4,t_4)\rangle \qquad [4]$$

If $G^{(2)}$ is considered for two spacetime points $r_1 = r_2$, the connection to intensity fluctuations becomes obvious:

$$G_{\mathrm{I}}^{(2)}(\tau) = 4\langle I(t_1)I(t_2)\rangle = \langle \varepsilon^{*}(t_1)\varepsilon(t_1)\varepsilon^{*}(t_2)\varepsilon(t_2)\rangle \qquad [5]$$

The subscript I indicates that we have to deal with intensity correlations; τ stands for $t_2 - t_1$.

In connection with the Hanbury-Brown, Twiss experiment, in general, the normalized intensity correlation is given by

$$g_{\mathrm{I}}^{(2)}(\tau) = \langle I(t)I(t+\tau)\rangle / \langle I(t)\rangle^2 \qquad [6]$$

$I(t)$ stands for the intensity which is given by the mean value $\langle I(t)\rangle$ plus fluctuations $\Delta I(t)$ for which the mean value is zero. The mean value of the squared intensity is then $\langle I^2\rangle = \langle I\rangle^2 + \langle \Delta I^2\rangle$. It follows for the normalized intensity correlation function:

$$g_{\mathrm{I}}^{(2)}(\tau) = \langle I(t)I(t+\tau)\rangle / \langle I(t)\rangle^2 = \begin{cases} 1 + \langle \Delta I^2\rangle / \langle I\rangle^2 & \text{for } \tau = 0 \\ 1 & \text{for } \tau \to \infty \end{cases} \qquad [7]$$

For $\tau \to \infty$, the intensities are not correlated and $g_{\mathrm{I}}^{(2)}(\tau)$ becomes 1. Otherwise $\langle \Delta I^2\rangle / \langle I\rangle^2 \geq 0$; this means that $g_{\mathrm{I}}^{(2)}(\tau)$ is always equal to or larger than 1, and $g_{\mathrm{I}}^{(2)}(\tau)$ smaller than 1 is not possible classically. The photon correlation is usually measured by the classical Hanbury-Brown, Twiss setup shown in Figure 1.

The maximum of $g_{\mathrm{I}}^{(2)}(\tau)$ at $\tau = 0$ is called intensity bunching and was first observed by Hanbury-Brown and Twiss. The decrease of $g_{\mathrm{I}}^{(2)}(\tau)$ as a function of τ is a measure of the coherence length of the light source.

When the experiment in Figure 1 is considered in the photon picture there is a principal difference compared to the classical intensity. In the classical case, the intensity on the two detectors is the same if the beamsplitter is dividing the light beam in equal portions. Both detectors, therefore, measure the same fluctuations. In the quantum picture, however, a photon can only be detected in one of the two detectors; this leads to the result that values for $g_{\mathrm{I}}^{(2)}(\tau)$ smaller than 1 can be found. The effect of photon bunching was initially thought to be an inherent property of light owing to the boson nature of photons. Therefore, it came as a big surprise when Glauber showed theoretically that for the quantized radiation field $g_{\mathrm{I}}^{(2)}(\tau)$, <1 is possible. This effect, known as photon antibunching, and its experimental observation constitutes an unambiguous proof of the quantum nature of light.

In the quantum description of the electromagnetic field, the electric field amplitudes ε and ε^* are replaced by $\hat{a}$ and $\hat{a}^+$, the photon annihilation and creation operators.

In this case, the electric field operator is written as

$$\hat{E} \propto \frac{\hat{a} + \hat{a}^+}{2} \cos\omega t \, \frac{\hat{a} - \hat{a}^+}{2\mathrm{i}} \sin\omega t \qquad [8]$$

In analogy, the operators $\hat{a}_1 = (\hat{a} + \hat{a}^+)/2$ and $\hat{a}_2 = (\hat{a} - \hat{a}^+)/2\mathrm{i}$, can be defined describing the amplitude of the cosine and sine parts of the wave. $\hat{a}_1$ and $\hat{a}_2$ do not commute $[\hat{a}_1, \hat{a}_2] = (\mathrm{i}/2)1$, therefore, the expectation values of the two operators $\hat{a}_1$ and $\hat{a}_2$ underlie an uncertainty relation given by

$$\langle \Delta\hat{a}_1^2\rangle = \langle \hat{a}_2^2\rangle - \langle \Delta\hat{a}_i\rangle^2 \geq 1/16 \qquad [9]$$

with $\langle \Delta\hat{a}_i^2\rangle = \langle \hat{a}_i^2\rangle - \langle \Delta\hat{a}_i\rangle^2$. In the corresponding phase diagram, the expectation values for $\hat{a}_1$ and $\hat{a}_2$ are represented by a shaded area defined by the uncertainty (Figure 2). The state of the radiation field, where both phase and amplitude fluctuations are symmetrically minimized, $\langle \Delta\hat{a}_1^2\rangle = \langle \Delta\hat{a}_2^2\rangle = \frac{1}{4}$, best approximates the classical wave with well-defined phase and amplitude. The state with symmetrical minimum uncertainty is the coherent state describing laser radiation. It is an eigenstate of $\hat{a}$ with a photon number fluctuation given by a Poissonian distribution with $\langle \Delta n^2\rangle = \langle n\rangle$.

There are other minimum uncertainty states, however, with unsymmetrical uncertainty regions

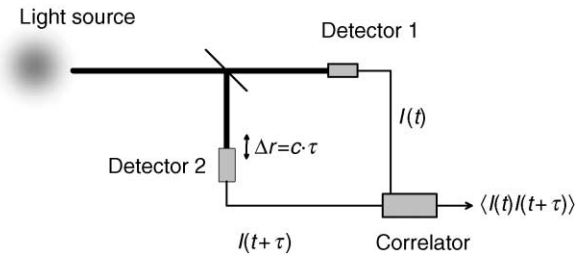

Figure 1 Experimental setup for the Hanbury-Brown, Twiss experiment.

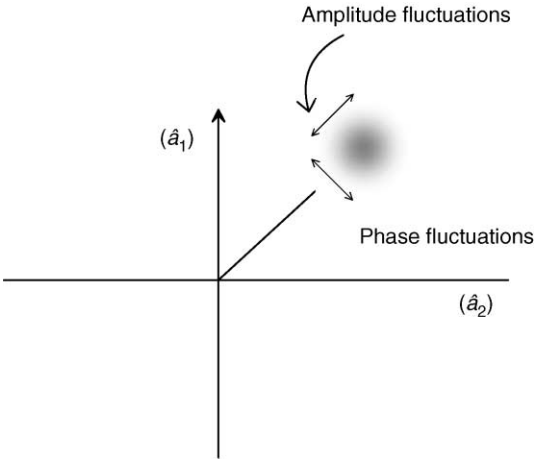

Figure 2 Phase diagram of the quantum mechanical field amplitudes $\langle \hat{a}_1\rangle$ and $\langle \hat{a}_2\rangle$ for coherent radiation.

with the uncertainty squeezed into mainly one component. These states, which are called squeezed states, are defined by $\langle \Delta \hat{a}_1^2 \rangle < 0.25$ or $\langle \Delta \hat{a}_2 \rangle < 0.25$. Squeezed state may also refer to a state which is not a minimum uncertainty state but where, nevertheless, the mean square fluctuation in one of the two components is less than 0.25.

A classical electromagnetic field consists of waves with well-defined amplitude and phase. This is not the case in a quantum treatment: fluctuations are associated with both conjugate variables. The case of a coherent state that most nearly describes a classical electromagnetic field has an equal amount of uncertainty in the two variables (when normalized to the field of a single photon). Equivalently, the field can be described in two conjugate quadrature components and the uncertainties in the two conjugate variables satisfy an uncertainty relation. The coherent state represents a minimum uncertainty state with equal uncertainties in the two quadrature components. This case is usually called the shot-noise limit; it is represented in Figure 2 as a phase diagram.

In a quantum treatment of radiation, it is also possible to generate states that are not present in the classical limit. They can show fluctuations reduced below the classical limit in one of the quadrature components, while the canonically conjugate quadrature component must display enhanced fluctuations in order to fulfill the uncertainty relation. Those states are called 'squeezed states.' An electromagnetic field with fluctuations below the standard quantum limit in one of the quadrature components has, in principle, many attractive applications, for example, in optical communication, in precision and sensitive measurements such as gravitational wave detection, or in noise-free amplification. Therefore, there has been great interest in generating squeezed radiation. Optical measurements have three characteristics that enable them to reach the quantum noise level more readily than in other fields of physics: (i) optical signals are naturally immune to external sources of noise; (ii) thermal noise at room temperature is negligible in the optical domain; and (iii) the outstanding equalities of the optical sources and detectors allow a very-low-level instrumental noise.

Squeezed states with reduced photon number fluctuations (sub-Poissonian photon statistics) correspond to a light beam in which the photons arrive more equally spaced than in a coherent beam for which $g_I^{(2)}(0) = 1$. Therefore, sub-Poissonian number fluctuations correspond to photon antibunching. This shows that photon antibunching and squeezing are related. The state with the largest possible antibunching is the number state, represented by a circle in the phase diagram. It has large fluctuations in both components a_1 and a_2 and, therefore, is not a squeezed state. Thus, it is obvious that antibunching does not imply squeezing. On the other hand, weak squeezing of a coherent state may result in antibunching. If the state is squeezed harder the a_1 component will be better defined. The amplitude fluctuations, however, will start increasing and there will be a transition from antibunching to bunching.

The quantum calculation of the normalized second-order correlation function leads to the following result:

$$g_I^{(2)}(0) = 1 + (\langle \Delta n^2 \rangle - \langle n \rangle / \langle n \rangle^2) \qquad [10]$$

A pure number state of the radiation field with $\langle \Delta n^2 \rangle = 0$, leads to $g_I^{(2)}(0) < 1$, as discussed above. For a coherent state, $\langle \Delta n^2 \rangle = \langle n \rangle$ yielding $g_I^{(2)}(0) = 1$, corresponding to the classical calculations.

It can be concluded that although antibunching and squeezing are related and nonclassical phenomena, one does not imply the other. Thus, the detection schemes necessary to determine the existence of one or the other are quite different. Antibunching or sub-Poissonian statistics can be detected via intensity correlations. Squeezing, on the other hand, is a property of either $\langle a_1 \rangle$ or $\langle a_2 \rangle$, and phase sensitive homo- or heterodyne detection is needed.

Nonclassical states of the radiation field are very sensitive to linear attenuation. Coherent and thermal light fields are the only ones that do not change their photon statistics when attenuated. This is different for nonclassical light. The change depends on the particular case and has to be carefully evaluated.

The first observation of squeezing was achieved in 1985, in an experiment of parametric generation involving four-wave mixing in sodium vapor.

Nonclassical Light from a Single Atom

Resonance fluorescence of atoms is a basic process in radiation–atom interactions, and has therefore always generated considerable interest. The methods of experimental investigation have changed continuously due to the availability of new experimental tools. A considerable step forward occurred when tunable and narrowband dye laser radiation became available. These laser sources are sufficiently intense to easily saturate an atomic transition. In addition, the lasers provide highly monochromatic light with coherence times much longer than typical natural lifetimes of excited atomic states. Excitation spectra with laser light using well-collimated atomic

beams lead to a width, being practically the natural width of the resonance transition, therefore it became possible to investigate the frequency spectrum of the fluorescence radiation with high resolution and to also study the photon statistics of the fluorescent light.

Previous experiments to investigate antibunching in resonance fluorescence have been performed by means of laser-excited collimated atomic beams. The initial results obtained in 1977 showed for the second-order correlation function $g^{(2)}(t)$, a positive slope characteristic of photon antibunching, but $g^2(0)$ was larger than $g^2(t)$ for $t \to \infty$. This was due to number fluctuations in the atomic beam and to the finite interaction time of the atoms. In 1978, the analysis of the experiment was refined and in 1982, another experiment with a longer interaction time was performed. In the latter experiment, the photon correlation was also measured for very low laser intensities. The ideal experiment to study the photon statistics in resonance fluorescence is the investigation of a trapped ion since, in such an experiment, the fluctuations of the atomic number are excluded.

The fluorescence of a single ion should also display the following property. The probability distribution of the photon number recorded in a finite time interval t is narrower than Poissonian, which means, that the variance is smaller than the mean value of the photon number. This is because the single ion can only emit a single photon. Antibunching and sub-Poissonian statistics are often associated. They are, nevertheless, distinct properties and need not necessarily be simultaneously observed, as is the case in the experiment described here. Although there is evidence of antibunching in the atomic-beam experiments, the photon counts are not sub-Poissonian as a result of fluctuations in the number of atoms. In further experiments this effect was excluded by use of a special trigger scheme for the single-atom event. In the setup with a trapped ion these precautions are not necessary since there are no fluctuations in the atomic number. Figure 3 shows the photon correlation of a single trapped ion. The measurements are performed using the $3^2S_{1/2} - 3^2P_{3/2}$ transition of the $^{24}Mg^+$-ion at a wavelength of 280 nm. The laser is tuned slightly below resonance in order to Doppler-cool the secular motion of the ion.

The investigation of the photon correlation employed the ordinary Hanbury-Brown and Twiss setup with two photomultipliers and a beamsplitter (Figure 1). The time delay τ between the photomultiplier signals was converted by a time-to-amplitude converter into a voltage amplitude proportional to the time delay. A delay line of 100 ns

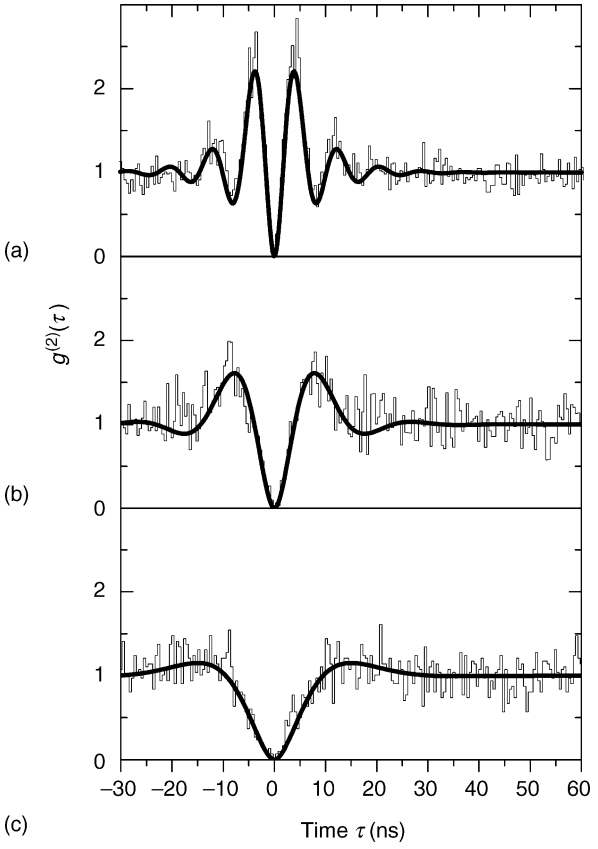

Figure 3 Antibunching signals of a single $^{24}Mg^+$-ion for different laser intensities (decreasing from (a) to (c)). At larger intensities (a) and (b) the Rabi oscillations owing to a strong coherent coupling between ground and excited state are observed.

in the stop channel allowed for the measurement of $g^{(2)}(\tau)$ for both positive and negative τ in order to check the symmetry of the measured signal. The output of the time-to-amplitude converter was accumulated by a multichannel analyzer in pulse height analyzing mode. Three typical measurements, each at small values of the laser intensity but with different detunings, are shown in Figure 3. The solid curve is a theoretical fit to the measurements. For small time delays (<20 ns), the nonclassical antibunching effect is observed, superimposed with Rabi oscillations being damped out with a time constant corresponding to the lifetime of the excited state.

Recently it also became possible to combine a trapped ion with a cavity. In this way the emission of a photon in the cavity mode can be achieved. This leads to a directed emission of the photon being more efficient than the fluorescence occurring in the entire 4π geometry. In this way, a deterministic single photon source is obtained.

Survey on the Experiments on Squeezing

In order to produce squeezed light from nonlinear optical phenomena, a variety of methods has been used, depending on the type of nonlinearity and the number of interacting modes involved. The choice of optical nonlinearity reduces to either three-wave or four-wave mixing, leading to quadratic or cubic nonlinear response functions, respectively. Each of these methods has advantages and disadvantages. Three-wave mixing requires a pump field at twice the frequency of the field-mode being squeezed. However, it has the advantage as any sidebands induced on the pump, owing to phase noise, have a large frequency offset from the squeezed fields. The other method, the much simpler four-wave mixing, does not require any frequency-doubling step. This was, therefore, the first method used to obtain squeezing with quadrature noise below the vacuum level.

Most of the early experiments on squeezing were performed with one or two cavity modes with the squeezed modes being transferred to propagating external modes via beamsplitters for measurement. This narrowband procedure is followed in more recent experiments commonly used for three-wave (parametric) squeezing. Also squeezing in waveguides was achieved leading to a relatively simple and broadband implementation of squeezing, with, mostly a four-wave mixing with short pulses or solitons being performed.

The main limiting factors that remain include control over the driving laser phase and intensity noise, absorption in the dielectric material and associated devices, and phase fluctuations caused both by low-frequency technical noise in components, and by intrinsic material properties of phonon interactions and refractive index fluctuations. It appears not impossible to reach squeezing levels of 10 dB or more below shot noise, over bandwidths of up to 1 THz. At this level of noise reduction, the main problem is the issue of improving detector technology to allow such low noise levels to be investigated.

Squeezing in Lasers

The quantum noise properties of the laser were studied intensively after its invention in the early 1960s. The conclusion of these studies is that the laser output approaches quite closely the noise properties of a coherent state, provided the laser is operated well above threshold. That is, the spectral variance of the photon number and phase fluctuations at high enough Fourier frequencies will be at the Poissonian or quantum noise limit (also referred to as the shot noise level). On the other hand, the phase of the laser is unconstrained and drifts as a function of time, so-called laser phase diffusion. As a result, the phase fluctuations show excess noise at low frequencies.

In the early 1980s, it was realized that if the pumping mechanism for the laser could be made sub-Poissonian then amplitude squeezing could be obtained at low frequency. A few years later it was shown that sub-Poissonian pumping could be realized in semi-conductor lasers by regularizing the pump current. An experimental demonstration of amplitude squeezing from semi-conductor lasers was soon achieved. Although still requiring rather specialized lasers, many groups now routinely obtain squeezing from semi-conductor lasers.

There are a number of disadvantages to semi-conductor lasers, including their poor beam quality and short coherence length. As a result, interest in other possible squeezing mechanisms continues. It has been found that intrinsic dynamical effects can also lead to amplitude squeezing in the laser output.

Laser squeezing is of a different character to that produced by more 'traditional squeezers.' For example, in parametric amplification, the de-amplification of phase fluctuations is accompanied by an equal and opposite amplification of amplitude fluctuations which preserves the uncertainty relationship between them. However, in laser squeezing the reduction in amplitude fluctuations is not linked to any increase in phase fluctuations. Thus, in laser squeezing we take advantage of the fact that the laser output is not in a minimum uncertainty state to suppress amplitude noise. This means that laser squeezing is always amplitude or intensity squeezing.

Application of Nonclassical Light

The applications of nonclassical light are numerous. The single photon sources discussed above have their main applications in quantum communication with single photons where they may be used to establish secure signal transmission. There is also a decisive advance in the field of quantum information expected from the combination of local atomic quantum processing with photonic transmission of quantum states. Conceptually, new possibilities would arise to enhance quantum computational capabilities. For example, separate local quantum processors of moderate size could be linked in a quantum network, with quantum information being exchanged by means of photons.

Although a large number of phenomena have been predicted in which the quantum nature of the squeezed vacuum plays an essential role in modifying

atomic properties, only the linear dependence of the two-photon absorption rate of a three-level ladder atom has been confirmed experimentally but classical sources show a quadratic dependence. In 1998 an important series of experiments was reported which investigated the interaction of a beam of Cs atoms with squeezed light in the Fabry–Perot cavity environment. The principal phenomena examined were the modification of the transmission spectrum of a weak, tunable probe beam due to the presence of the squeezed light, and the variation of the transmission modulation with the phase of the squeezed vacuum relative to that of an applied, saturating, coherent field.

There have been many proposed practical applications of squeezed light, and some experiments have already demonstrated its potential in precision measurements and improvement of spectroscopic sensitivity. Squeezed light may be used in optical communications to enhance signal-to-noise ratio, gravitational wave detection, and quantum nondemolition measurements.

The wider applications of squeezed light are numerous. An idea of the range and variety of applications is provided by the following selection: the protective measurement of a single squeezed harmonic oscillator state, coherent nonlinear spectroscopy using number squeezed light, the improvement of quantum nondemolition measurements using a squeezed meter input, sub-shot-noise Doppler anemometry with amplitude squeezed light, noiseless transfer of nonclassical light through bistable systems, generation of few photon states from squeezed atoms, and spin squeezing in a collection of atoms illuminated with squeezed light.

Einstein–Podolsky–Rosen (EPR) Correlations and Entanglement of Photons

In 1986, a quantum nondemolition experiment confirming the quantum correlation of the quadrature phase amplitudes of two spatially separated fields, was reported. In 1987, two-mode squeezing with two spatially separated detectors was experimentally demonstrated using parametric oscillation. With the experimental realization of such two-mode squeezing and quantum nondemolition measurements, the possibility of testing for continuous variable EPR-type correlations became apparent. In these proposals, the conjugate 'position' and 'momentum' observables would be the two orthogonal quadrature phase amplitudes of the field. The high efficiency of detectors used in the quadrature phase amplitude squeezing experiments was an important issue in this connection. Experimental tests of EPR correlations at the time were based on Bohm's version of the EPR paradox, and in fact, focused on Bell's extension of this work. These tests involved measurements performed on individual photon pairs, and used very inefficient detectors.

A specific proposal and a criterion to demonstrate the continuous variable EPR correlations for real experiments by way of a realization of the 1935 EPR paradox, was put forward in 1989. This proposal employed the two-mode squeezed state as the EPR source. The first experimental achievement, using the parametric oscillator, of the 1989 EPR criterion, for efficient measurements with continuous variable outcomes, was reported in 1992.

The EPR fields have proved significant in enabling the experimental realization of continuous variable quantum teleportation, and may have application also to quantum cryptography. Again, because of the efficient nature of the measurement of field quadrature phase amplitudes, and the intrinsic macroscopic nature of the correlated fields, continuous variable teleportation and cryptography may provide large advantages over protocols using a finite number state basis, where signals of individual photons are sent. At the moment, several groups are working in this promising direction.

Conclusions

In this contribution the generation of nonclassical light was reviewed. The generation of nonclassical light became possible after stable and reliable laser sources were available. There are many sources of nonclassical light available now. It is clear that we will see many new applications in the future. Especially in connection with optical communication, rather interesting improvements can be expected.

NONLINEAR OPTICS AT THE CRITICAL FIELD LIMIT

G A Mourou, University of Michigan, Ann Arbor, MI, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

It is now possible to produce, with compact lasers, intensities so large that the relativistic character of the electrons dominates laser–matter interactions. This is a fundamentally new regime in optics where optics, confined to the study of eV characteristic phenomena, are now addressing phenomena with characteristic energies vastly greater in the MeV–GeV (TeV in the near future) range. With relativistic optics, the field of nonlinear optics found a number of novel applications, including fast ignition of inertially

compressed fusion target, bright sources of energetic electrons, protons, ions, positrons, pions, etc., but also nuclear physics, high energy physics, astrophysics, and general relativity.

Relative optics has been one of the most active fields of optics and it is impossible to describe all the applications here. So, this new regime will be illustrated with few examples of the key relativistic mechanisms – reminiscent of conventional nonlinear optics, such as relativistic harmonics, relativistic optical rectification (wake-field acceleration), and relativistic self-focusing in refraction and reflection. We finally show that relativistic optics offers a new and efficient gateway to attosecond physics and nonlinear quantum electrodynamics (QED).

Optics is the study of how electrons respond to light. All material optical properties are the consequence of how light interacts with electrons in materials. Because, in the visible regime the photon energy is of the order of 1 eV, optics deals with phenomena with eV characteristic energy. Light is a wave composed of coupled electric and magnetic fields oscillating in synchrony at high frequencies. The electric and magnetic field oscillate perpendicular to each other, and perpendicular to the direction of propagation, k. Because of the electric field E, electrons under the action of the Lorentz force, $F = eE$, moves a distance $x = a_1 E$ transversally to the propagation direction. In classical optics, the oscillation amplitude x is small compared to the wavelength, and the electrons oscillate and radiate at the laser frequency. The radiated field amplitude and phase depend on how the electron is bound to the atom of the material. The invention of the laser in 1960 gave access to much larger intensities and electromagnetic fields. The laser field became strong enough that the electron displacement, x, in this field could no longer be considered as strictly proportional to the laser field. This departure from linearity is addressed by the addition of new terms in the Taylor series expansion of the displacement:

$$x = a_1 E + a_2 E^2 + a_3 E^3 + \cdots \qquad [1]$$

These additional terms are responsible for all the effects that form the field of nonlinear optics. Note here that the field is still not strong enough to ionize an electron from its parent atom and is therefore below the field that could irreversibly damage the material. Thus, the typical intensity must be kept to a value of less than $\sim 10^{14}\,\mathrm{W/cm^2}$, where the quiver energy E_Q starts to challenge the ionization energy of a few eV, depending on the material:

$$E_Q = \left\langle \frac{e^2 E^2}{4m\omega^2} \right\rangle \qquad [2]$$

The bracket denotes the time average over one cycle and ω is the laser angular frequency. Above this limit, the material response is dominated by multiphoton ionization or tunneling, as shown in Figure 1. During the ionization event, high harmonics are produced. Note here again that because the electron is still bound to its nucleus during the emission, we can consider the process of high harmonic generation as bound-electron nonlinear optics. As the intensity increases from 10^{14} to $10^{18}\,\mathrm{W/cm^2}$ (Figure 1), we are entering the regime of relativistic intensity or relativistic nonlinear optics. This is a regime that was predicted and discussed in the 1960s but that could be accessed only after the technique of chirped pulse amplification (CPA) was demonstrated, followed by significant progress in the areas of short pulse generation and pulse focusing.

Relativistic Optics

In classical optics one always assumes that during a laser oscillation period the electron mass m_0 stays constant. It is a reasonable assumption since the quiver velocity v of the electron is small compared to the speed of light c. As the intensity is increased a point is reached where the electron quiver velocity approaches the speed of light. This has several implications; first, the mass of the electron changes to become

$$m = \gamma m_0 \qquad [3]$$

where γ is the Lorentz factor given by

$$\gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1} \qquad [4]$$

Second, because v is close to c, the magnetic force component needs to be added and the Lorentz force becomes:

$$\vec{F} = e\vec{E} + \frac{\vec{v}}{c} \times \vec{B} \qquad [5]$$

Until recently, in classical optics and laser physics, the $v \times B$ component was totally ignored. However, in the relativistic regime, this component is as large as

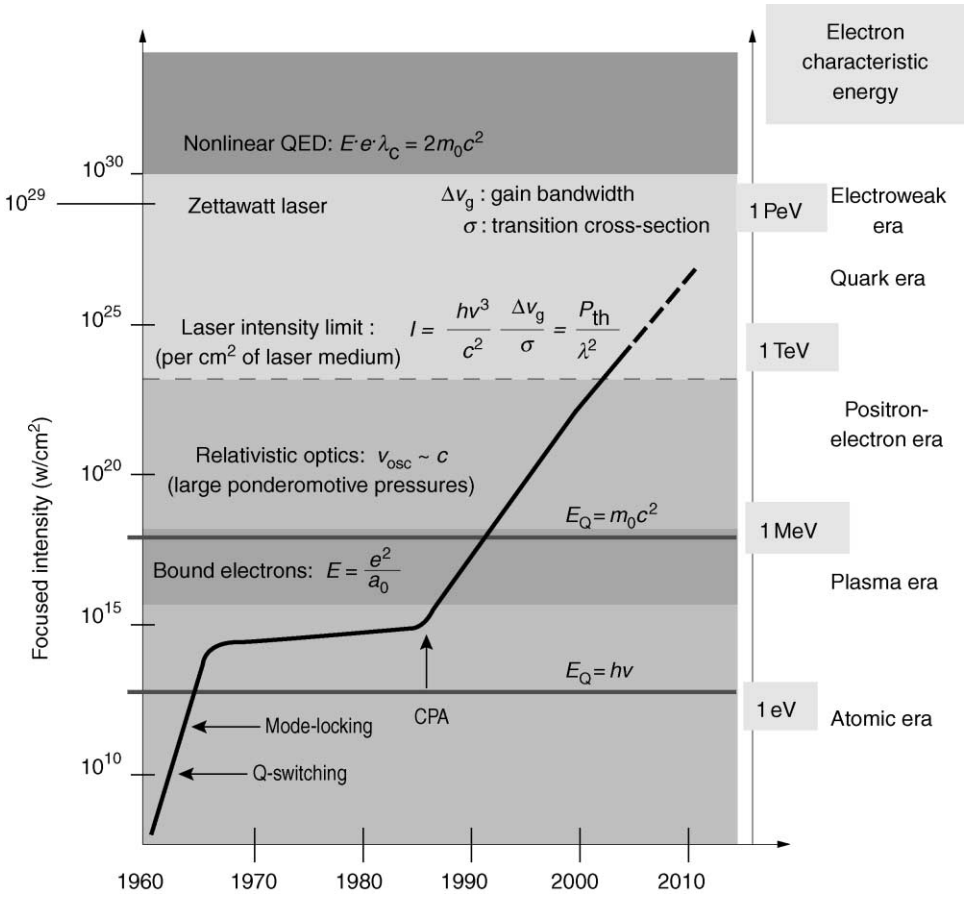

Figure 1 Laser intensity versus years. Note the very steep slope in intensities that occurs during the 1960s. This period corresponds to the discovery of most nonlinear optics effects. Since 1985 after the CPA invention followed by the successive laser short pulse improvements, we are experiencing a similar increase in intensity opening a new regime in optics at 10^{18} W/cm^2 dominated by the relativistic character of the electrons.

the electric one. It pushes the electron forward and is the tenet of the relativistic regime.

At this point, it is convenient to introduce the normalized vector potential:

$$a_0 = \frac{e\lambda E}{m_0 c^2} \qquad [6]$$

which represents the energy gain by the electron over one period (λ) normalized to the electron rest mass energy. At $a_0 = 1$, corresponding to 10^{18} W/cm^2 for 1 μm wavelength light, the laser–matter interaction is strongly dominated by the relativistic character of the electrons. At these intensities, the motion of the electrons becomes relativistic and the trajectory of the electron dramatically changes. Figure 2 depicts the difference between the two regimes. It can be shown that independently of the intensity regime, the electron transverse motion is always proportional to a_0, while the longitudinal motion is always proportional to a_0^2. This means that for classical

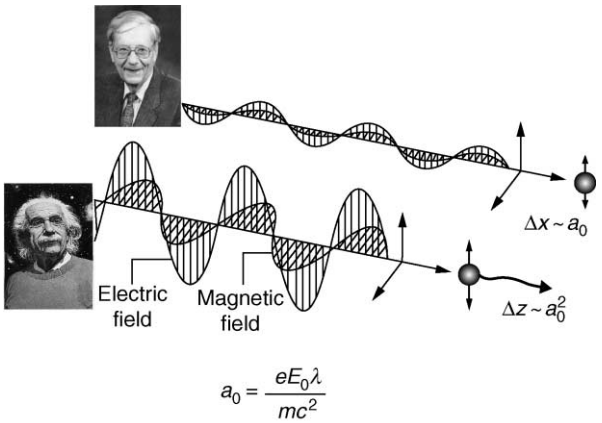

Figure 2 A comparison between classical optics and relativistic optics. The transverse electron displacement scales as a_0 and the longitudinal scales as a_0^2. (a) In classical optics $a_0 < 1$ the transverse electron displacement is proportional to a_0. It is larger than the longitudinal proportional to a_0^2. (b) In relativistic optics it is the opposite, $a_0 > 1$ the transverse displacement becomes smaller than a_0^2.

optics or even bound-electron nonlinear optics with a_0 varying from 10^{-10} to 10^{-4}, the longitudinal motion is $\sim 10^{-10}$ to 10^{-4} smaller than the transverse motion. Of course, the situation reverses completely for $a_0 > 1$, where the longitudinal motion becomes larger than the transverse motion. The departure of the electron motion from the linear regime, due to its relativistic character, gives rise to a new kind of nonlinear optical effects that constitutes the field of relativistic nonlinear optics. This area has become one of the most active in laser physics. In many cases, there are strong similarities between conventional and relativistic optics, and it is the purpose of this article to illustrate the field of relativistic optics by using some of the effects well established in bound electron nonlinear optics.

Considering the rapid progress in laser intensities that the field experienced in the 1960s, as indicated in Figure 1, scientists expected to observe the manifestation of relativistic effects in the 1970s. Formidable intensities on the order of 10^{18} W/cm^2 for 1 μm wavelength light were necessary, however, and could not be readily obtained. Such intensity levels could only be produced in the early 1980s with large-scale sources such as the Helios laser at Los Alamos National Laboratory (LANL) (Figure 3a). Work in relativistic optics virtually could not be conducted in university research laboratories, but rather only in government laboratories. The first relativistic harmonics produced by the critical surface nonlinear motion were observed in 1980 with a kJ-pulse-energy laser at mHz repetition rates (one shot/20 m).

The advent of CPA (Figure 4) revolutionized the field of relativistic optics, placing it within reach of more researchers through enormous reductions in laser size and cost. Further advances in the ultrashort-pulse duration of lasers and in laser focusing made relativistic optics more accessible, especially to universities. Relativistic intensities can be achieved with mJ energy levels at kHz repetition rates by university-size lasers (Figure 3b) instead of with large, kJ, sub-Hz-repetition-rate government-type lasers. Figures 3a and b illustrate the revolution in the relativistic laser evolution representing the Helios (LANL) system. Figure 3b depicts the relativistic λ^3 laser target chamber. The λ^3 laser reaches its relativistic intensity (10^{18} W/cm^2) with pulse energy only on the order of 1 mJ and pulse duration on the order of 10 fs, i.e., a few light periods. Its energy is concentrated on a single wavelength spot size using an f#1 paraboloid corrected by a deformable mirror. Note that all the energy is contained in a focal volume of a few λ^3, hence its name.

(a)

(b)

Figure 3 Two relativistic lasers. (a) Helios at LANL, was the first relativistic laser with $a_0 \sim 1$ at mHz repetition rate. (b) The λ^3 at the University of Michigan has an $a_0 \sim 1$ at kHz repetition rate.

Some Examples of Relativistic Nonlinear Optics

We will illustrate the field of relativistic optics by comparing relativistic effects with some well-known nonlinear effects.

(a) Relativistic optical rectification (laser wake-field acceleration of electrons and ions)

One well-known bound-electron optical effect coming from the second-order term in eqn [1] is optical rectification. This effect, which takes place in noncentrosymmetric crystals, gives rise to a DC field transverse to the propagation direction. In the relativistic regime, a similar effect known as wake-field acceleration will also contribute to rectification of the optical field. We have seen that in vacuum, electrons are strongly pushed forward by $v \times B$ force. In a plasma, the electromagnetic wave will also push

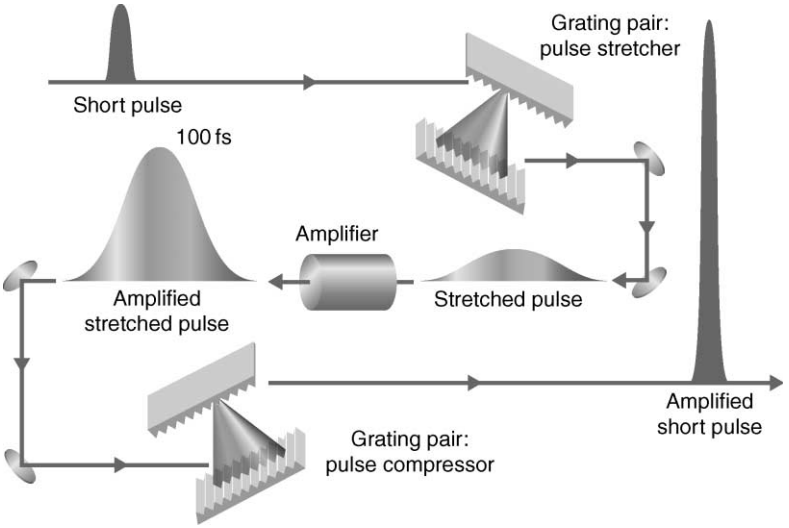

Figure 4 The concept of CPA is the key technique to get relativistic intensity. An initial short pulse is first stretched out (chirped) by a factor $\sim 10^4$, for instance by a pair of diffraction gratings. The stretched pulse intensity becomes lowered by the same factor of $\sim 10^4$. The stretched pulse intensity can then be amplified to a level 10^4 times higher. Once the laser energy has been extracted from the amplifier the stretched pulse is recompressed by the same factor ($\sim 10^4$) to its initial value. This way the laser intensity has been boosted to 10^4 times the peak intensity that the amplifier could have withstood.

forward the electrons, dragging the much heavier positive ions behind, as shown in Figures 5a and b. The charge separation that ensues will produce a strong electrostatic field that can be of the order of the transverse light electric field, which is huge. Unlike in classical optical rectification, in the relativistic regime the effect can be very efficient. Of the order of 10% or more of the transverse field may be rectified. For an intensity of 10^{18} W/cm^2, the electric field can be on the order of 10^{12} V/m (CERN on one meter), or 10^5 times larger than the field that can be obtained by more conventional technology. In addition, the rectified field is flipped along the longitudinal direction. Note also that since the field is created within a plasma, the medium cannot be broken down further and can support these extremely high fields. This effect had to wait for the relativistic-intensity lasers to become a reality before being demonstrated. Today energies up to 200 MeV have been demonstrated by using a 50 TW laser focused on a gas jet. Because the electrons drag the ions, a beam of ions is also observed concomitant with the electron beam. The generation of protons with energy up to 56 MeV has been reported by LLNL.

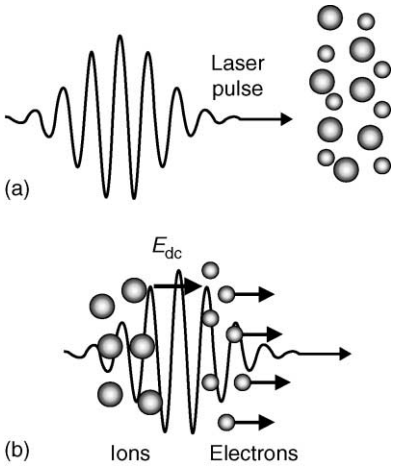

Figure 5 Relativistic rectification in plasma. (a) The high intensity pulse before entering the plasma. (b) Illustrate the $v \times B$ pushing first the plasma electrons. The electrons then drag the heavy ions behind them like a horse pulling a cart. The longitudinal electrostatic field that is generated is almost as large as the transverse laser field.

(b) Relativistic harmonic generation

Harmonic generation in the relativistic regime can be produced in two ways, as a result of the laser plasma interaction with electron density n_e, either below or above the critical density n_c. The first is for $n_e < n_c$ and corresponds to an underdense plasma where light can propagate. Harmonics generation was predicted in the late 1960s. Even-order harmonics are observed with linear and circular polarizations. This is the signature of relativistic effects since even-harmonics cannot occur in conventional nonlinear optics in centrosymmetric media.

Harmonic generation can also be produced in over-critical plasmas, where $n > n_c$. In this case, the light cannot propagate and be reflected. The strong $v \times B$ oscillatory force applied to the critical surface will produce a self-modulated reflected beam. This effect was first observed using the Helios laser. The idea of the moving-mirror model was first put forward in the early 1980s. Generation of frequencies up to the 70th harmonic has been demonstrated so this method could provide an efficient way to produce high harmonics. This technique has the advantage over conventional high harmonic generation in that it is capable of accommodating a pulse of large energy, since one can focus the beam over a small area, limited only by the laser wavelength, without fear of disrupting the plasma.

(c) Relativistic self-focusing in refraction

In bound-electron nonlinear optics, the third-order term in eqn [1] is responsible for self-focusing. A similar effect also exists in relativistic optics; it is described in Figure 6a. In the relativistic regime, the electron driven by the laser field changes its mass. In turn, this mass change will modify the index of refraction according to:

$$n^2 = 1 - \left(\frac{\omega_p}{\omega}\right)^2 \qquad [7]$$

where the plasma frequency is given by

$$\omega_p^2 = \frac{e^2}{m} n_e \qquad [8]$$

where n_e is the plasma electron density, and m is the intensity-dependent mass according to eqn [1].

For $\omega > \omega_p$, the index of refraction is positive and the pulse can propagate in the plasma. For the higher-beam-intensity part of the beam, i.e., on the beam axis, the plasma frequency will be less than the frequencies corresponding to the pulse wing. This will cause a modification of the laser wavefront and the beam to self-focus.

(d) Relativistic self-focusing in reflection and isolated attosecond pulse generation

For $\omega < \omega_p$, (eqn [7]) is negative and the pulse cannot propagate and so is reflected at the critical surface. However, the large light pressure will push the plasma critical-density surface at twice the laser frequency, making it cancel out the beam spatial intensity profile. In the relativistic λ^3 regime, the laser is focused at one wavelength. If the light is linearly polarized, the electron density will be collectively moved back and forth along the critical surface. This time-dependent deformation of the critical surface will produce a deflection of each electromagnetic half-cycle in a specific direction (Figure 7), providing a simple means for generating isolated attosecond pulses efficiently. The relativistic motion of the critical surface compresses (relativistic Doppler) the incident femtosecond pulse to the attosecond regime. To understand this compression, recall that the incident pulse travels opposite to the mirror motion formed by the critical surface (for a fraction of the cycle). As we have seen in this regime the critical surface moves also at close to the speed of light, v. Since the reflected light must also travel at c, it has no choice but to be compressed, producing an electromagnetic accumulation along the critical surface. The compression factor will

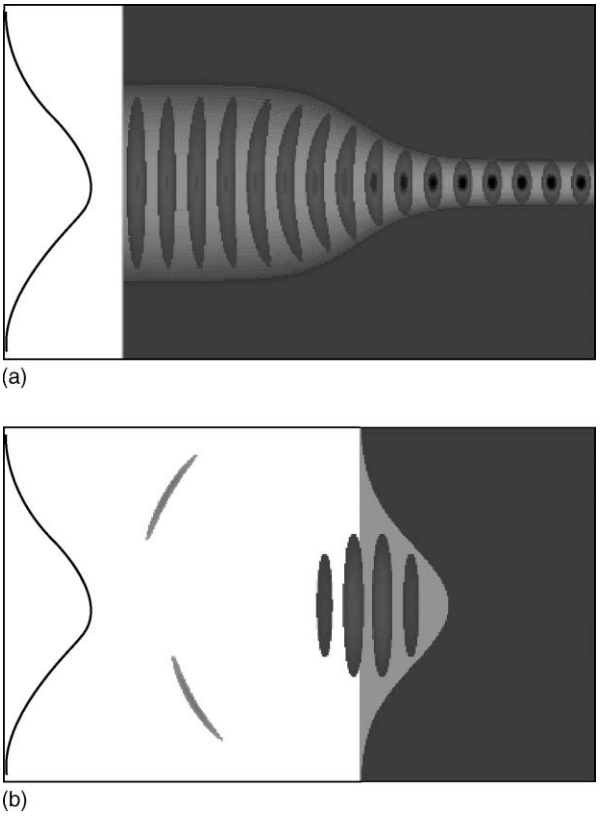

Figure 6 Relativistic self-focusing. (a) Relativistic self-focusing in refraction. Here the index of refraction is modified by the change in the electron mass. The electron mass change will in turn modify the plasma frequency across the beam and consequently the index of refraction. (b) Relativistic self-focusing in reflection showing the deformation of the critical surface by the light pressure from a strongly focused beam. The light is reflected in a series of ultrashort pulses in the attosecond domain.

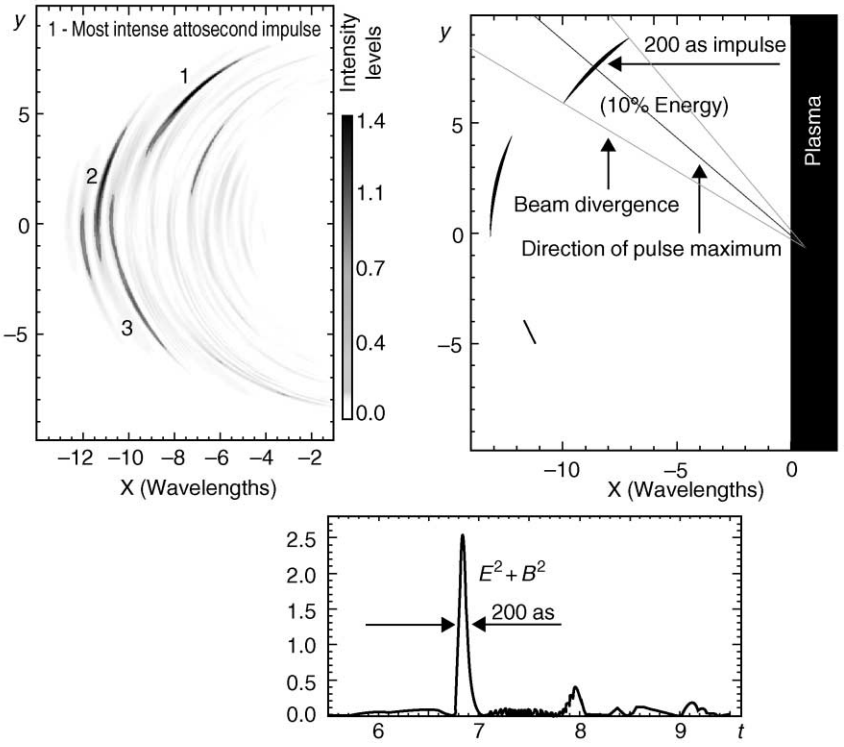

Figure 7 Compressed and deflected attosecond pulses. The combination of relativistic deflection and compression leads to 200 as isolated pulses.

depend on the critical surface velocity and is dependent on the plasma stiffness, i.e., the plasma density. Low-density plasmas are softer than high-density ones; here, n_c is the plasma critical density. The compressed pulse duration has been determined by a particles-in-cell (PIC) simulation to be given by $\tau = 600/a_0$. From the PIC simulation, it can be determined that the compressed pulse optimum duration is obtained for $n_e = a_0 n_c/2$. This technique is an interesting alternative to the one based on high-harmonic generation due to bound electrons, which has been recently demonstrated. The advantage of the relativistic optics approach is that it can be scaled up to large energies, from the mJ to the several-joule level, in contrast with demonstrated attosecond schemes that can only compress mJ pulse energies with an efficiency of 10^{-6}. For $a_0 \sim 100$, corresponding to incident intensities of $\sim 10^{22}$ W/cm^2, a 10-as pulse can be produced by relativistic compression and deflection.

(e) Nonlinear QED on a table top

Looking at Figure 1, we see that there is a regime around 10^{29} W/cm^2 where it becomes possible to produce electron–positron pairs. The condition to fulfill this is given by

$$E_s \lambda_c e = 2 m_0 c^2 \qquad [9]$$

Here $\lambda_c = h/m_0 c$ is the Compton wavelength, E_s the Schwinger field, and h the Planck constant. This expression states that for pair creation the work of the laser field over a Compton wavelength must be equal to the electron–positron rest-mass energy. This field E_s, also known as the critical field, $E_s \sim 10^{16}$ V/cm, corresponds to a laser intensity of 10^{29} W/cm^2.

An alternative way to depict the process of electron–positron generation from vacuum is by considering the vacuum as a dielectric medium with a gap $E_G = 2 m_0 c^2$. The field to produce an electron–positron pair is the one necessary to bend the bands so that an electron can tunnel from the Dirac sea into the vacuum states (Figure 8). The probability for such an event is given by

$$W \propto \exp\left(-\frac{\pi E_s}{E}\right) \qquad [10]$$

Today, the intensity necessary to reach pair creation is more than six orders of magnitude higher

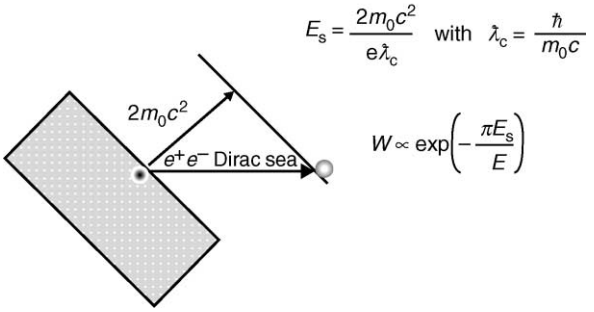

Figure 8 Pair creation. Electron tunneling from the Dirac sea into the vacuum state.

than what we could produce, $\sim 10^{22}$ W/cm^2. To bridge this enormous gap the electric field has been enhanced by colliding a short and intense pulse with a Stanford Linear Accelerator Center (SLAC) super-relativistic, 50 GeV electron beam. The Lorentz factor is $\gamma = 10^5$, and the laser field of 210^{10} V/cm (corresponding to an intensity of 10^{18} W/cm^2) can be enhanced by 10^5 to reach the critical field.

The progress in relativistic compression described above could make possible the generation of electron–positron pairs directly from the laser. We are on the verge of having a tabletop laser that could produce an intensity close to 10^{23} W/cm^2, corresponding to $a_0 > 100$. From the scaling law described previously, we should get $\tau < 6$, where the wavelength of such a compressed pulse would also be reduced by $\sim$100. The focal volume would then be reduced by six orders of magnitude. If we assume an efficiency of 10^{-1}, an intensity close to the critical intensity of 10^{29} W/cm could be reached with a tabletop laser and boil vacuum.

Conclusion

Today, laser intensities are such that during light–matter interaction, the electron motion is dominated by relativistic effects responsible for a new type of nonlinear optics called relativistic nonlinear optics. Relativistic nonlinear optics is characterized by extreme field gradients (TV/m) and light pressure in the Gbar regime. Relativistic nonlinear optics offers an attractive and novel way for efficient attosecond pulse generation with intensities near the critical (Schwinger) field, opening optics to vast new horizons.

Phase Matching

A V Smith, Sandia National Laboratories, Albuquerque, NM, USA

Introduction

Phase matching is important in any process that coherently transfers energy from one optical mode to another over a long interaction length. We will start by illustrating the principle, by imagining that the original mode is a single transverse mode of a waveguide, and that microscopic scattering centers distributed uniformly throughout the waveguide weakly scatter light into a second mode with orthogonal polarization. Then suppose that the scattering process preserves phase so the phase of the wavelet scattered at each point into mode two is the same as that of the original wave in mode one. Such a process is shown in Figure 1 where the propagation constant of the initially excited mode is k_1 and the propagation constant of the second mode is k_2. At each z location the light scattered into the second mode has the phase $\phi = k_1 z$, and after propagating to the end of the waveguide ($z = L$) with the phase velocity characteristic of the second mode, it has the phase $\phi_z = [k_1 z + k_2(L - z)] = [k_2 L + z(k_1 - k_2)]$. Coherently summing the fields scattered at all of the z positions, gives the net output field in the second mode. Figure 2 shows how this field can be constructed graphically. The rotation angle of each phasor represents its phase, ϕ_z, while the length of each phasor represents the magnitude of the field contribution from the corresponding z segment. It is apparent that the energy transfer is maximized if the contributions from all z positions have the same phase, in which case the phasors form a straight line, and the power in the second mode is proportional to L^2. This corresponds to $(k_1 - k_2 = 0)$. When this condition is met the waves in the two

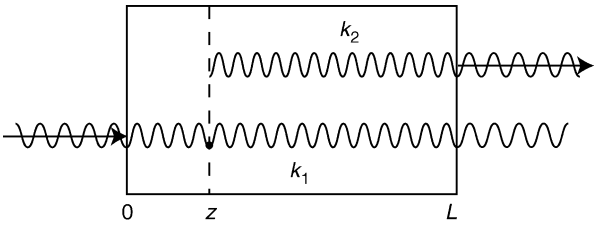

Figure 1 An input wave with propagation constant k_1 in a waveguide mode is weakly scattered into a second waveguide mode with propagation constant k_2. The phase mismatch is $\Delta k \equiv k_2 - k_1$.

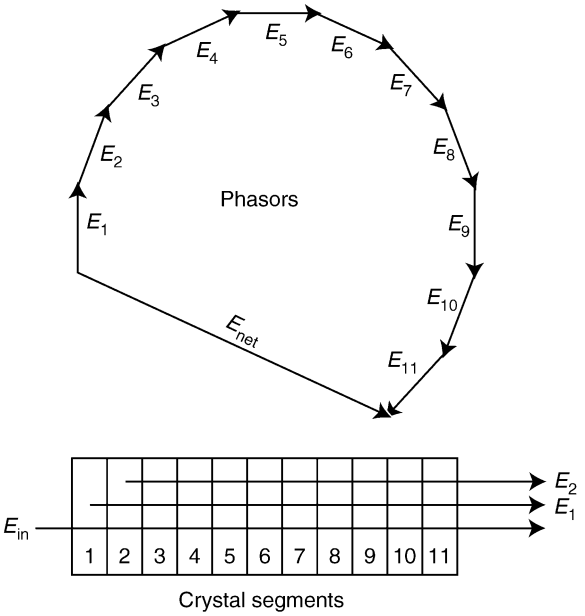

Figure 2 Phasor diagram showing the net output field contributions from segments 1–11. The net field at the output end, E_{net}, is the vector sum of the phasors. The phasors are complex quantities whose angles represent their relative phases according to $E_n = E_o \exp(i\phi_n)$ where $\phi_n = \phi_o - \Delta k(z_n - z_1)$.

modes have equal phase velocities, and the process is phase matched.

The quantity $(k_2 - k_1)$ is called Δk, the phase mismatch. If $\Delta k \neq 0$ the phasors curl to form a section of a circle, reducing the net field in mode two. If all the phasors have the same length, as they would if the wave in mode one is undepleted, the size of the mode two field at position z is

$$E(z) = Kz\frac{\sin(\Delta kz/2)}{\Delta kz/2} = Kz\,\mathrm{sinc}\left(\frac{\Delta kz}{2}\right) \qquad [1]$$

where K is a constant describing the scattering strength. The corresponding power in mode two is plotted in Figure 3 for various values of Δk. When $\Delta k = 0$ the power grows quadratically with z, but for $\Delta k \neq 0$ it is proportional to $\sin^2(\Delta kz/2)/\Delta k^2$. If we plot the normalized output power in mode two ($z = L$) versus Δk, we have the curve shown in Figure 4 which is $\mathrm{sinc}^2(\Delta kL/2)$.

When $\Delta k = 2\pi/L$ the phasors form a complete circle so the power in mode two first grows with z but then shrinks back to zero at $z = L$. For a given value of Δk the length for which the phasors form a complete circle is known as the coherence length, $L_{\mathrm{coh}} = 2\pi/\Delta k$.

Reducing the z increments to infinitesimals, we can write the output field for mode two in integral form:

$$E_{\mathrm{net}} = \int_0^L S(z)e^{-i\Delta kz}\,\mathrm{d}z \qquad [2]$$

This shows that when Δk is independent of z, the output field is the Fourier transform of a source term, $S(z)$, transformed into Δk space. Where $S(z)$ has a constant value from $z = 0$ to $z = L$ and is zero outside that range, the Fourier transform has the form given by eqn [1], with $z = L$.

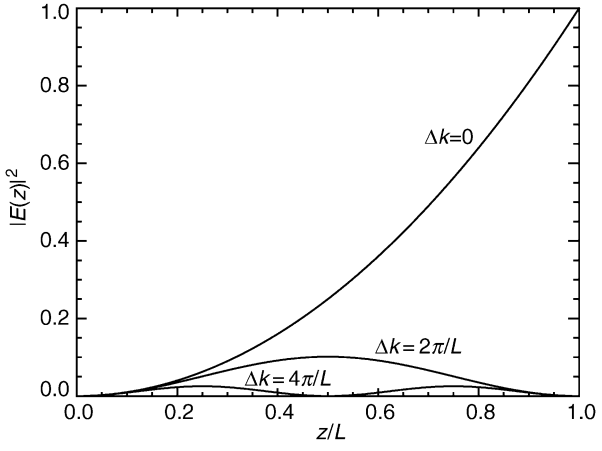

Figure 3 Plot of power in second mode versus z for different values of Δk. For $\Delta k = 0$ the power is proportional to z^2. For $\Delta k = 2\pi$/L the phasors form a closed circle so the net field is zero at $z = L$. For $\Delta k = 4\pi$/L the phasors trace two complete overlapped circles so again the field is zero at the $z = L/2$ and at $z = L$.

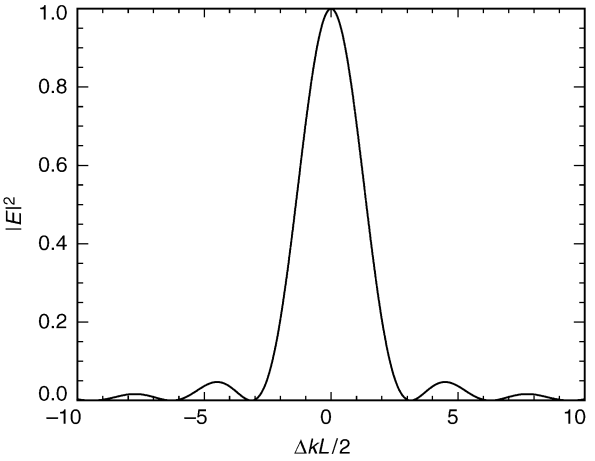

Figure 4 The plotted function indicates the relative irradiance of the output field, $|E|^2$, versus the phase mismatch Δk. The full width at half maximum is $\Delta k = 1.77\pi/L = 5.57/L$.

The $L^2\,\mathrm{sinc}^2(\Delta kL/2)$ form for the output power is ubiquitous in functions that describe the efficiency of nonlinear optical interactions, as well as acousto-optic and electro-optic modulation of light waves. However, it should be kept in mind that $L^2\,\mathrm{sinc}^2(\Delta kL/2)$ holds only when $S(z)$ is independent of z. If the scattering is strong enough to alter the phase or amplitude of the driving wave, or if the coupling strength varies with z for any other reason, $S(z)$ is not independent of z and the $L^2\,\mathrm{sinc}^2(\Delta kL/2)$ dependence is modified.

Our simple example relied on scattering in a waveguide, with a source term that was linear in the field in mode one. In practice, most optical devices that couple light between modes, rely on nonlinear interactions among multiple optical fields, or between an optical field and an acoustic or an rf electric wave. These nonlinear interactions produce a polarization wave in a suitable material at a sum or difference frequency. Each point of this polarization radiates a wavelet in all directions. These wavelets interfere constructively only in directions that are nearly phase matched. Examples include traveling wave acousto-optic filters, in which an acoustic wave traveling parallel to an input light beam of one polarization in a birefringent material, couples light into the orthogonal polarization via the elasto-optic effect. Traveling wave electro-optic modulators are similar but rely on the linear electro-optic effect for the coupling. Optical frequency mixing uses the nonlinearity of various

materials to mix multiple optical waves, creating polarization waves at sum and difference frequencies. A wide variety of such nonlinear interactions is discussed in textbooks on nonlinear optics, electro-optics, and acousto-optics. In all of these cases the phase velocity mismatch of interest is that between an induced polarization wave and a radiated mode, and the phase mismatch is $\Delta k = k_{\text{radiation}} - k_{\text{polarization}}$.

To find $S(z)$ and Δk for these nonlinear mixing processes, we must construct the polarization wave. We consider only monochromatic plane waves here, considering beams with spatial or temporal structure in a later section. The electric field of a monochromatic plane optical wave propagating in direction $\mathbf{r}_o$ can be described by

$$\begin{aligned} E &= E_o \cos(\omega_o t - \mathbf{k}_o \cdot \mathbf{r}_o + \phi_o) \\ &= \tfrac{1}{2}[E\, e^{-i(\omega_o t - \mathbf{k}_o \cdot \mathbf{r}_o)} + E^*\, e^{i(\omega_o t - \mathbf{k}_o \cdot \mathbf{r}_o)}] \end{aligned} \quad [3]$$

The complex notation is a convenience that simplifies algebraic book-keeping. Similarly, an acoustic field propagating in direction $\mathbf{r}_a$ can be written:

$$\begin{aligned} A &= A_o \cos(\omega_a t - \mathbf{k}_a \cdot \mathbf{r}_a + \phi_a) \\ &= \tfrac{1}{2}[A\, e^{-i(\omega_a t - \mathbf{k}_a \cdot \mathbf{r}_a)} + A^*\, e^{i(\omega_a t - \mathbf{k}_a \cdot \mathbf{r}_a)}] \end{aligned} \quad [4]$$

In a suitable material the polarization induced by the product of the optical and acoustic waves has a term of the form:

$$P = sEA \quad [5]$$

P has components at both the sum and difference frequency. The sum frequency component is:

$$P_{\omega_o+\omega_a} = \frac{1}{4} s[EA\, e^{-i(\omega_o+\omega_a)t + i(\mathbf{k}_o+\mathbf{k}_a)\cdot\mathbf{r}} + \text{cc}] \quad [6]$$

where 'cc' indicates the complex conjugate of the first term. The component at the difference frequency is

$$P_{\omega_o-\omega_a} = \frac{1}{4} s[EA^*\, e^{-i(\omega_o-\omega_a)t + i(\mathbf{k}_o-\mathbf{k}_a)\cdot\mathbf{r}} + \text{cc}] \quad [7]$$

An important point is that the k vector of the sum-frequency polarization is $(\mathbf{k}_o + \mathbf{k}_a)$. Phase matching requires that the radiated sum-frequency wave has the same propagation vector. The radiated difference frequency wave must have the propagation vector $(\mathbf{k}_o - \mathbf{k}_a)$ to be phase matched. Phase matching for these two cases is shown in Figure 5. Note the general rule that if the frequency of a wave appears as $+\omega$ in the induced polarization, the associated k vector contribution to the polarization wave is $+\mathbf{k}$, while if it appears as $-\omega$, the k vector contribution is $-\mathbf{k}$. For example, the acoustic wave in $P_{\omega_o+\omega_a}$ is associated with $+\mathbf{k}_a$ contribution to the polarization wave, while in $P_{\omega_o-\omega_a}$ it is associated with a $-\mathbf{k}_a$ contribution.

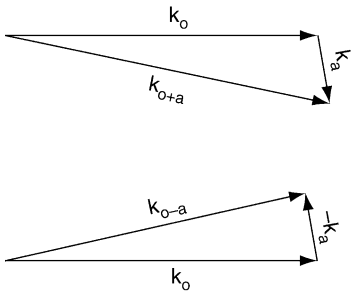

Figure 5 An optical wave with propagation vector k_o and an acoustic wave with propagation vector k_a produce a polarization wave at the sum frequency with the propagation vector k_{o+a} (top diagram), and a polarization wave at the difference frequency with the propagation vector k_{o-a} (bottom diagram).

Using the definition of k:

$$\mathbf{k} = \frac{2\pi}{\lambda}\hat{\mathbf{k}} = \frac{\omega}{v}\hat{\mathbf{k}} \quad [8]$$

where v is the phase velocity, we can write Δk as

$$\begin{aligned} \Delta\mathbf{k} &= \mathbf{k}_{o+a} - \mathbf{k}_o - \mathbf{k}_a \\ &= \left(\frac{\omega_{o+a}}{v_{o+a}}\hat{\mathbf{k}}_{o+a} - \frac{\omega_o}{v_o}\hat{\mathbf{k}}_o - \frac{\omega_a}{v_a}\hat{\mathbf{k}}_a\right) \end{aligned} \quad [9]$$

Clearly, if all of the waves had equal phase velocities, phase matching would be achieved for collinear interactions, where all of the propagation vectors are parallel, because the frequencies inside the parentheses sum to zero. This is seldom the case as for example, the phase velocity of an acoustic wave is much less than that of an optical wave, making an acoustic wave's k-vector disproportionately long compared with that of an optical wave. On the other hand, an rf wave usually has a disproportionately short k-vector compared with an optical wave. Even when all of the waves are optical, dispersion of the refractive index usually makes the k-vector of the bluer waves disproportionately long compared with those of the red waves. A wide variety of methods are used separately or in combinations to compensate for these effects in order to achieve phase matching and these are discussed below.

Phase Matching Techniques

Noncollinear Phase Matching

If one of the low frequency waves in a three wave mixing process, such as the acousto-optic interaction discussed above, has a lower phase velocity than the bluest wave, then noncollinear phase matching may be possible. Acousto-optic deflectors are often phase matched with a noncollinear geometry, such as that shown in Figure 6. An input optical wave of frequency ω_o reflects from a traveling acoustic wave with frequency ω_a in an optically isotropic material to produce an output optical wave of frequency $\omega_o + \omega_a$. The Bragg condition for efficient reflection is

$$\sin\theta = \frac{k_a}{2k_o} \qquad [10]$$

which may be seen from the figure to be the same as the phase matching condition, assuming k_{out} and k_{in} have the same magnitude, which is a good approximation for typical acoustic frequencies less than a few GHz.

Stimulated Brillouin scattering is another example of noncollinear mixing of acoustic and optical waves. One possible geometry has the input optical and acoustic waves traveling in opposite directions to create a reflected optical wave at the sum frequency. The phase matching condition is then

$$k_{acoustic} \approx 2k_{optical} \qquad [11]$$

which implies

$$\omega_{acoustic} = \frac{2n\omega_{optical}}{c} v_{acoustic} \qquad [12]$$

The acoustic frequency that phase matches such counter propagating Brillouin scattering is usually a few GHz in liquids and solids.

If noncollinear phase matching in an isotropic material is not possible, as is usually the case for electro-optic modulation and for all-optical sum and difference frequency mixing, it is sometimes possible to use the properties of nonisotropic media to adjust the phase velocity of one or more of the waves. There are several possibilities, such as natural birefringence, form birefringence, photonic band edge tuning, wave guide modal propagation, and various forms of quasi phase matching. Each is briefly described below.

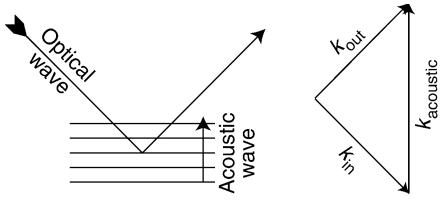

Figure 6 Phase matching in an acousto-optic deflector.

Birefringent Phase Matching

Natural birefringence

Naturally birefringent crystals can be categorized as either uniaxial or biaxial. In either case, light propagating along any direction (except along an optical axis) has two orthogonal eigen polarizations with different refractive indices. In uniaxial crystals, one of these indices is independent of the propagation direction and is called the ordinary index, n_o. The refractive index for the other polarization, known as the extraordinary polarization, is given by

$$\frac{1}{n_e^2(\theta)} = \frac{\sin^2\theta}{n_e^2} + \frac{\cos^2\theta}{n_o^2} \qquad [13]$$

where θ specifies the propagation direction measured from the z, or optical, axis, and n_e and n_o are the refractive indices for light polarized parallel and perpendicular to z. The two eigen polarizations are aligned with the lines of constant or latitude (o-wave) or constant longitude (e-wave). The variation of the two refractive indices with propagation angle θ is shown in Figure 7 for a negative uniaxial crystal which is characterized by $n_e < n_o$, and for a positive uniaxial crystal, characterized by $n_e > n_o$.

The acousto-optic tunable filter relies on natural birefringence to achieve a phase match. An optical and an acoustic wave propagate normal to the optical axis of a uniaxial crystal. If the crystal is negative uniaxial, with an input optical polarization of 'e', and an output optical polarization of 'o', the k vector of the acoustic wave must make up the difference

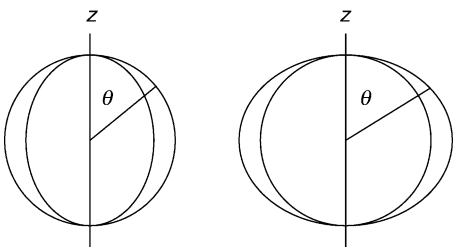

Figure 7 The circle and ellipse represent the two refractive indices for a negative uniaxial crystal (left diagram) and a positive uniaxial crystal (right diagram) for different propagation directions specified by the angles (θ, ϕ) with ϕ fixed. These curves are independent of the azimuthal angle ϕ, so in three dimensions the ordinary refractive index, n_o, forms a sphere in both cases, while the extraordinary index, n_e, forms a prolate ellipsoid for a negative uniaxial crystal, or an oblate ellipsoid for a positive uniaxial crystal.

$k_o - k_e$. This may be expressed as

$$k_a = \frac{\omega_a}{v_a} = \frac{(\omega + \omega_a)n_o}{c} - \frac{\omega n_e}{c} \qquad [14]$$

or, ignoring the difference between ω and $\omega + \omega_a$, the optical frequency that is phase matched is

$$\omega = \frac{\omega_a c}{v_a \Delta n} \qquad [15]$$

where v_a is the phase velocity of the acoustic wave, and $\Delta n = n_o - n_e$. The phase matched optical frequency is seen to be tunable with ω_a. A typical acoustic frequency for a visible filter is a few hundred MHz. The phase matching bandwidth set by the $\text{sinc}^2(\Delta kL/2)$ function can be quite narrow, with a subnanometer optical bandpass in a crystal a few cm long.

Natural birefringence is also widely used to phase match all-optical sum and difference frequency mixing. To counter normal optical dispersion, the bluest wave is polarized in the direction associated with the smaller refractive index, while at least one of the two redder waves has the opposite polarization. By adjusting the propagation angle, θ, the refractive index of the extraordinary waves can be adjusted until exact phase matching is achieved. If the two redder waves both have the high index polarization the process is sometimes called type I, whereas if they have opposite polarizations it is called type II.

Figure 8 illustrates type I phase matched second harmonic generation in a negative uniaxial crystal. The fundamental wave with frequency ω is o-polarized, while the second harmonic wave at frequency 2ω is e-polarized. The circle drawn in dashes represents the line swept out by the polarization wave vector $2k_\omega$ as the propagation direction θ is swept, while the ellipse represents the loci of $k_{2\omega}$ for the same angle. Collinear phase matching is achieved at the point of intersection of the two curves. This sets the angle θ_{pm}. For angles greater than θ_{pm}, dispersion is over-compensated and $\Delta k < 0$ so noncollinear phase matching is possible. All ϕ angles have equivalent propagation properties, so the loci of phase matched propagation directions form a cone at $\theta = \theta_{pm}$. Usually the propagation angle ϕ is chosen to maximize the nonlinear response of the crystal.

Biaxial crystals share with uniaxial crystals the property of two orthogonal eigen polarizations with different refractive indices, but the angular dependence of the indices is more complex. The two indices associated with propagation along direction (θ, ϕ) can be found by solving

$$\frac{\sin^2\theta\,\cos^2\phi}{1/n^2 - 1/n_x^2} + \frac{\sin^2\theta\,\sin^2\phi}{1/n^2 - 1/n_y^2} + \frac{\cos^2\phi}{1/n^2 - 1/n_z^2} = 0 \qquad [16]$$

for the two possible values of n. Here n_x, n_y, and n_z are the refractive indices for light polarized along the respective principal axes, where the convention is $n_x < n_y < n_z$. There are two optical axes lying in the x–z plane at an angle determined by the values of n_x, n_y, and n_z. The phase matching loci are no longer lines of constant latitude as they were for uniaxial crystals, but instead are curves that encircle either the optical axes or one of the principal axes. Figure 9 shows an

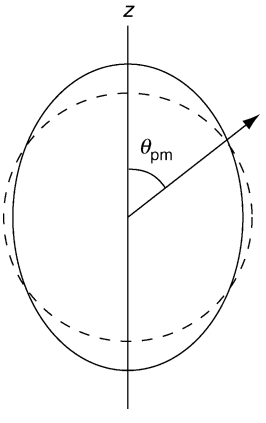

Figure 8 Collinear phase matching of second harmonic generation in a negative uniaxial crystal. The second harmonic light is e-polarized with a refractive index indicated by the solid line while the fundamental light is o-polarized as indicated by the dashed line. The crossing point of the two refractive indices determines the phase matching angle θ_{pm}.

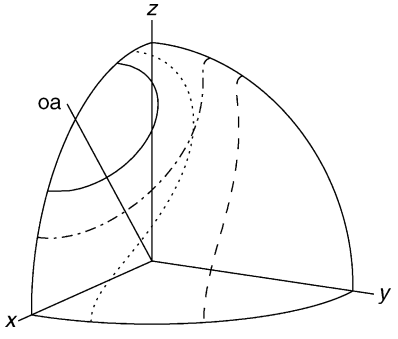

Figure 9 Calculated loci of propagation directions that achieve birefringent phase matching for type I collinear second harmonic generation of different wavelengths in the crystal CsB_3O_5. The fundamental wavelengths are 2,700 nm (dotted curve looping around the x axis), 3,000 nm (dashed curve looping around the y axis), 1,000 nm (solid curve looping around the optical axis 'oa'), and 800 nm (chained curve looping around the z axis). For clarity only a single octant of the sphere of propagation directions is shown. The loci in the other octants of the sphere are formed by reflections in the three principal planes.

example of each type of phase matching curve associated with second harmonic generation of different wavelengths in the crystal CsB_3O_5.

Note that because these curves always intersect at least one of the principal planes, if phase matching in biaxial crystals is possible at all, it is also possible in a principal plane. Biaxial crystals are usually phase matched in a principal plane, but phase matching outside the principal planes can in some cases maximize the nonlinear response, minimize the temperature sensitivity, or adjust the relative group velocities.

Form birefringence

Some materials, such as GaAs, have a strong nonlinear optical response but are not birefringent, so optical frequency mixing cannot be phase matched using natural birefringence. However, form birefringence can be engineered by layered growth, and it can be used to phase match. If many alternating layers of two materials with different refractive indices are stacked together with a layer thickness comparable to the wavelength of light, the material is birefringent for light propagating parallel to the layers. Light polarized with its E field parallel to the layers will have a higher refractive index than light polarized with its field perpendicular to the layers. The strength of birefringence, $(n_{\parallel} - n_{\perp})$, can be engineered by varying the relative thicknesses and refractive indices of the two layered materials. This has been demonstrated in GaAs/AlAs waveguide structures in which the AlAs layers were oxidized to form Al_2O_3, which has a refractive index of 1.6, compared with an index of 3.4 for GaAs. The resulting large birefringence was used to phase match infrared difference frequency mixing.

Photonic Lattice Phase Matching

The propagation constant of a light wave can be controlled by tuning its frequency near the bandgap of a Bragg structure. The Bragg structure can be a stack of layers with alternating refractive index. If the stack consists of layers of thickness and refractive index l_1, n_1 and l_2, n_2, the Bragg condition at normal incidence is

$$\phi_1 + \phi_2 = \frac{\omega_{\text{Bragg}}}{c}(n_1 l_1 + n_2 l_2) = m\pi \qquad [17]$$

where m is an integer. Frequencies near ω_{Bragg} are strongly reflected. The width of the reflective band of a structure with many layers is proportional to the refractive index contrast, $(n_1 - n_2)/(n_1 + n_2)$. At certain frequencies, on both sides of the bandgap, the reflectivity vanishes. The first transmission peak on the red side of the bandgap has an effective refractive index that is greater than the average $(n_1 + n_2)/2$, while the first peak on the blue side has an effective index less than the average. This effect can be used to adjust the effective value of Δk in the structure. As a bonus, operating on one of the transmission peaks near the bandgap enhances the optical field in the material, increasing the strength of the nonlinear interaction.

It is also possible to use a Bragg structure in reflection mode. Tuning to the red side of the band center increases the effective refractive index of the reflected wave, while tuning to the blue side decreases it. The internal fields are not enhanced in this case and the interaction length may be quite short.

Quasi-Phase Matching (QPM)

Quasi-phase matching uses spatial modulation of the polarization source with a modulation period of $L_{\text{mod}} = 2\pi/\Delta k$ to boost the efficiency of the mixing process even though $\Delta k \neq 0$. We can consider the periodic modulation as another interacting wave that is included in the creation of the polarization wave. The modulation wave has $\omega = 0$ and is stationary with period L_{mod}. Because the modulation is usually a square wave rather than sinusoidal, it is made up of multiple sinusoidal waves with periods L_{mod}/m, all of which can participate in generating a polarization wave. Like traveling waves, the stationary modulation waves can be oriented in any direction, and any Fourier component of the modulation wave with wave vector $\Lambda_m = 2\pi m/L_{\text{mod}}$ can participate in (quasi) phase matching, as shown in Figure 10.

Usually the spatial modulation is achieved by periodically reversing the sign of the nonlinear coupling coefficient. Figure 11 shows the associated phasor diagram for perfect first-order QPM. The net fields from the first two modulation periods are labeled E_1 and E_2. If the sign of the nonlinearity in the first half of the modulation period were not reversed in the second half, the phasors would form a complete circle resulting in a null net field. All following periods would also produce null net fields. However, if the sign is reversed midway through the first period, the phasors from the second half are sign reversed and the net field is E_1 as shown. The magnitude of E_1 is smaller than for a truly phase matched segment by the

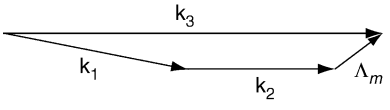

Figure 10 Quasi-phase matching vector diagram for sum frequency mixing. The mth Fourier component of the grating vector is indicated by Λm.

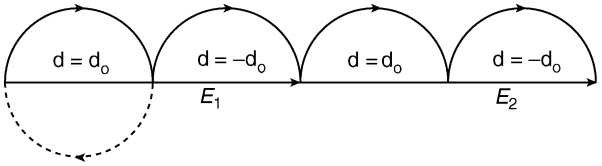

Figure 11 Phasor diagram for a quasi-phase matched interaction in a material with alternating signs of the nonlinear coefficient. The contributions from four segments, each of length $L_{coh}/2$ are shown. The net field from the first QPM period is labeled E_1, and that from the second period is E_2. The dashed line shows the path the phasors would trace if the nonlinear coefficient were not sign reversed in the even numbered segments.

ratio of the diameter of the circle to its circumference, or by $2/\pi$. Coherence lengths in crystals are typically 5–50 μm so crystals that are several mm long have a large number of periods, in which case the net phasors $E_1, E_2, \ldots$ can themselves be considered elementary phasors that form the net field for the full crystal. For example, if the modulation period L_{mod} is not exactly equal to $2\pi/\Delta k$, QPM is imperfect and phasors $E_1, E_2, \ldots$ curl up to give a net field of $\text{sinc}(\Delta k' L/2)$ where $\Delta k' = \Delta k - 2\pi/L_{\text{mod}}$. For all practical purposes, a QPM crystal containing many modulation periods performs the same as a phase matched crystal with its nonlinear coupling reduced by $2/\pi$.

Referring to eqn [2], we note that periodic modulation of the source term $S(z)$ produces peaks in the phase matching curves at $\Delta k = m2\pi/L_{\text{mod}}$ where m is an integer. If $S(z)$ is a square wave of alternating sign over $0 < z < L$, its Fourier transform is the convolution of $\text{sinc}(\Delta kL/2)$ with a picket fence function with spikes at $\Delta k = m2\pi/L_{\text{mod}}$. If $L_{\text{mod}} \ll L$, the crystal contains many periods of the square wave and the spikes are separated by many times the width of the $\text{sinc}(\Delta kL/2)$ function. This results in well separated sinc functions centered at $\Delta k = 2\pi m/L_{\text{mod}}$, and any process with a coherence length of L_{mod}/m will be quasi-phase matched. That is, one of the Fourier peaks in Δk space will be centered on the corresponding value of Δk.

The magnitudes of the QPM peaks are maximized if the modulation of $S(z)$ is a sign reversal, as described above. If the positive and negative segments have unequal lengths, we can define the duty cycle as $D = l_+/(l_+ + l_-)$. The heights of the pickets in the picket fence are then

$$h_m = \frac{2}{m\pi}\sin(\pi m D) \qquad [18]$$

The largest magnitude peak is for $m = 1$ and $D = 0.5$ in which case $h_1 = 2/\pi$.

Unlike birefringent phase matching, QPM can, in principle, phase match any set of polarizations for the interacting waves. This makes it possible to use a polarization set that maximizes the nonlinear response of the crystal.

Ferroelectric poling

There are various ways to achieve QPM. By far the most popular and versatile is by ferroelectric poling. Ferroelectric crystals have an internal electric field that can be reversed by the application of a sufficiently strong external poling field. Reversing the internal field also reverses the sign of the nonlinearity for some light polarizations but does not alter the refractive indices. Crystals of $LiNbO_3$ and $KTiOPO_4$, with thickness up to 1 mm, can be poled with periods as short as 5 μm. This is sufficient to quasi-phase match frequency mixing of visible or near infrared light. Figure 12 shows an example of the orientation of the internal fields of patterned ferroelectric domains.

It is possible to pole a crystal aperiodically so that multiple mixing processes are quasi-phase matched simultaneously. To design the poling pattern for such a device, the Fourier transform of an initial trial pattern can be calculated and compared with the target spectrum in Δk space. Iterative algorithms can be used to modify the poling pattern, zeroing in on the target spectrum.

Ferroelectric poling can also form two-dimensional poling patterns, corresponding to a two-dimensional set of Fourier components in Δk space. It can also produce chirped gratings which have a broad phase matching peak. Chirped gratings can be used to simultaneously frequency convert and tailor the temporal shapes of the output pulse when the input pulses are frequency chirped. Poling can also yield fanned poling patterns so the poling period and thus the phase matching wavelength can be shifted by translating the grating.

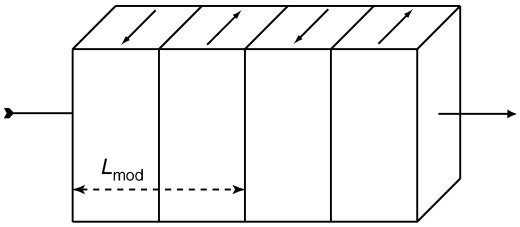

Figure 12 Diagram of a poled ferroelectric crystal. The four crystal segments represent four ferroelectric domains with internal crystal field directions indicated by the arrows. Reversal of the internal field is accompanied by reversal of the nonlinear coefficient, so this is a quasi-phase matched structure with alternating signs of d_{eff}.

Wafer stacking and patterned crystal growth

Another method of quasi-phase matching relies on stacks of thin plates oriented so the sign of the nonlinearity reverses in adjacent plates. Each plate has a thickness of $mL_{coh}/2$ where m is an odd integer. If all the plates are identically prepared crystals, it is often possible to reverse the sign of their nonlinearity by reorienting them. It is sometimes possible to optically contact the plates or even to diffusion bond them, avoiding reflective losses at the interfaces. This technique is conducive to large aperture QPM crystals. However, the plates are thin so fabrication is a challenge.

Quasi-phase matched crystals of GaAs have also been epitaxially grown on patterned substrates. The patterning serves as a template for growth of zones with alternating crystal orientation and sign of the nonlinear coefficient.

Total internal reflection

Total internal reflection in a thin slab has also been exploited for QPM (Figure 13). Two effects contribute to the source modulation, one is the rephasing of the waves on total internal reflection; the other is the change in nonlinearity that may accompany the change in propagation direction. Usually plates much thicker than one coherence length are used, so the quasi-phase matching is of high order ($m \gg 1$).

Wave Guide Modal Phase Matching

In waveguides the size and shape of the guide influence the transverse field distributions and the propagation constants for the transverse modes. Generally the higher order transverse modes have higher phase velocities than the lower order modes. This can be used to counteract index dispersion in three wave mixing if the bluest wave propagates in a higher order mode than the redder waves. A problem frequently encountered in using this effect is that the transverse modes are orthogonal, or nearly so. Because the nonlinear response is proportional to the overlap integral

$$d_{eff} \propto \int\int_A d(x,y)E_1(x,y)E_2(x,y)E_3(x,y)dx\,dy \qquad [19]$$

where the E's are the transverse field distributions of the three waves, the nonlinear response is often quite small. If the local nonlinearity $d(x,y)$ can be engineered to maximize the integral, this problem can be alleviated. This may be thought of as transverse quasi-phase matching.

Waveguides can also be designed for Cerenkov phase matching where the phase velocity of the radiated wave is less than that of the polarization wave. Figure 14 shows an example. The emission angle is

$$\cos\theta = \frac{2k_\omega}{k_{2\omega}} = \frac{v_{2\omega}}{v_\omega} \qquad [20]$$

where the v's are phase velocities. The transverse momentum Λ must be supplied by the waveguide. In other words, the source harmonic polarization must have a transverse Fourier component with spatial frequency Λ. This is another example of transverse quasi-phase matching.

Another application of waveguide phase matching is in traveling wave electro-optic modulation, where the rf wave travels along an rf waveguide parallel to the light path. For maximum modulation bandwidth, the phase velocity of the rf wave should equal that of the light wave over the desired modulation bandwidth. Because the phase velocity of the rf wave in the bulk medium is usually faster than that of the light wave, the rf guide must be designed for a slow phase velocity.

Compensated Phase Matching (CPM)

Compensated phase matching is somewhat like QPM in that multiple crystal segments are used, but it differs by requiring that sequential crystal segments have ΔkL's of equal magnitude but opposite sign. Ideally the nonlinearity would be the same in all segments. Figure 15 shows the phasor diagram for one such arrangement, in this case with unequal nonlinearity in alternating segments. CPM is realized

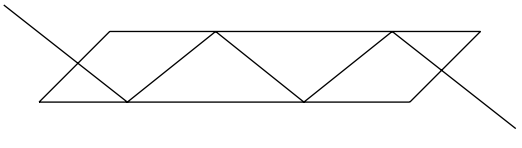

Figure 13 Diagram of quasi-phase matching based on total internal reflection. Relative phases acquired by the waves upon total internal reflection, combined with the path lengths and possible changes in the value of d_{eff} for alternating legs, can be combined to achieve quasi-phase matching.

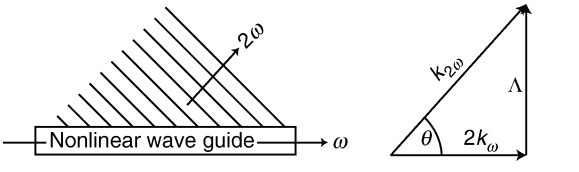

Figure 14 Cerenkov phase matched second harmonic generation. The phase velocity of the fundamental wave in the waveguide is greater than the phase velocity of the harmonic wave in the cladding.

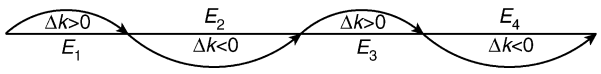

Figure 15 Phasor diagram for four segments of a device with compensated phase matching device. The magnitude of ΔkL is equal in each segment but the sign of Δk alternates. The length of the E_n field from segment n is proportional to $\text{sinc}(\Delta kL/2)$ so the net field ΣE_n must also be proportional to this function.

in walkoff compensated geometries where a sequence of crystals is arranged so $\Delta k = 0$ in each for a particular monochromatic plane wave. In the case of spatial walkoff compensation the walkoff direction in alternating crystals is reversed so the walkoff is exactly compensated in pairs of adjacent crystals. Tilting the input beams by a small amount changes the values of the Δk's in such a way that CPM is achieved. In the case of temporal walkoff compensation, temporal walkoff is reversed in alternating crystals, in which case tuning the input frequency leads to CPM. The advantage of CPM is that the acceptance bands, which will be discussed in the next section, are those of the individual crystal segments which are larger than those of a single crystal of equivalent length without walkoff compensation.

Spatial and Temporal Effects

Acceptance Bands

Our discussion to this point has been based on monochromatic plane waves. Real beams have spatial and temporal structure which means they can be decomposed into sets of monochromatic plane waves with tilted propagation directions relative to the nominal direction, and with detuned frequencies relative to the nominal frequency. As we showed above for monochromatic plane waves, there is a range of angles and frequencies, called the acceptance bands, over which $\Delta kL < 2\pi$. If the interacting beams' angular spectra and frequency spectra lie within these bands, the process is well phase matched for all angular and frequency components, and efficiency is maximized. This statement is equivalent to saying that if the spatial walkoff due to beam tilts and birefringence, and the temporal walkoff due to differing group velocities are small enough that the interacting beams stay well overlapped in space and time, the efficiency of energy transfer to the output channel does not suffer. Consider, for example, second harmonic generation of short pulses. The frequency acceptance bandwidth for the fundamental wave, $\Delta\omega_1$, is found using

$$\frac{\mathrm{d}(\Delta k)}{\mathrm{d}\omega_1}\Delta\omega_1 = \left(\frac{2\mathrm{d}k_2}{\mathrm{d}\omega_2} - \frac{2\mathrm{d}k_1}{\mathrm{d}\omega_1}\right)\Delta\omega_1 = \frac{2\pi}{L} \qquad [21]$$

Using the usual definition of the group velocity:

$$v_\mathrm{g} = \frac{\mathrm{d}\omega}{\mathrm{d}k} \qquad [22]$$

this can be written

$$\Delta\omega_1 = \frac{\pi}{L(1/v_{\mathrm{g}2} - 1/v_{\mathrm{g}1})} = \frac{\pi}{\tau_2 - \tau_1} = \frac{\pi}{\Delta\tau} \qquad [23]$$

where τ_1 and τ_2 are the passage times through a crystal of length L for the fundamental and harmonic pulses, and $\Delta\tau = (\tau_2 - \tau_1)$ is the temporal walkoff between the two. This shows that the acceptance bandwidth is approximately equal to the transform bandwidth of a pulse whose duration is equal to the temporal walkoff $\Delta\tau$. Input pulses shorter than $\Delta\tau$ will not convert efficiently because the fundamental and harmonic pulses do not remain overlapped as they propagate through the crystal. In the frequency domain it is said that pulses shorter than the $\Delta\tau$ have spectral widths larger than the acceptance bandwidth, meaning they are not well phase matched across their full spectra, and hence do not convert efficiently. Parallel arguments apply to spatial walkoff and angular acceptance bandwidths. Beams that do not remain spatially overlapped through the crystal do not convert efficiently. Equivalently, if the angular spectra of the beams exceed the acceptance angle, efficiency suffers.

Sometimes these notions are described in terms of an effective interaction length or an effective crystal length. For short pulses the effective interaction length is that for which temporal walkoff is equal to the pulse duration. Equivalently it is the length for which the acceptance bandwidth is equal to the spectral width of the pulse. Crystals shorter than this will have mixing efficiencies nearly equal to that expected for a phase matched process, while longer crystals have efficiencies that fall short of this expectation.

Focused beams

Focused Gaussian beams are a particularly important class of spatially structured beams. In passing through a focus, a lowest order Gaussian beam acquires a phase shift relative to an unfocused beam. The phase velocity near the focus is higher for the focused beam, leading to a phase shift of π through the focus. For second harmonic generation the phase shift of the second harmonic polarization is twice this, or 2π.

A second harmonic wave also acquires a phase shift of π, but this leaves a π phase shift between the harmonic polarization source wave and a freely propagating harmonic wave. The phasors representing harmonic radiation from symmetrically located points well before and well after the focus will therefore be 180° out of phase. Point pairs closer to the focus will have less severe cancelation, but it is not surprising that the maximum efficiency is achieved, not at $\Delta k = 0$, but for a slightly negative value Δk. The phase matching function $\mathrm{sinc}(\Delta kL/2)$ is shifted and distorted for focused beams. Its exact shape depends on the nature of the mixing process. For example, the phase matching peak is different for third harmonic generation and second harmonic generation, and it is different for mixing with small birefringence and mixing with large birefringence.

Phase Conjugation

Degenerate four-wave mixing

Some wave mixing processes are automatically phase matched. One example is phase conjugation by degenerate four wave mixing. This process creates a polarization wave that is the time reversed image of one of the input waves. Figure 16 compares the reflection from a conventional mirror with that from a phase conjugate mirror.

The mixing process shown in Figure 17 is one that can act as a phase conjugate mirror. Waves f and b are strong pump waves that are phase conjugates of one another. In their presence a weak signal field at the same frequency produces a polarization given by

$$P = sE_fE_bE_s^*\, e^{-i\omega t + i(\mathbf{k}_f - \mathbf{k}_b - \mathbf{k}_s)\cdot\mathbf{r}} \qquad [24]$$

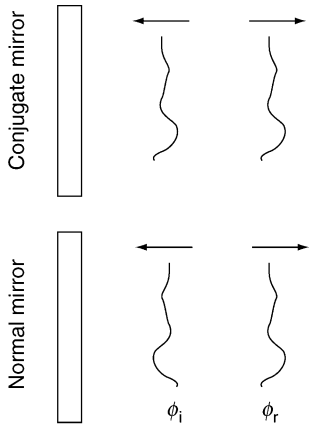

Figure 16 Comparison of a normal and a phase conjugate mirror. The wavy lines represent the phases of the incident and reflected waves.

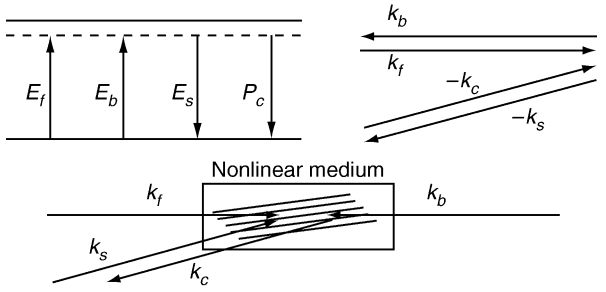

Figure 17 Phase conjugation via degenerate four wave mixing near a one photon resonance. Two counter propagating pump waves with fields E_f and E_b interact with a signal beam, E_s, to produce a polarization wave P_c where the frequencies obey $\omega_f - \omega_s + \omega_b = \omega_c$ (upper left), implying the k-vector of the polarization wave is given by $k_c = k_f - k_s + k_b$ (upper right). The lower diagram shows the grating induced by waves f and s that scatters wave b into the direction of c.

The two pump propagation vectors cancel one another leaving

$$P = sE_fE_b(E_s^*\, e^{-i\omega t - i\mathbf{k}_s\cdot\mathbf{r}}) \qquad [25]$$

The quantity in parentheses is the phase conjugate of the signal wave, so the polarization wave exactly phase matches a radiated conjugate wave.

Brillouin scattering

Other possibilities for automatic phase matching are processes that involve a stimulated wave in the nonlinear medium such as an acoustic wave (Brillouin scattering) or waves of coherent molecular vibration or rotation (Raman scattering). Phase conjugation, based on Brillouin scattering, is widely used to reduce phase distortions acquired on passing through an amplifier, for example. A single beam of light is focused into a material that has a high polarizability. Example media include high pressure gases Xe and SF_6, liquids acetone and freon, and fused silica. The conjugation process is not as simple to describe as it was in the case of four wave mixing because many acoustic waves can be generated. The key is that the phase conjugate wave has the highest gain under certain conditions and can dominate the Brillouin scattering process, so the reflected wave is nearly a phase conjugate of the incoming wave.

Pulse Compression via Nonlinear Optics

M F S Ferreira, University of Aveiro, Aveiro, Portugal

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Ultrashort pulses have a great potential in several areas of research and application, such as measurements of ultrafast physical processes, infrared time-resolved spectroscopy, and sampling systems, but they are also invaluable for communications. With increasing demands being put on the performance of optical fiber communications, the emphasis now is on producing a source of ultrashort optical pulses that can be used in high-bit rate and long-distance optical communication systems.

Several optical pulse compression techniques are described in the literature. These techniques utilize dispersion, possibly from gratings or prisms, simultaneously to compensate for chirp and achieve pulse compression. In fact, when a chirped optical pulse propagates in a linear dispersive medium, it acquires a dispersion-induced chirp. If the initial chirp is in the opposite direction to that imposed by the group-velocity dispersion (GVD), the two tend to cancel each other, resulting in the compression of the optical pulse.

Early work on optical pulse compression did not make use of any nonlinear optical effects. Only during the 1980s, when the use of single-mode silica fibers as nonlinear media became widespread, the self-phase modulation (SPM) effect was used to achieve pulse compression. It has led, in 1987, to the production of optical pulses as short as 6 fs in the 620 nm wavelength region. Such advances were possible, only after having understood the evolution of optical pulses in silica fibers.

We can consider two main categories of pulse compressors which make use of nonlinear effects in optical fibers: grating-fiber and soliton-effect compressors. In a grating-fiber compressor, the input pulse is propagated in the normal-dispersion regime of the fiber, which imposes a nearly linear, positive chirp on the pulse through a combination of SPM and GVD. The output pulse is then sent through a grating pair where it experiences anomalous GVD and gets compressed. In the case of a soliton-effect compressor, the fiber itself acts as a compressor without the need of an external grating pair. The input pulse propagates in the anomalous-GVD regime of the fiber and is compressed through an interplay between SPM and GVD. This compression mechanism is related to a fundamental property of the higher-order solitons. These solitons follow a periodic evolution pattern such that they go through an initial narrowing phase at the beginning of each period. If the fiber length is suitably chosen, the input pulses can be compressed by a factor that depends on the soliton order.

Grating-Fiber Compressors

The grating-fiber compressor is generally used at wavelengths $\lambda < 1.3\ \mu$m. At these wavelengths, optical pulses acquire a positive chirp across its entire width during their passage through conventional silica fibers. A schematic of a grating-fiber compressor in the double pass configuration is shown in Figure 1. After the propagation in the fiber, the optical pulse is sent through a grating pair, which provides the anomalous (or negative) GVD required to get the pulse compression.

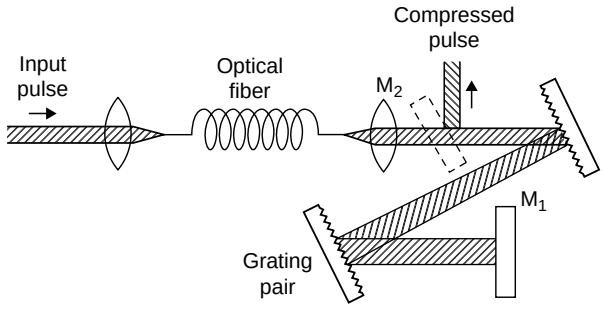

Figure 1 Schematic representation of a grating-fiber compressor in the double-pass configuration. (Reproduced with permission from Agarwal GP (2001) *Applications of Nonlinear Fiber Optics*. San Diego: Academic Press.)

Different frequency components of an optical pulse incident at one grating are diffracted at slightly different angles. As a consequence, they experience different time delays during their passage through the grating pair, the blue-shifted components arriving earlier than the red-shifted ones. In the case of an optical pulse with a positive chirp, the blue-shifted components occur near the trailing edge of the pulse and the passage through the grating pair provides its compression.

A limitation of the grating pair is that the spectral components of the pulse are dispersed not only temporally but also spatially. As a consequence, the optical beam becomes deformed, which is undesirable. This problem can be avoided simply by using a mirror to reflect the pulse back through the grating pair. Mirror M_1, in Figure 1, performs this function. Reversing the direction of propagation not only allows the beam to recover its original cross-section, but also doubles the amount of GVD, thereby reducing the grating separation by a factor of 2. The mirror M_2 in Figure 1 is used to deflect the compressed pulse out of the compressor.

The phase shift acquired by the spectral component of the pulse at the frequency ω passing through the grating pair can be written in the form:

$$\phi_g = \phi_0 + \phi_1(\omega - \omega_0) + \frac{1}{2}\phi_2(\omega - \omega_0)^2 + \frac{1}{6}\phi_3(\omega - \omega_0)^3 + \cdots \quad [1]$$

where ω_0 is the pulse center frequency, ϕ_0 is a constant, ϕ_1 is a constant delay, and ϕ_2 and ϕ_3 are parameters that take into account the GVD effects associated with the grating pairs. These parameters depend on the grating period (line spacing), as well as on the orientation and separation of the two gratings. In most cases of practical interest, the spectral width of the pulse satisfies the condition $\Delta\omega \ll \omega_0$ and the cubic and higher-order terms in eqn [1] can be neglected.

To achieve optimum performance from a grating-fiber compressor, it is necessary to optimize the fiber length, as well as the grating separation. Concerning the first aspect, the effects of both GVD and SPM during the propagation of the pulse inside the fiber must be considered. SPM alone determines a linear chirp only over the central part of an optical pulse. Since the grating pair compresses only this region, while a significant amount of energy remains in the wings, the compressed pulse is not of high quality in this case. The effect of GVD turns out to be important, since it broadens and reshapes the pulse, which develops a nearly linear chirp across its entire width. In these circumstances, the grating pair can compress most of the pulse energy into a narrow pulse.

The balanced effects of both GVD and SPM explain the existence of an optimum fiber length, z_{opt}, for maximum pulse compression. In fact, when the fiber length is less than z_{opt}, the SPM-induced chirp has not yet been linearized. On the other hand, when it is longer than z_{opt}, the SPM effects become negligible due to the GVD-induced pulse broadening.

If the input pulse is unchirped and presents a hyperbolic secant shape, the optimum fiber length for maximum pulse compression is well approximated by

$$z_{opt} \approx (6L_D L_{NL})^{1/2} \quad [2]$$

where

$$L_D = \frac{T_0^2}{|\beta_2|} \quad [3]$$

and

$$L_{NL} = \frac{1}{\gamma P_0} \quad [4]$$

are length scales associated with the GVD and the SMP effects, respectively. In eqns [3] and [4], T_0 is the input pulsewidth, β_2 is the fiber GVD parameter, γ is the nonlinearity parameter of the fiber, and P_0 is the peak power of the input pulse.

If the input pulse presents a negative chirp, this must be compensated for by the positive chirp provided by the fiber. As a result, the optimum fiber length increases. The opposite occurs in the case of an input pulse with a positive chirp.

The optimum compression factor, F_{opt}, in the case of a grating-pair compressor, is given by

$$F_{opt} = \frac{T_{FWHM}}{T_{comp}} \approx 0.625\left(\frac{L_D}{L_{NL}}\right)^{1/2} \quad [5]$$

where T_{FWHM} is the full width at half maximum (FWHM) of the input pulse ($T_{FWHM} \approx 1.76T_0$ for a hyperbolic secant pulse) and T_{comp} is the FWHM of the compressed pulse. Equations [2] and [5] provide a good estimate even for pulse shapes other than a hyperbolic secant as long as $\frac{L_D}{L_{NL}} > 100$.

The previous results were obtained neglecting the higher-order nonlinear and dispersive effects, which is acceptable for pulsewidths $T_0 > 0.1$ ps. However, when shorter pulses are used at the input, their spectral width $\Delta\omega$ is large enough that the cubic term in the expansion [1] must be taken into account. In this case, the compression factor turns out to be smaller than that given by eqn [5].

The third-order dispersion (TOD) of the grating pair, resulting from cubic term in eqn [1], has been compensated for in one experiment using a combination of gratings and prisms. Performing such compensation, a reduction of the pulsewidth to about 6 fs has been achieved. Such a pulse at 620 nm consists of only three optical cycles.

Even though the compression factor $F_c \propto \sqrt{P_0}$, the peak power of the input pulse must be kept below the Raman threshold to avoid the loss of pulse energy through the stimulated Raman scattering (SRS) process. If this condition is not then satisfied, besides the energy loss problem, the Raman pulse can interact with the input pulse through cross-phase modulation and deform the linear nature of the frequency chirp. As a result, the compression factor is reduced from the predictions of eqn [5].

Fiber Bragg Gratings

A uniform fiber Bragg grating (FBG) reflects light whose wavelength is within the stop-band centered at the Bragg wavelength. The GVD is anomalous on the high-frequency side of the stop-band and becomes normal on the low-frequency side. Near the stop-band edges, the grating exhibits large GVD. Since a FBG acts as a dispersive delay line, it can be used in place of the bulk-grating pair in a grating-fiber compressor, providing a compact all-fiber device. In fact, a typical 1 cm long fiber grating may provide as much dispersion as a bulk-grating pair with more than one meter spacing. However, the grating induced TOD can affect significantly the quality of the pulses when the optical frequency falls close to the edges of the stop-band.

The compression factor as well as the pulse quality can be significantly improved by using a FBG in which the grating optical period changes along its length – the so-called chirped fiber grating. In this case, different frequency components of the pulse are reflected from different regions of the grating. Such a device has been used since the mid-1990s to compensate for dispersion-induced broadening of pulses in fiber-optic communication systems, and compression factors above 100 have been achieved. In practice, the only disadvantage of a chirped fiber grating is that the compressed pulse is reflected rather than transmitted.

Soliton-Effect Compressors

Optical pulses at wavelengths exceeding 1.3 μm generally experience both SPM and anomalous GVD during their propagation in silica fibers. Such a fiber can act as a compressor by itself without the need of an external grating pair. In the case of a fundamental or first-order soliton, the effects of SPM cancel the effects of anomalous GVD perfectly, and the soliton propagates whilst preserving its hyperbolic secant shape in a lossless optical fiber. A higher-order soliton, on the other hand, changes its shape periodically as it propagates in a fiber. Such a soliton always experiences an initial pulse narrowing phase before recovering its original hyperbolic secant profile at integral multiples of the soliton period z_0, and this behavior is exploited to achieve pulse compression. Optimum compression is achieved when the higher-order soliton leaves the fiber just as it attains its narrowest width.

The evolution of a soliton of order N inside an optical fiber is governed by the nonlinear Schrödinger equation (NLSE), which can be written in the following form:

$$i\frac{\partial q}{\partial \xi} + \frac{1}{2}\frac{\partial^2 q}{\partial \tau^2} + N^2|q|^2 q = 0 \qquad [6]$$

where q is the normalized amplitude, $\xi = z/L_D$, $\tau = T/T_0$, and the parameter N is the soliton order, given by

$$N^2 = \frac{L_D}{L_{NL}} = \frac{\gamma P_0 T_0^2}{|\beta_2|} \qquad [7]$$

The soliton period, z_0, is given by

$$z_0 = \frac{\pi}{2}L_D = \frac{\pi T_0^2}{2|\beta_2|} \qquad [8]$$

In writing eqn [6], the fiber losses were neglected, since fiber lengths employed in practice are relatively small. Even though higher-order solitons follow an exact periodic evolution only for integer values of N, eqn [6] can be used to describe pulse evolution for arbitrary values of N.

In practice, soliton effect compression is carried out by initially amplifying optical pulses up to the power level required for the formation of higher-order solitons. The peak optical power of the initial pulse required for the formation of the *N*th-order soliton is given by

$$P_{\mathrm{N}} = 3.11\,\frac{|\beta_2|N^2}{\gamma T_{\mathrm{FWHM}}^2} \qquad [9]$$

These *N*th-order solitons are then passed through the appropriate length of optical fiber to achieve a highly compressed pulse. The optimum fiber length, z_{opt}, and the optimum pulse compression factor, F_{opt}, of a soliton-effect compressor can be estimated from the following empirical relations:

$$z_{\mathrm{opt}} \approx z_0\left(\frac{0.32}{N} + \frac{1.1}{N^2}\right) \qquad [10]$$

$$F_{\mathrm{opt}} \approx 4.1N \qquad [11]$$

These relations are accurate to within a few percent for $N > 10$.

Compression factors as large as 500 have been attained using soliton-effect compressors. In fact, considering the same input pulse, the soliton-effect compressor provides a pulse compression that is larger with a fiber that is shorter than a grating-fiber compressor. However, the pulse quality is poorer, since the compressed pulse carries only a fraction of the input energy, while the remaining energy appears in the form of a broad pedestal. From a practical point of view, the pedestal is deleterious since it causes the compressed pulse to be unstable, making it unsuitable for some applications. Despite this, soliton-effect compressed pulses can still be useful because there are some techniques that can eliminate the pedestal.

One difficulty faced, when using the soliton-effect compressor, is that pulses with high peak power are required for the formation of high-order solitons in conventional fibers. As suggested by eqn [9], the use of dispersion-shifted fibers (DSFs) with small values of β_2 at the operating wavelength can reduce the peak power required for soliton generation by an order of magnitude. However, because the soliton period z_0 is inversely proportional to $|\beta_2|$ (see eqn [8]), eqn [10], indicates that longer lengths of DSFs will be required for solitons to achieve optimum compression. As a result, the total fiber loss experienced by those solitons will be larger and the loss-induced pulse broadening will have a significant impact on the compressor global performance.

Another problem introduced by the use of DSFs in soliton-effect compressors is the TOD, which generally degrades the quality of the compressed pulse. In the case of soliton-effect compressors using conventional optical fibers, the effects of TOD become significant only when the widths of the compressed pulse become very short ($\ll$1 ps). In DSFs, however, the relative importance of TOD is increased and those effects become more pronounced because the GVD parameter, β_2, is small. In this case, TOD is detrimental in the compression, even of pulses with widths of a few picoseconds, resulting in serious degradation of the optimum compression factor F_{opt}.

The result given by eqn [11] for the optimum compression factor holds only for the case of an ideal soliton-effect compressor, when high-order nonlinear and dispersive effects, such as intrapulse Raman scattering (IRS), TOD and self-steepening, are neglected. However, these effects cannot be neglected for the highly compressed pulses because of their subpicosecond widths and high intensities.

For not-too-short optical pulses (widths >50 fs) propagating not too close to the zero-dispersion wavelength of the fiber, the dominant higher-order effect is IRS, which manifests as a shift of the pulse spectrum toward the red side – the so-called soliton self-frequency shift. As a consequence, the group velocity is reduced and there is a delay of the optical pulse. This delay affects substantially the interplay between GVD and SPM that is responsible for pulse compression.

Interestingly, the IRS effect can be used to improve the quality of the compressed pulse, by removing the pedestal mentioned above. In fact, as a consequence of the change in the group velocity induced by the IRS effect, the sharp narrow spike corresponding to the compressed pulse travels more slowly than the pedestal and separates from it. Moreover, the pedestal can be removed by spectral filtering and a red-shifted, pedestal-free, and highly compressed pulse is then produced.

Compression of Fundamental Solitons

As described in the last section, the propagation of higher-order solitons provide a rapid compression method, but it suffers from the existence of residual pedestals. Some techniques can help to reduce or even eliminate those pedestals, but energy is always wasted in this process.

A less rapid technique that provides better pulse quality is adiabatic amplification of fundamental or first-order solitons, which are of primary importance in the domain of optical communications. Solitons have fixed area, so the increased energy from amplification is accommodated by an increase in

power and a decrease in width. To avoid distortion, the amplification per soliton period cannot be too great.

The same effect as adiabatic amplification can be achieved using an optical fiber with dispersion that decreases along the length of the fiber. In fact, for optical solitons, a small variation in the dispersion has a similar perturbative effect as an amplification or loss: such a variation perturbs the equilibrium between the dispersion and nonlinearity in such a way that when, for example, the dispersion decreases, the soliton pulse is compressed. It can be seen from eqn [7] that if the value of $|\beta_2|$ decreases along the fiber and to keep the soliton order N ($N = 1$ for the fundamental soliton), the pulsewidth must indeed decrease as $|\beta_2|^{1/2}$. Hence, the use of fibers with variable dispersion is viewed as a passive and effective method to control optical solitons in soliton communication systems. Dispersion-decreasing fibers (DDFs), in particular, have been recognized to be very useful for high-quality, stable, polarization-insensitive, adiabatic soliton pulse compression and soliton train generation. These fibers can be made by tapering the core diameter of a single-mode fiber during the drawing process, and hence changing the waveguide contribution to the second-order dispersion.

In a DDF of certain length, the dispersion is monotonically and smoothly decreased from an initial value to a smaller value at the end of the length according to some specified profile. Provided the dispersion variation in the DDF is sufficiently gradual, soliton compression can be an adiabatic process where an input fundamental soliton pulse can be ideally compressed as it propagates, while retaining its soliton character and conserving the energy.

The evolution of the fundamental soliton in a DDF can be described by the following NLSE:

$$\mathrm{i}\frac{\partial q}{\partial \xi} + \frac{1}{2}p(\xi)\frac{\partial^2 q}{\partial \tau^2} + |q|^2 q = 0 \qquad [12]$$

where the variable coefficient $p(\xi) = |\beta_2(\xi)/\beta_2(0)|$ takes into account the variation of dispersion along the fiber. Using the transformations $s = \int_0^{\xi} p(y)\mathrm{d}y$ and $U = q/\sqrt{p}$, eqn [12] assumes the form:

$$\mathrm{i}\frac{\partial U}{\partial s} + \frac{1}{2}\frac{\partial^2 U}{\partial \tau^2} + |U|^2 U = \mathrm{i}GU \qquad [13]$$

where

$$G = -\frac{1}{2p}\frac{\mathrm{d}p}{\mathrm{d}s} \qquad [14]$$

Equation [13] shows clearly that the effect of decreasing dispersion is mathematically equivalent to the effect of an optical amplifier, adding a gain term to the NLSE. The effective gain coefficient G is related to the rate at which GVD decreases along the fiber.

Since decreasing dispersion is equivalent to an effective gain, a DDF can be used in place of a conventional fiber amplifier to generate a train of ultrashort pulses. To achieve such an objective, a continuous wave (CW) beam with a weak sinusoidal modulation imposed on it is injected into the DDF. The sinusoidal modulation can be imposed, for example, by beating two optical signals. As a result of the combined effect of GVD, SPM, and decreasing GVD, the nearly CW beam is converted into a high-quality train of ultrashort solitons, whose repetition rate is governed by the frequency of the initial sinusoidal modulation.

Different approaches have been developed to determine the optimum GVD profile and its dependence on the width and peak power of input pulses. In the case of picosecond soliton pulse compression, direct numerical simulations of the NLSE show that linear, Gaussian, and exponential dispersion profiles may all be used effectively to provide ideal, adiabatic compression, where the input pulse energy is conserved and remains localized within the pulse. In this case, the final pulse compression factor at the end of a certain length L of DDF is equal to the ratio of the initial to the final second-order dispersions:

$$F_c = \frac{T_{\mathrm{FWHM}}}{T_{\mathrm{comp}}} = \frac{\beta_2(0)}{\beta_2(L)} \qquad [15]$$

Compression factors larger than 50 are possible launching input pulses with peak powers corresponding to the fundamental soliton into a DDF whose length is about one soliton period. This technique takes advantage of soliton-effect compression but requires lower peak powers and produces compressed pulses of better quality.

In the case of subpicosecond soliton pulses, the influence of higher-order nonlinear and dispersive effects must be accounted for. Some studies show that, in this case, the linear and Gaussian dispersion profiles are the most suitable to achieve high-quality, pedestal-free, adiabatic compression of fundamental solitons. However, in the presence of higher-order effects, the final compression factor is generally lower, and after reaching a maximum at a particular length of DDF, it decreases steadily. This can be explained in terms of pulse compression stabilization, which originates from a competition between the rate of dispersion decrease in the DDF and the rate of dispersion increase due to the combined effects of soliton self-frequency shift and third-order dispersion.

List of Units and Nomenclature

F_c	compression factor
F_{opt}	optimum compression factor
G	amplifier gain
L	fiber length (m)
L_D	dispersion length (m)
L_{NL}	nonlinear length (m)
N	soliton order
P_N	peak power of the Nth-order soliton (W)
P_0	pulse peak power (W)
q	normalized pulse amplitude
T_0	input pulse (s)
T_{comp}	compressed pulse FWHM (s)
T_{FWHM}	pulse full width at half maximum (s)
z_0	soliton period (m)
z_{opt}	optimum fiber length (m)
β_2	group-velocity dispersion coefficient ($s^2\,m^{-1}$)
γ	fiber nonlinearity coefficient ($W^{-1}\,m^{-1}$)
ξ	normalized distance
τ	normalized time
ϕ_g	phase shift induced by the grating pair (rad)
ω_0	pulse center frequency (rad s^{-1})
ω	optical frequency (rad s^{-1})
$\Delta\omega$	pulse spectral width (rad s^{-1})

Raman Lasers

M Santagiustina, Istituto Nazionale di Fisica della Materia, Università degli Studi di Padova, Padova, Italy

The Raman effect bears the name of the Indian scientist Chandrasekhara V. Raman (1888–1970) who received the Nobel Prize in the year 1930 for the discovery, published in 1928, of this scattering phenomenon.

The Raman effect is an inelastic light scattering process, occurring in gaseous, liquid, and solid media. The frequency of the scattered photon can be either down-shifted or up-shifted and the result of the process is the generation of new radiation. Frequency down-shifted and up-shifted waves are respectively called Stokes and anti-Stokes waves. The energy difference between input and output photons is either absorbed by, or released from, the atoms or molecules of the medium, which are left in different energy states; jumps can be between electronic states, but more often they are among vibrational or rotational states. The upper energy state involved in the scattering process can be either a true energy state, and this case is referred to as resonant Raman scattering, or a virtual one. The off-resonance effect has a lower probability to occur and high-power beams are needed to observe it. The emission of anti-Stokes waves requires either an inverted Raman medium or particular four-wave-mixing phase-matching conditions to be satisfied in order to occur. The second condition is referred to as coherent anti-Stokes Raman scattering. Here we will consider mainly Stokes wave generation, which is the most common in Raman lasers.

When pumping is very hard, or a seed wave is provided, stimulated Raman scattering can also occur and a high percentage of the input pump radiation can be converted into Stokes, or anti-Stokes, radiation. The stimulated process efficiency, defined as the ratio between the output Raman wave energy

and the input pump wave energy, depends on the imaginary part of the third-order nonlinear susceptibility coefficient and on the pump intensity. Stimulated Raman scattering observation dates back to 1962 during the pioneering studies with lasers sources by Woodbury and Ng; their experiment with a ruby laser was actually the first example of an intracavity Raman laser.

Since its discovery, Raman scattering has become a valuable tool for spectroscopy and a practical technique to extend laser light emission to wavelengths not directly generated by laser active materials. This fundamental property stems from the fact that Raman scattering does not require an upper energy state to occur. Hence, the frequency of the emitted radiation can be any, if a suitable incident radiation wavelength is provided. New frequencies are constrained only by the available powerful pump laser sources and by Raman medium shifts.

The frequency shifts provided by some of the materials that are most often used in Raman lasers are presented in Table 1. Finally, it is important to note that Raman scattering can also occur for the newly generated radiation through an identical process in which a Stokes photon is Raman scattered. This radiation, which is generated if the Stokes radiation intensity grows large enough, is referred to as a second-order Stokes wave. For very large pump intensity, a cascading process to several Stokes orders can take place, thus extending the range of generated frequencies to the far-infrared portion of the spectrum.

We will describe the design of Raman lasers that are most commonly used, as well as their performances, also taking into consideration the Raman medium that sets the main constraint to the laser characteristics. Continuous wave as well as pulse Raman lasers will be described and the tuning capability will be discussed.

Raman Shifters

The simplest conversion scheme is obtained when a Raman medium is placed at the output end of a laser. This single-pass setup, shown in Figure 1, provides a fairly efficient frequency shifter.

Single-pass amplification of the spontaneous scattering or of an injected seed copropagating with an intense pump is usually modeled by a couple of equations whose derivation, under a plane, continuous wave approximation, can be found in the

Table 1 Measured Raman frequency shifts and steady-state gain for some of the most important Raman media

Medium	*Frequency shift [THz]*	*Gain [cm/GW]*
Calcite ($CaCO_3$)	32.58[1]	5.5[1]
Lithium iodate ($LiIO_3$)	23.1–24.66[2]	4.8[3]

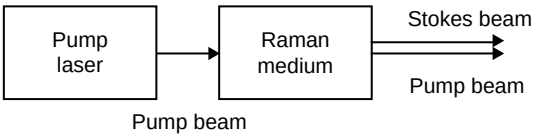

Figure 1 Experimental setup of a single-pass Raman shifter.

literature:

$$\frac{dI_S(z)}{dz} = g_R I_S(z) I_P(z) - \alpha_S I_S(z) \qquad [1]$$

I_S, I_P are the continuous wave intensities of the Stokes and pump waves, z is the propagation distance, g_R the Raman steady-state gain coefficient, and α_S, α_P are the attenuation coefficients at the Stokes and pump frequencies. The Raman gain coefficients, whose general expression as a function of the microscopic material properties can be found in many textbooks, of some of the most commonly used Raman laser media are listed in Table 1.

For short propagation lengths the medium loss can usually be neglected, and if the pump beam is well collimated, the pump intensity can be considered as a constant. For a long interaction length or very absorptive media, the evolution of the pump intensity must also be considered. Though the pump beam is depleted by the scattering process an undepleted pump approximation is often used until high conversion is reached. Under this approximation, the evolution of the pump intensity is mainly governed by diffraction spreading, by losses or by both. In bulk media, single-pass scattered radiation has a coaxial component whose divergence is dictated by the geometry of the pump beam, because Stokes radiation is close to the diffraction limit. Besides this radiation, a nonaxial component can also be observed; this phenomenon stems from the well-known effect of conical emission, which is a phase-matched parametric process. If the Raman medium is within a waveguide, losses are usually the dominating effect. In the undepleted approximation, the evolution of the pump beam intensity as a function of the propagation distance z, either dictated by diffraction or by losses, is known. Then the general solution of eqn [1] is:

$$I_S(z) = I_S(0) \exp\left[g_R \int_0^z I_P(z')dz' - \alpha_S z \right] \qquad [2]$$

where $I_S(0)$ is either the input Stokes signal intensity or an equivalent spontaneous scattering intensity. Then, the amplification gain G of the Stokes beam in the single-pass shifter, for a medium of length L, is given by

$$G = \frac{I_S(L)}{I_S(0)} = \exp\left[g_R \int_0^L I_P(z')dz' - \alpha_S L \right] \qquad [3]$$

Though single-pass Raman shifters are appealing for their simplicity, their application is hampered by the high power necessary for reaching a sufficient efficiency due to the short interaction length that can be obtained, in particular in bulk media, where diffraction dominates. Q-switched pulsed pump lasers are often required, but the propagation in the Raman medium of very powerful pulses requires special precautions to prevent other linear and nonlinear effects occurring. In fact, optical breakdown, thermal and Kerr self-focusing, four-wave mixing, and Brillouin scattering can take place, thus reducing the efficiency of the converter. Precautions may include the optimization of the pump pulse duration, of the focusing, of the interaction length, and the control of the input beam spot size. The multipass configuration has also been exploited to avoid many of the single-pass configuration shortcomings; the typical experimental setup is presented in Figure 2. Note that neither the pump nor the Stokes wave are resonant within the cavity.

The primary advantage of the multipass configuration is the lowering of the pump power required to realize an appreciable conversion. This is due to the increased total gain coefficient, that has been found to be equal to

$$G_n = G\frac{1 - R^n}{1 - R} + (n - 1)\log R \qquad [4]$$

where G is the single-pass gain of eqn [3], R the reflectivity of the mirrors at the Stokes wavelength, and n the number of passes through the Raman medium. There are two main drawbacks of multipass Raman shifters that finally limit the conversion efficiency of this setup. The first is the simultaneous generation of many undesired and uncontrolled Stokes orders, because the first-order Stokes intensity grows rapidly during propagation. The second is the

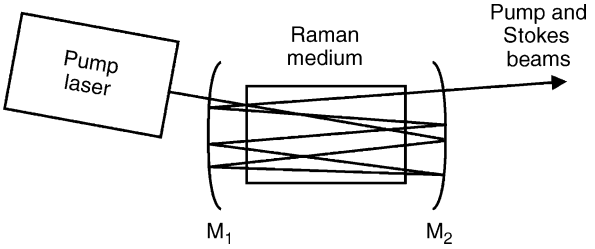

Figure 2 Experimental setup of a multipass Raman shifter. Mirrors M_1 and M_2 reflect both Stokes and pump waves.

intensity decrease associated with the dispersion of pulses, in particular if the Raman medium is a solid. These problems have limited the applications of multipass shifters to hydrogen gas.

Raman Lasers

By placing the Raman medium into an optical cavity, Stokes radiation can be selectively enhanced and Raman oscillation takes place. The two main experimental setups, either with the Raman medium placed in an external cavity or within the pump laser cavity (intracavity), are represented in Figures 3 and 4. In some cases, for the intracavity configuration, the Raman medium may also be the host of the doping laser active material.

For the external resonator Raman laser, the reflectivity of the mirrors is such that they are almost transparent for the pump but highly reflective (resonant) for the shifted radiation. The threshold condition of Raman lasers can be obtained by requiring that the net round trip gain equals the total cavity losses. The net round trip gain, under the plane wave, steady-state, undepleted pump approximation, is given by the single-pass gain G, multiplied by a factor of two to account for the forward and backward amplification. In fact, Raman scattering takes place also between the pump and the counter-propagating Stokes wave reflected by mirror M_2.

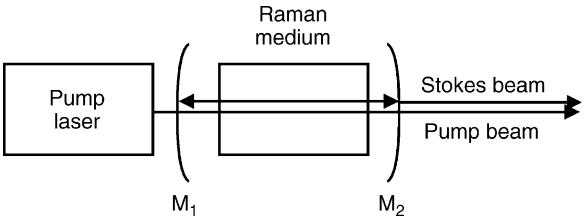

Figure 3 Experimental setup of an externally pumped Raman oscillator. Mirrors M_1 and M_2 are highly reflective for the Stokes wave but not for the pump wave.

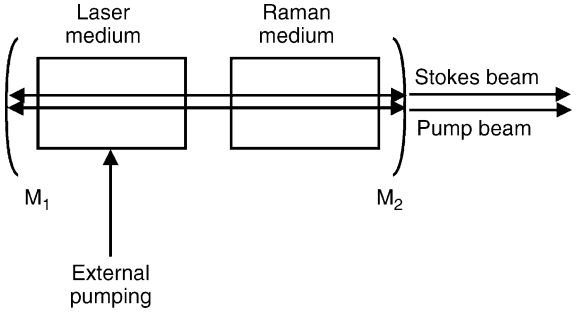

Figure 4 Experimental setup of an intracavity Raman oscillator. Mirrors M_1 and M_2 are highly reflective for both the Stokes and the pump wave.

Losses are given by the medium contribution, which is already accounted for in eqns [2] and [3], and by the energy leakage from the mirrors. Assuming that the mean reflectivities of the mirrors, at the Stokes wavelength, are respectively R_1, R_2, then the threshold condition is $GR_1R_2 = 1$. Through eqn [3] we obtain

$$g_R \int_0^L I_P(z')dz' - \alpha_S L = -\log(R_1R_2) \qquad [5]$$

Equation [5] can be used to evaluate the pump intensity because at threshold low depletion occurs and the approximation taken to obtain [5] is valid. Raman steady-state gain is not very different for gases, liquids and crystals, as shown in Table 1 and oscillation thresholds depend more on the interaction length and the focusing properties of the pump and Stokes beams. Nonetheless, the type of Raman medium imposes many practical constraints for laser design, which are addressed in the next paragraphs.

With gas media it is hard to maintain a high pump intensity over the entire length of the cell, which must be used to contain the gas. Usually gas cells can be from 5 to 30 cm long; this means that Q-switched pump lasers are required to set intensities above 10^4 GW m^{-2}, that is the typical threshold value of Raman oscillation. Continuous wave oscillation of gas Raman lasers is, nonetheless, possible when the pump wavelength is near a medium resonance. In fact, the imaginary part of the third-order non-linear polarization coefficient, to which the Raman gain is proportional, is enhanced near energy transitions because of the resonance in correspondence of that photon energy. The main limitations of this setup are that pump wavelengths are dictated by the Raman medium transitions, and thus also Stokes wavelengths are fixed, and finally conversion efficiency is usually low (about 5% is reported) possibly because of the high absorption. Off-resonance, continuous wave operation can also be attained by using high finesse cavities in a doubly resonant cavity. In fact, by resonating both Stokes and pump wave with high reflectivity mirrors ($R \geq 0.999$), the threshold intensity is lowered and conversion efficiency is high (about 35% has been demonstrated). In spite of the relatively high Raman gain and the large Stokes shifts obtainable, the exploitation of gas cell Raman oscillators is mainly hampered by the need of a high-pressure-resistant vessel and a constant gas flow. The latter is needed because of the low thermal conductivity of gases that might cause local temperature variations and thermal-optical distortions that diminish the output beam uniformity and stability. Moreover the repetition rate of pump pulses must be small (below 50 Hz) so as not to impose a too strong thermal load on the gas.

Liquid media suffer basically the same problems as gases and, moreover, they show higher non-linear refractive indices that result in strong self-focusing. This lens effect results in filamentation, optical breakdown, and high beam divergence. Often Raman liquids are also toxic and very volatile; their use has been slowly but steadily decreasing.

Solid media, in particular crystals, do not show many of the problems listed above and present the advantages of solid-state technology such as compactness, low maintenance, and opportunity of integration. The high density and the restricted atom motion result in high Raman steady-state gains and minimal line broadening. Precise resonance enhancement, as well as low threshold intensities, can be obtained by choosing an adequate mirror reflectivity spectral response. Pump intensities as low as 10^3 GW m^{-2} were reported for the oscillation of an external cavity Raman laser whose medium was a 5-cm-long, barium nitrate (see Table 1) crystal, with mirror reflectivity $R = 0.49$ at the Stokes wavelength. Though the intensity threshold is about an order of magnitude smaller than for gas Raman lasers, Q-switched input pump pulses are still required. Solid-state Raman lasers can be easily forced to oscillate on a $TEM_{0,0}$ mode with divergence close to the diffraction limit even with multimode pumps. Moreover the Stokes beam is subject to a very complex clean-up process; this can be basically explained by the fact that the Stokes beam, growing from the spontaneous emission, does not retain the pump spatial characteristics. Pulse duration is equal to or slightly less than the input one. Conversion efficiency, which depends strongly on mirror reflectivity, can reach 60%, where saturation occurs due to higher-order Stokes wave generation. Solid-state Raman lasers can be easily forced to oscillate also at these higher-order Stokes frequencies if mirror reflectivity is large enough at the relative wavelengths. Second- and third-order Stokes conversion efficiencies of 30% and 20% have been reported.

The theoretical determination of the cavity pump and Stokes fields does not have an analytical solution. For continuous wave or long Q-switched pulsed lasers, eqns [1] must be extended to include all forward and backward Stokes and pump waves and boundary conditions due to the mirrors must be imposed. This problem can only be solved numerically.

The experimental setup of intracavity Raman lasers is shown in Figure 4; both the Raman and the laser medium are placed within the cavity and sometimes the two media coincide. This is, for example, the case of potassium gadolinium tungstate which can be doped with neodymium ions (see Table 1). The cavity is usually resonant for both the pump and the Stokes waves; very high conversion efficiency (up to 80%) is attained when special dichroic coatings are provided such that pump output is suppressed (high-finesse cavity for the pump). Besides the nearly diffraction-limited property of output radiation and clean output beams that are common characteristics of all Raman lasers, enhanced brightness is also observed in this setup. This effect is probably due to the high thermal loading, the consequent linear and nonlinear lens effects, and also to a short pulse generation mechanism that increases output beam intensity. This regime can be reached by reducing the Stokes cavity length with respect to the pump cavity length. A first setup is to use an additional dichroic intracavity mirror that is transparent for the pump but highly reflective for the Stokes; an alternative setup exploits a double ring cavity configuration as depicted in Figure 5.

The principle governing the compression can be explained as follows. The optical paths of the pump and Stokes pulses are made different by an amount ΔL. Then the Stokes pulse generated within the Raman medium, once re-injected into the cavity from mirror M_{S1}, will overlap with an undepleted portion of the recirculating pump pulse. Hence, another Stokes pulse is generated at each round trip, until the pump pulse is completely depleted; the Stokes output finally consists of a train of pulses of duration $\Delta L/c$, at a repetition rate equal to the cavity round-trip. This mechanism leads to pulses as short as the limit imposed by the Raman gain bandwidth. In fact, when the pulse duration becomes comparable to the inverse of the gain bandwidth, transient effects take place because of the delay in the nonlinear medium response. Ring Raman lasers have been obtained with

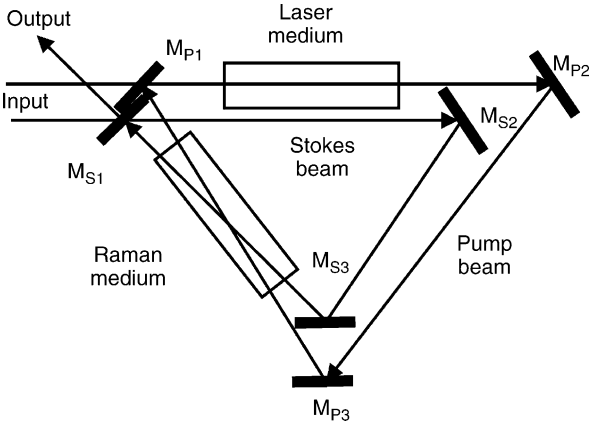

Figure 5 Experimental setup of an intracavity, double ring, Raman oscillator. Mirrors M_{S2}, M_{S3}, M_{P2}, and M_{P3} are highly reflective respectively for the Stokes and the pump wave. M_{S1}, M_{P1} are partially reflective respectively for the Stokes and pump wave.

gases (e.g., hydrogen) and crystal media (barium nitrate and lithium iodate).

Another commonly used experimental setup is that of synchronously pumped ring Raman lasers. In such devices, whose typical setup is sketched in Figure 6, a new input pump pulse is synchronized with the output Stokes pulse thus enhancing the conversion within the Raman medium.

Though electronic trigger detection is needed to lock the pump pulse time repetition rate to a multiple or submultiple of the cavity round-trip, synchronously pumped Raman lasers are relatively simple, stable, high repetition rate sources of radiation. Very compact and reliable synchronously pumped Raman lasers can be realized with optical fibers; in this case the feedback of the ring resonator can be realized by means of a fiber directional coupler. The device, besides the high integration achieved by the all-fiber technology, can also be continuously tuned over a large bandwidth.

Continuous tuning of the same laser source is a very desirable property; the Raman lasers so far described can generate radiation at wavelengths restricted to a few values. In fact, output spectral lines can be changed either by replacing the Raman medium, or the pump laser, or by exploiting cascade Raman scattering or finally resonating a different vibrational line of the same material (if there are many as for example in hydrogen gas); all these cases require substantial cavity changes. Frequency switching without setup changes is attained only in case of potassium gadolinium tungstate. For this medium there exist two independent directions, orthogonal to the crystal optical axis, for which the Raman shifts are different if the pump polarization changes. Then, the wavelength selection is just a matter of controlling the input pump polarization. Though Raman lasers can greatly expand the wavelength range of available laser sources, controlled, continuous tuning of the same Raman laser over a certain frequency band can be obtained only in a few particular cases.

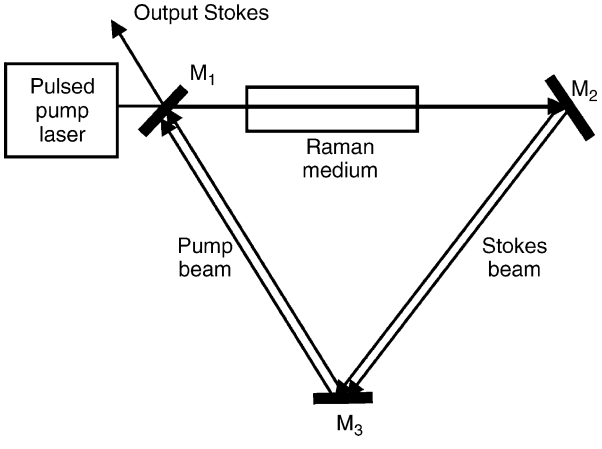

Figure 6 Experimental setup of a synchronously pumped, ring, Raman oscillator. Mirrors M_2 and M_3 are highly reflective for both the Stokes and the pump wave. M_1 is partially reflective for both the Stokes and pump wave.

Wavelength tuning can be attained by selecting the direction of propagation in polar crystals (like lithium niobate and lithium iodate). Different directions allow for wavevector matching of polariton scattering at different frequencies. Also phase matching of parametric interactions, like four-wave mixing, is a possible technique to attain wavelength tuning. However, such Raman lasers cannot operate at maximum gain, and this fact decreases the output energy, the conversion efficiency, and the stability, and increases the pump intensity threshold. Continuous tuning with an external control parameter is attained in the spin-flip Raman semiconductor laser. Semiconductors are Raman media that can be exploited to build far-infrared or even submillimeter Raman lasers, with pump intensity thresholds that are comparable with those of gas and liquid media. Though frequency shifts are fixed, under normal conditions, tuneable operation can be achieved if the semiconductor is placed in a magnetic field. Each energy level of an electron in the solid is, in fact, split into two, depending on the orientation of the electron spin with respect to the magnetic field. When there is a transition involving Raman scattering, the electron spin can change its direction. Then the wavelength of the laser can be continuously varied by changing the magnetic field applied. Tuning over a range of several micrometers in the infrared has been attained and spin-flip Raman lasers have been developed with semiconductors like InSb, $Hg_{0.77}Cd_{0.23}Te$, and $Pb_{0.88}Sn_{0.12}Te$. Use of this technique is severely limited by the need for magnetic field sources.

The simplest method to achieve tuneable radiation is through the use of a material that shows a broad Raman linewidth. Inhomogeneous broadening of the energy level is a well-known effect that takes place in noncrystalline solid media, such as glasses. Though line broadening is accompanied by a decrease in the steady-state Raman gain of about two orders of magnitude with respect to a crystalline medium, this disadvantage can be over-compensated by the increase in the Raman medium length that can be of 3 or 4 orders of magnitude. In fact, glasses are commonly exploited to make optical waveguides, in particular optical fibers, that present very low optical absorption coefficients, in the near-infrared part of the spectrum (1200–1600 nm).

Optical fiber Raman lasers based on silica telecommunication fibers are very versatile, compact,

and simple to implement. In principle the setup is not very different from the corresponding external cavity or intracavity Raman lasers so far presented; however, fiber lasers show the great advantage of an integrated, all-fiber technology.

Cavity mirrors can be replaced by fiber Bragg grating reflectors (Figure 7) that can be constructed with a very well-defined spectral reflectivity, thus allowing fine enhancement or suppression of the desired wavelengths. By splicing the Raman fiber, which can be several hundred meters long, with the gratings, the net losses are very low, finally decreasing the pump intensity threshold. The pump threshold for first-order Stokes generation can be easily as low as 200 mW; this means that diode lasers can be used for pumping. Moreover, the need for cavity alignment is eliminated, the laser stability increased and the construction simplified. This simplification allows us to build, much more easily than by using bulk optics, nested multiple resonant cavities, to generate higher-order Stokes beams (Figure 8).

Continuous-wave lasing of up to six Stokes orders has been reported for a fiber Raman laser of this type, with a total injected power of about 7 W. Another key advantage of Bragg gratings is that their reflectivity can be adjusted by means of a piezoelectric stretching of the fiber support; this allows one to control the output intensity of all waves. As previously mentioned, ring cavities can also be constructed by exploiting an all-fiber technology, if feedback is provided by a fiber directional coupler (Figure 9).

Pulsed operation of fiber Raman lasers has been obtained too; due to the long interaction length, Q-switched pump lasers are no longer needed but rather mode-locked sources can be used. This means that trains of very short laser pulses, down to the hundreds of femto-second regime, can be obtained from fiber Raman lasers, the limit being represented by the Raman bandwidth, which is as large as about 7 THz, at the half maximum, in silica fibers. Propagation of short and intense laser pulses in an optical fiber may induce several other nonlinear effects, like self-, cross-phase modulation, and four-wave mixing. Besides nonlinearity, linear dispersion and velocity mismatch become important too, due to the long propagation. All these linear and non-linear effects limit the Stokes pulse quality. In more detail: self- and cross-phase modulations lead to the spectral broadening of both pump and Stokes waves; broadening is asymmetric, because of the contemporary action of group velocity mismatch. In fact during the propagation the Raman pulse walks off the pump pulse, because of velocity mismatch, and this induces an asymmetry in gain depletion and in nonlinear index modulation. The final outcome is that Stokes waves can be asymmetric both in time and in frequency, and also highly chirped. Four-wave mixing is usually negligible, if phase-matching conditions are not imposed and Brillouin scattering is not an issue for short pulses. Very symmetric and low chirped pulses are attained as soon as the fiber Raman laser is working in the soliton regime, that is when compensation between the dispersion and the nonlinear phase shift occurs. Synchronously pumped, fiber Raman, soliton lasers are able to provide 200-fs pulses, at various wavelengths and with very high conversion efficiency (50%). Intracavity fiber Raman lasers have

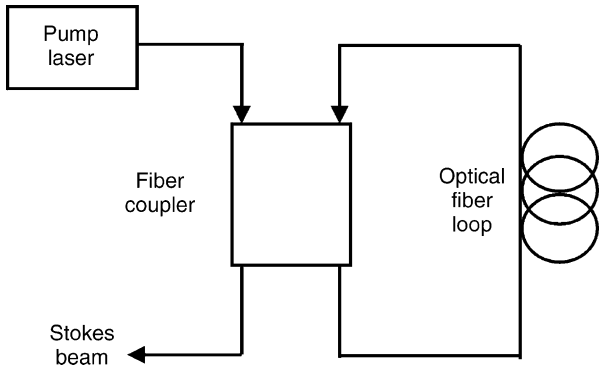

Figure 9 Experimental setup of an all-fiber, ring Raman oscillator.

also been realized by doping the fiber with neodymium, erbium, or ytterbium ions.

The extremely broad Raman spectral linewidth of the glass allows for broadband tuning of the emitted wavelength. For continuous and pulsed wave operation the change in the peak Stokes wavelength can be attained through an intracavity frequency selective element, like for example a prism or a grating. In this case tuning is not obtained in an all-fiber configuration but rather with bulk optical elements and thus additional lenses or objective are needed to collimate the Stokes wave at the fiber ends. The experimental setup is shown in Figure 10.

The laser can be continuously tuned, over about 6 THz, by adjusting the prism or grating rotation. All-fiber Raman laser tuning is possible in a double ring configuration with an inserted optical filter, whose experimental setup is shown in Figure 11. Stokes and pump waves are counterpropagating in the Raman fiber; the Stokes wave frequency is selected by the tuneable optical filter.

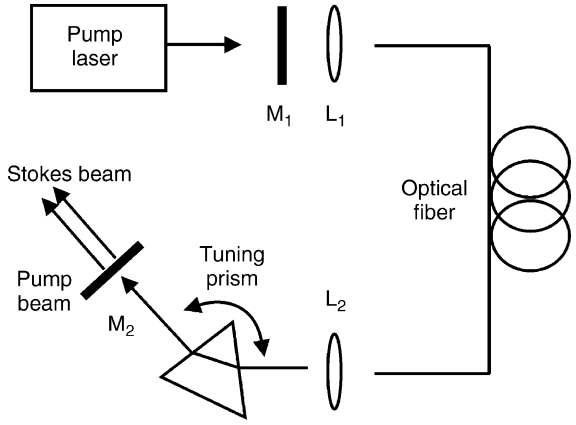

Figure 10 Experimental setup of a tuneable, fiber Raman oscillator. Mirrors M_1 and M_2 are highly reflective for the Stokes wave but not for the pump wave. L_1 and L_2 are collimating lenses or objectives. The tuning prism is rotated to control wavelength selection.

The devices of Figures 10 and 11 stop emitting Stokes radiation for frequencies at which the Raman gain has decreased to a level such that laser threshold is higher than the pump intensity. Due to the fact that Raman gain in fibers is almost constant over about 3 THz, tuning within this frequency range does not lead to any sensible decrease in conversion efficiency. For synchronously pumped ring fiber Raman lasers another technique, named time dispersion tuning, can be used. The experimental setup is shown in Figure 12.

The output fiber end is placed on a moveable mount, that controls the relative delay between the Stokes pulse and the new pump pulse at the fiber input. Since Stokes pulses are dispersed during fiber propagation, to each time slot within a pulse there corresponds a certain portion of the Stokes spectrum. By properly delaying the time of injection of the Stokes pulse back into the fiber the most powerful part of the pump pulse is overlapped to a different part of the Stokes pulse, and this causes a preferred amplification of certain frequencies with respect to others. The shift of the Stokes peak wavelength $\Delta\lambda$ is given by:

$$\Delta\lambda = \frac{\Delta l}{cLD(\lambda)} \qquad [6]$$

where Δl is the translation step, c the speed of light, L the fiber length, and $D(\lambda)$ the fiber dispersion at the Stokes wavelength λ. A total tuning range of 10 nm can be obtained with this technique that can also be used as a test measurement of fiber dispersion.

Applications

Raman lasers have found a large variety of applications. Gas and liquid Raman lasers are fundamental tools for spectroscopic investigation. Solid-state Raman lasers have been shown to be very powerful, eye-safe sources for light detection and ranging (LIDAR) and medical applications. Fiber Raman lasers are exploited for long-haul fiber optics transmission. They can be either sources of short pulses and solitons or high-power continuous-wave sources at multiple wavelengths for subsequent link-distributed Raman broadband amplification.

Introduction

When an intense beam of light with axial symmetry propagates in a medium possessing a nonlinear index of refraction, it will induce its own lens in the medium and be focused. This phenomenon, first discovered just a few years after the invention of the laser, is called self-focusing. It is one of many phenomena under the general classification of self-action, which includes such effects as self-trapping, self-bending, self-phase modulation, and self-steepening. This general class of phenomena involves action on the beam of light induced by the beam itself: light causes a change in an optical property of the medium, which

in turn produces an effect back on the light beam. We will discuss the mechanisms responsible for self-focusing in nonlinear optical media and the resultant action on the optical beam. In this we will see how the topics of self-trapping and self-phase modulation are intimately connected to self-focusing. This will lead to a discussion of related effects as well as many potential applications.

It is instructive to first review the properties of a conventional thin lens, illustrated in Figure 1. By 'thin', we mean that just before and just after the lens, the beam size and shape are approximately the same. However, the phase of the optical wave is changed on passage through the lens. We apply the paraxial (aberrationless) approximation where only rays that lie near the lens axis are considered. In this treatment the spherical surfaces of the lens are approximated as parabolic surfaces. For a symmetric double-convex lens (as shown in Figure 1), this phase change is

$$\Delta\varphi(r) = -k(n-1)\frac{r^2}{R} \equiv -\frac{kr^2}{2f}, \qquad f^{-1} = (n-1)\frac{2}{R} \qquad [1]$$

where n is the index of refraction of the lens material, and R is the radius of curvature of the lens surfaces. The light beam has a wavevector $k = \omega/c$, where ω is the frequency and c the speed of light in a vacuum. The phase retardation is a maximum on the lens axis (z) and decreases quadratically with the radial coordinate r. In other words, the phase advances quadratically with distance from the axis and forms a spherical, converging wave that comes to focus on the z-axis a distance f (the focal length) from the lens.

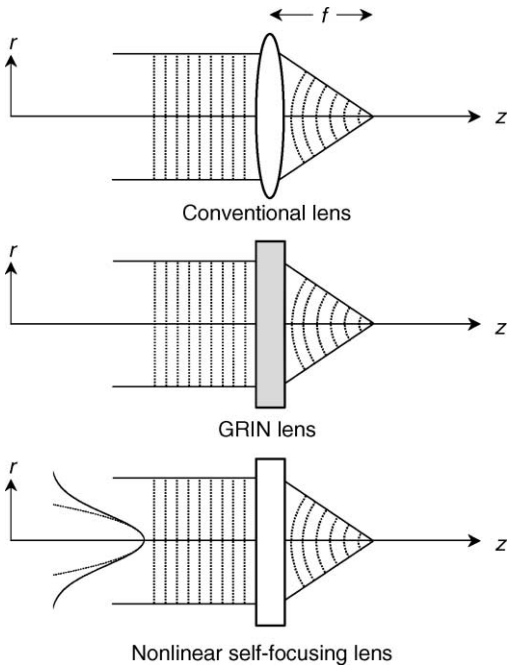

Figure 1 Focusing with a conventional lens, a graded-index (GRIN) lens, and a nonlinear self-focusing lens.

Next consider a graded-index (GRIN) lens, also illustrated in Figure 1. This is a flat slab of material with thickness L and an inhomogeneous index of refraction given by $n(r) = n_0(1 - 1/2\alpha^2 r^2)$. The index has a maximum (n_0) on the lens axis and decreases quadratically with radial distance from the axis. The constant α is a measure of the rate of the index change with r. Upon passage of light through a GRIN lens, the phase change is

$$\Delta\varphi(r) = -kn_0\alpha^2 L\frac{r^2}{2} \equiv -\frac{kr^2}{2f}, \quad f^{-1} = n_0\alpha^2 L \qquad [2]$$

Because of the parabolic nature of the index distribution, the phase retardation again decreases quadratically with r and thus forms a converging spherical wave. Notice that for both the conventional and GRIN lenses, the optical thickness of the lens is parabolic. In the conventional lens the index is constant, but the physical thickness varies continuously. In the GRIN lens, the physical thickness remains constant while the index varies continuously. Both produce the same kind of focusing action.

Finally, consider a flat slab of homogeneous material that has a nonlinear index of refraction. Light of intensity I induces a change in the refractive index given by $\Delta n = n_2 I$. The parameter n_2 is called the nonlinear refractive index coefficient and has physical units of $\text{cm}^2\ \text{W}^{-1}$. There are other definitions of n_2 given in the literature where the index change is given in terms of the square of the electric field, which would obviously have different physical units. We will adopt the intensity form of n_2 in this discussion. We now assume the light incident on this slab is a plane wave with a Gaussian intensity distribution given by $I(r) = I_0 \exp(-2r^2/w^2)$ as shown in Figure 1. I_0 is the peak intensity along the z-axis, and w is the radius of the beam at $1/e^2$ of the peak intensity. Consistent with the paraxial approximation, we expand the exponential function, keeping only the first two terms, to yield $I(r) \approx I_0(1 - 2r^2/w^2)$. This parabolic approximation to the intensity is sketched as the dotted curve in Figure 1. The index distribution induced in the medium by the intensity approximately follows this parabolic shape, and the resultant

phase change is

$$\Delta\varphi(r) = -k4n_2I_0\frac{L}{w^2}\frac{r^2}{2} \equiv -\frac{kr^2}{2f}, \qquad f^{-1} = \frac{4n_2I_0L}{w^2} \qquad [3]$$

Note the similarity to the GRIN lens, with the association of the peak index $n_0 \rightarrow n_2I_0$, and $\alpha^2 \rightarrow 4/w^2$. We can say that the nonlinear medium acts like a GRIN lens with an intensity-dependent focal length. However, this correspondence is only accurate within the parabolic approximation, and the nonlinear lens can introduce significant aberrations to the focal properties of the full beam.

In the paraxial approximation, the conventional, GRIN, and nonlinear lenses all have the same effect on an incident beam of light. Although we have considered only plane parallel incident waves, it should be obvious that the GRIN and nonlinear lenses will produce analogous effects on converging and diverging wavefronts as the conventional lens. The effect of a stack of nonlinear lenses in an optical train can also be analyzed in the same way as a stack of conventional lenses, with the exception that the focal length of each lens will depend on the local intensity and hence size of the beam. Finally, we note that if we change the sign of R, α^2, or n_2, we obtain a negative focal length. This is a diverging lens, and in the nonlinear optics realm the effect is called self-defocusing.

Nonlinear Index of Refraction

The concept of an intensity-dependent refractive index has its roots in the power series expression of the nonlinear dielectric polarization P in terms of the electric field E of the optical wave, which in its simplest form is

$$P = \varepsilon_0\left(\chi^{(1)}E + D^{(2)}\chi^{(2)}E^2 + D^{(3)}\chi^{(3)}E^3 + \cdots\right) = \varepsilon_0\left(\chi^{(1)} + D^{(2)}\chi^{(2)}E + D^{(3)}\chi^{(3)}E^2 + \cdots\right)E \qquad [4]$$

where $\chi^{(m)}$ $(m = 1, 2, 3\ldots)$ is called the m-th order susceptibility. The quantity $D^{(m)}$ is called the degeneracy factor and is 3 for $m = 3$ in the self-focusing case. This leads directly to the definition of a nonlinear susceptibility $\chi(E)$. All materials have first- and third-order susceptibilities. Centrosymmetric materials (e.g., gases, liquids, cubic crystals) do not possess a second-order susceptibility. Here, we will consider only centrosymmetric media and briefly discuss second-order materials later.

The refractive index is $n = [1 + \chi(E)]^{1/2}$. Consequently, the linear index (small electric field) is $n_0 = (1 + \chi^{(1)})^{1/2}$. The leading nonlinear term in $\chi(E)$ is generally small. Expanding the square root in a binomial series, the first nonlinear term in the refractive index can be approximated by $3\chi^{(3)}E^2/2n_0$. Since $I = 2\varepsilon_0 n_0 cE^2$, we see that

$$n = n_0 + n_2I \qquad [5]$$

where $n_2 = 3\chi^{(3)}/4\varepsilon_0 n_0^2 c$. Third-order (cubic) materials that exhibit an intensity-dependent refractive index described by eqn [5] are called Kerr or Kerr-like.

Several physical mechanisms produce a refractive index of the form given in eqn [5]. A list of the significant ones is presented in Table 1. We emphasize that these mechanisms lead to eqn [5] over a limited range of intensity. For example, in materials where the main mechanism is electronic state population redistribution, when the incident intensity becomes comparable with the saturation intensity, the index begins to saturate (i.e., the change of index with

Table 1 Physical mechanisms responsible for the nonlinear index of refraction

intensity becomes sublinear). The simple expression in eqn [5] no longer applies. These types of effects can be important and will be discussed later. Finally, we mention that other mechanisms exist that produce self-focusing related effects, but they are not Kerr-like and will be briefly discussed later.

We learn from Table 1 that values of n_2 range over several orders of magnitude. High-intensity lasers are required to observe the effects of small optical nonlinearities. Hence pulsed lasers are often used in self-focusing applications. Laser pulse widths can generally range from 100 s of nanoseconds to 10 s of femtoseconds. Consequently, one must keep in mind the response time of the mechanism/material when analyzing experiments. If the pulse width is long compared to the response time, a quasi-steady-state self-focusing regime results. If the pulse is too short, transient effects will appear. Also, as one goes to longer response time mechanisms, lower intensities can be used. In some cases it is even possible to use cw lasers.

Self-Lensing

Thin nonlinear media can be employed in self-lensing applications, where self-focusing is used to modify the far field properties of a beam, just as a conventional lens would do, but with effects dependent on the beam intensity. Gaussian beams are usually employed in the paraxial approximation.

A popular technique employing this effect to measure the magnitude and sign of n_2 is the Z-scan. A typical experiment is illustrated in Figure 2. A thin nonlinear medium is scanned axially between a focusing lens and an aperture in the far field. Consider a material with positive n_2. When the sample is close to the lens the intensity is too low to induce significant self-lensing. As the sample approaches the focal point of the lens, the intensity rises and a positive self-lens is induced that focuses the beam more strongly. This displaces the focus to the left, causing the beam to spread out more in the far field and less power to pass through the aperture. As the sample passes to the right of the focal point, the positive self-lens reduces the divergence of the beam so that more power is passed through the aperture. Near the focal point the self-lens is strongest, but a thin lens at this point has no effect on the beam passing through the far-field aperture. The measured aperture transmittance as a function of scan-position Z is sketched in Figure 2. The peak and valley of this dispersion-shaped curve will be interchanged for a negative n_2. For a small aperture and fixed power of the laser, the difference between the peak and valley transmittance is proportional $|n_2|$.

The same experimental configuration is also popular for measuring small absorption coefficients or thermo-optic coefficients ($\mathrm{d}n/\mathrm{d}T < 0$ for most materials). Under steady-state conditions (cw beam), the thermal n_2 is given by

$$n_2 = \frac{\alpha\tau}{\rho C}\frac{\mathrm{d}n}{\mathrm{d}T} \qquad [6]$$

where α is the absorption coefficient, τ is the thermal diffusion time, ρ is the mass density, and C is the specific heat. This technique is extremely sensitive and can easily be observed, for example, with a ~1 mW laser pointer and a 1 cm cuvette filled with minute quantities of ink or food coloring dissolved in methanol.

This combination of self-lensing and a hard aperture has also been put to use in devices. One such device is the optical power limiter. A typical configuration is similar to the Z-scan experiment in Figure 2, with the sample fixed near the lens focal point. Thick media in the focal region have also been used. At sufficiently low optical power, the medium acts like a flat window. As the input power rises, self-lensing sets in and spreads the beam out at the aperture, limiting the transmitted power. The higher the incident power gets, the more the beam spreads. The result is a transmitted power that is clamped below a preferred level. Thermal lensing has been used for cw beams, while positive Kerr

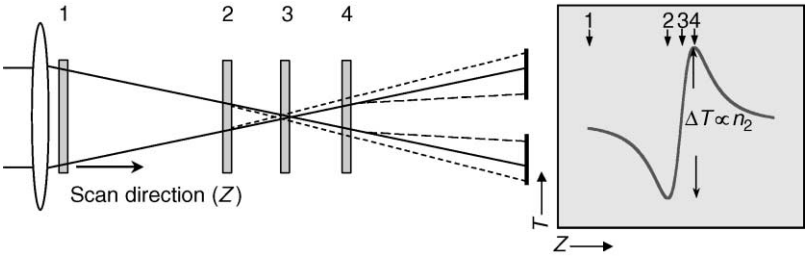

Figure 2 A Z-scan experiment. The transmittance through the aperture as a function of the position (Z) of the thin nonlinear medium is sketched at the right.

self-lensing has been employed for Q-switched lasers.

A less obvious but very important application of this configuration is for mode-locking lasers (see Figure 3). Mode-locking is a coherent phenomenon that locks the relative phase of multiple longitudinal modes in a laser having a broadband gain profile. These stabilized modes interfere to form a train of short pulses with pulsewidth inversely proportional to the gain bandwidth. A common technique for passively mode-locking a laser is to insert a saturable absorber into the laser cavity. A saturable absorber blocks low-power light, keeping the round-trip gain below the oscillation threshold, but transmits high-power light as the absorption coefficient saturates. Thus the mode-locked condition is favored for gain and oscillation since the peak power of the pulses is high. It turns out that transverse spatial modulation, due to self-focusing combined with an aperture, can produce the same type of effect in a laser cavity. The laser rod acts as both the gain medium and nonlinear lens. For example, titanium: sapphire ($Ti:Al_2O_3$) has $n_2 = 3 \times 10^{-16}\,cm^2\,W^{-1}$. Thus, in a $Ti:Al_2O_3$ laser the rod produces self-lensing that modifies the beam shape propagating through an intracavity aperture. The loss due to the aperture is intensity dependent, as in the Z-scan. Therefore, the net round-trip gain of the cavity is low for low-power but high for high-power pulses, and the mode-locking condition is fulfilled. These types of lasers are called Kerr lens mode-locked (KLM) lasers. KLM lasers are generally not self-starting, but can be self-sustaining. They, therefore, require some active means of starting the mode-locking. Ultrashort pulses (<100 fs) have been obtained with a cw KLM $Ti:Al_2O_3$ laser. For pulsewidths this short, the simple quasi-steady-state self-focusing picture is not entirely adequate to describe the dynamics. Other factors, such as group-velocity dispersion (GVD) and self-phase modulation (SPM), must be considered. Moreover, since the laser rod is typically several millimeters long, it is more appropriate to model it as a thick rather than a thin nonlinear lens.

Beam Trapping

When an intense beam propagates in a thick nonlinear medium, a question arises as to the ultimate fate of the beam. A possibility that has intrigued researchers for a long time is diffractionless propagation of a beam over long distances. In other words, self-focusing exactly balances diffraction to force the beam into a nonlinear waveguiding mode. This phenomenon is called beam trapping or self-trapping. A simplified analysis of a uniform beam captures the essential physics (see Figure 4). The refractive index inside the beam is higher than outside by eqn [5]. Therefore, light incident on the 'interface' at the edge of the beam can experience total internal reflection if its angle of incidence exceeds the critical angle, dependent on the value of the nonlinear index. If the complement of the critical angle matches the diffraction angle of the beam, the beam is trapped in its own self-induced waveguide. The critical power $\mathscr{P}_{cr2}$ at which this occurs is given in Table 2. The condition for beam trapping is independent of beam size since both diffraction and self-focusing depend on beam area, and these size effects cancel.

A detailed solution of the wave equation for a Gaussian beam using the parabolic approximation yields a slightly different critical power $\mathscr{P}_{cr1}$, also given in Table 2. Numerical analyses of the wave

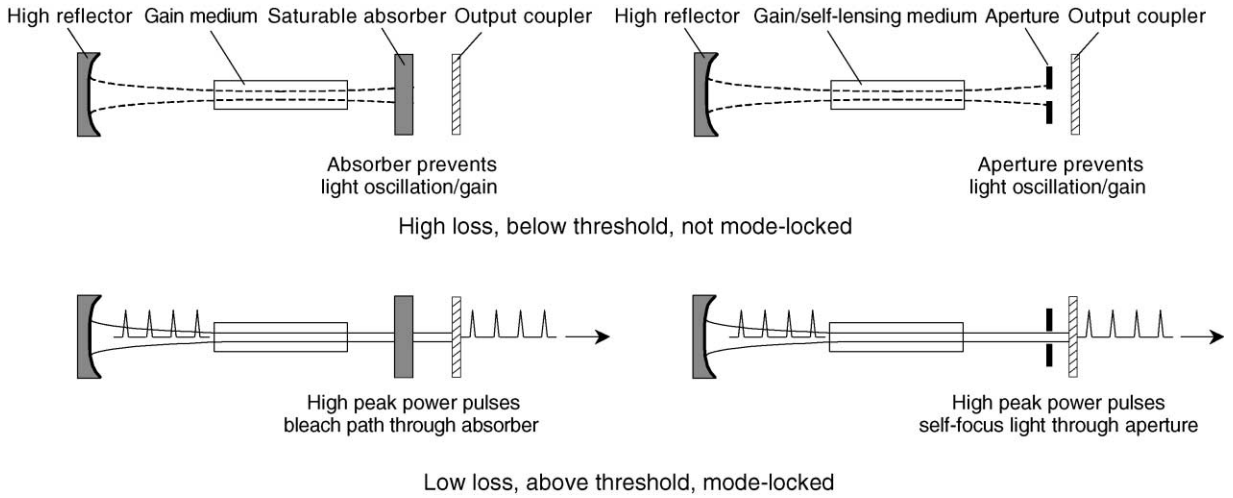

Figure 3 Laser mode-locking using a saturable absorber (left) and self-lensing in combination with an intracavity aperture (right).

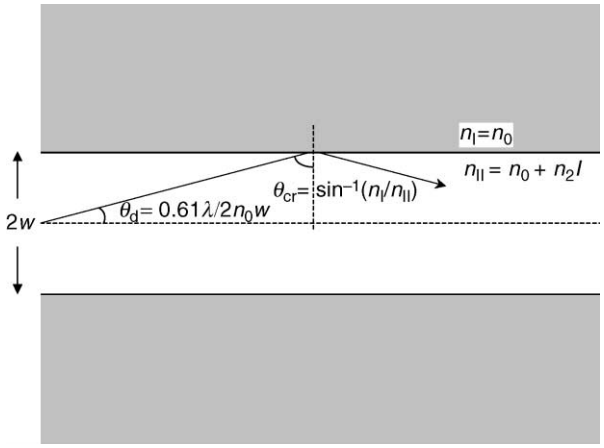

Figure 4 Self-trapping conditions for a uniform beam of intensity I and width $2w$ in a Kerr medium.

Table 2 Critical power for beam trapping (collapse)

Gaussian beam (parabolic approximation)	$\mathscr{P}_{cr1} = \frac{1}{2}\frac{\lambda^2}{4\pi n_0 n_2}$
Gaussian beam ('whole beam' collapse)	$\mathscr{P}_{cr2} \approx \frac{(1.22\pi)^2}{8}\frac{\lambda^2}{4\pi n_0 n_2}$
Townes soliton, lower bound for arbitrary beam shape	$\mathscr{P}_{crT} \approx 1.86225\frac{\lambda^2}{4\pi n_0 n_2}$
Arbitrary beam (upper bound)[a]	$\mathscr{P}_{cr3} = G[f]\frac{\lambda^2}{4\pi n_0 n_2}$

[a] $G[f]$ defined in text.

equation for a whole Gaussian beam have shown for incident power such that $\mathscr{P}_{cr1} < \mathscr{P} < \mathscr{P}_{cr2}$ the beam comes to a 'soft' focus and then diffracts (partial beam focusing), but for $\mathscr{P} > \mathscr{P}_{cr2}$ the whole beam catastrophically collapses (i.e., the beam approaches a singularity). Catastrophic self-focusing has been observed experimentally, but as the beam collapses the intensity becomes so large that additional nonlinear effects, such as multiphoton absorption and stimulated Raman scattering, come into play. These effects rob the beam of energy and terminate the collapse. At this stage the beam will then spread by diffraction.

A more rigorous analysis of this problem is obtained by examining the nonlinear wave equation in the slowly varying amplitude approximation (propagation along z), but including the transverse variation of the wave. If the electric field of the optical wave is of the form $E(\mathbf{r}) = A(\mathbf{r})\exp(ikz)$, where now $k = n_0\omega/c$, then the wave equation can be written as

$$2ik\frac{\partial A}{\partial z} + \nabla_\perp^2 A + 4\varepsilon_0 n_2 c k^2 |A|^2 A = 0 \qquad [7]$$

where the transverse Laplacian $\nabla_\perp^2$ is $\partial^2/\partial x^2 + \partial^2/\partial y^2$ in rectangular Cartesian coordinates, or $\partial^2/\partial r^2 + (1/r)\partial/\partial r$ in cylindrical coordinates (assuming azimuthal symmetry). This equation is known as the nonlinear Schrödinger equation (NLSE). In normalized coordinates $\xi = x/w$, $\eta = y/w$, $\rho = r/w$, $\zeta = z/2kw^2$, where w is the input beam radius, and $\psi = 2kw(c\varepsilon_0 n_2)^{1/2}A$, eqn [7] takes the normalized form of the NLSE:

$$i\frac{\partial\psi}{\partial\zeta} + \nabla_\perp^2\psi + |\psi|^2\psi = 0$$
$$\nabla_\perp^2 = \frac{\partial^2}{\partial\xi^2} + \frac{\partial^2}{\partial\eta^2} = \frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} \qquad [8]$$

A waveguiding (i.e., diffractionless) solution of the form $\psi(\zeta,\rho) = \exp(i\zeta)R(\rho)$ exists for eqn [8], where $R(\rho)$ is a solution of

$$\nabla_\perp^2 R - R + R^3 = 0, \quad R'(0) = 0, \quad R(\infty) = 0 \qquad [9]$$

$R(\rho)$ is known as the Townes soliton. It has a radial profile similar to a Gaussian but differing in fine detail. Since the Townes soliton exactly balances diffraction and self-focusing, it carries a critical power $\mathscr{P}_{crT}$ given by the expression in Table 2. For comparison, $(1.22\pi)^2/8 = 1.83624$. Therefore, $\mathscr{P}_{crT}$ and $\mathscr{P}_{cr2}$ differ by only about 1%. However, the Townes soliton is unstable. An analysis of the solutions of the NLSE shows that a beam will not catastrophically collapse (i.e., its intensity will not blow up) if its power is less than $\mathscr{P}_{crT}$. Thus $\mathscr{P}_{crT}$ forms a lower bound for the critical power. An upper bound can also be found from analysis of the NLSE. It depends on the input beam profile [$\psi(\rho,0) \propto f(\rho)$] and is given as $\mathscr{P}_{cr3}$ in Table 2. The quantity $G[f]$ characterizes the input beam profile and is given by

$$G[f] = \frac{2\int |f|^2\rho\mathrm{d}\rho \int |\nabla f|^2\rho\mathrm{d}\rho}{\int |f|^4\rho\mathrm{d}\rho} \qquad [10]$$

For example, a Townes soliton, a Gaussian beam, and a hyperbolic secant beam yield $G = 1.86225$, $G = 2$, and $G = 1.86257$, respectively. Thus, if the beam power is such that $\mathscr{P}_{crT} \le \mathscr{P} \le \mathscr{P}_{cr3}$, the beam may collapse, but it will definitely collapse if $\mathscr{P} > \mathscr{P}_{cr3}$. We note that if the input beam is elliptical, with ellipticity $e = b/a$ (where a and b are the semi-major and semi-minor widths, respectively), then

$$\mathscr{P}_{crT}(e) \approx \left(0.6 + 0.2\frac{e^2+1}{e}\right)\mathscr{P}_{crT} \qquad [11]$$

This expression is accurate to within 1.5% of numerical simulations of the NLSE, and also holds well for Gaussian input beams.

The conclusion is that there is no stable self-trapped (2 + 1)-D beam (two diffracting dimensions, one

propagating dimension) in a Kerr medium. The beam will diffract, blow up in a finite distance, or go through a single focusing–defocusing cycle. For an incident plane wave, the distance from the input plane to the blowup point is (assuming a Gaussian input)

$$z_f \approx \frac{0.369\pi w^2/\lambda}{(\mathscr{P}/\mathscr{P}_{cr2})^{1/2} - 0.858} \qquad [12]$$

where the approximation holds well for $\mathscr{P} > 1.2 \times \mathscr{P}_{cr2}$.

Why, then, does self-trapping appear to occur in Kerr media? Time integrated photographs show what appears to be the formation of a filament, and laser damage tracks in solids follow the shape of a self-trapped filament. This can be explained in terms of the moving focus model. In the quasi-steady-state approximation, each time slice of the pulse comes to focus independently at different times and positions. Figure 5 shows a series of snapshots of a Gaussian spatial and temporal pulse (assume axial symmetry), where the peak power of the pulse is greater than $\mathscr{P}_{cr2}$. Slices of the pulse with $\mathscr{P} > \mathscr{P}_{cr2}$ will come to a focus at a finite distance $z_f(\mathscr{P})$, which can be approximated by eqn [12]. The time at which that focus appears is determined by the time it takes for that slice of power $\mathscr{P}$ to propagate to the input plane ($z = 0$) plus propagate to $z_f(\mathscr{P})$. As illustrated in Figure 5, slice 1a takes the minimum time to come to a focus. At a later time slices 2a and 2′ come to focus simultaneously but at different positions, 2a to the left and 2′ to the right of 1a, since $\mathscr{P}(2a) > \mathscr{P}(1a)$ and $\mathscr{P}(2') < \mathscr{P}(1a)$. The solid curves in the left of Figure 5 are the trajectories of the beam rays showing where each slice will come to focus. Slice 2b, having the same power as 2a, comes to focus at the same position as 2a, but later in time, and so on. The original focus thus appears to split in two, with one branch propagating forward and the other backward. The backward branch comes to a turning point when slice 4 of maximum power in the pulse center comes to focus, then propagates forward as time slices in the back part of the pulse come to focus. The motion of the foci traces out the U-shaped curve shown to the right in Figure 5. The time-integrated picture that appears like a filament is thus just the tracks of moving foci.

The question remains, do conditions exist under which stable self-trapped beams can form? The answer is yes, and these types of beams are called spatial solitons. The $(1 + 1)$-dimensional NLSE admits the fundamental spatial soliton solution:

$$A(x, z) = A_0 \mathrm{sech}(x/w) \exp(iz/2kw^2)$$
$$|A_0|^2 = \frac{1}{2\varepsilon_0 c n_2 (kw)^2} \qquad [13]$$

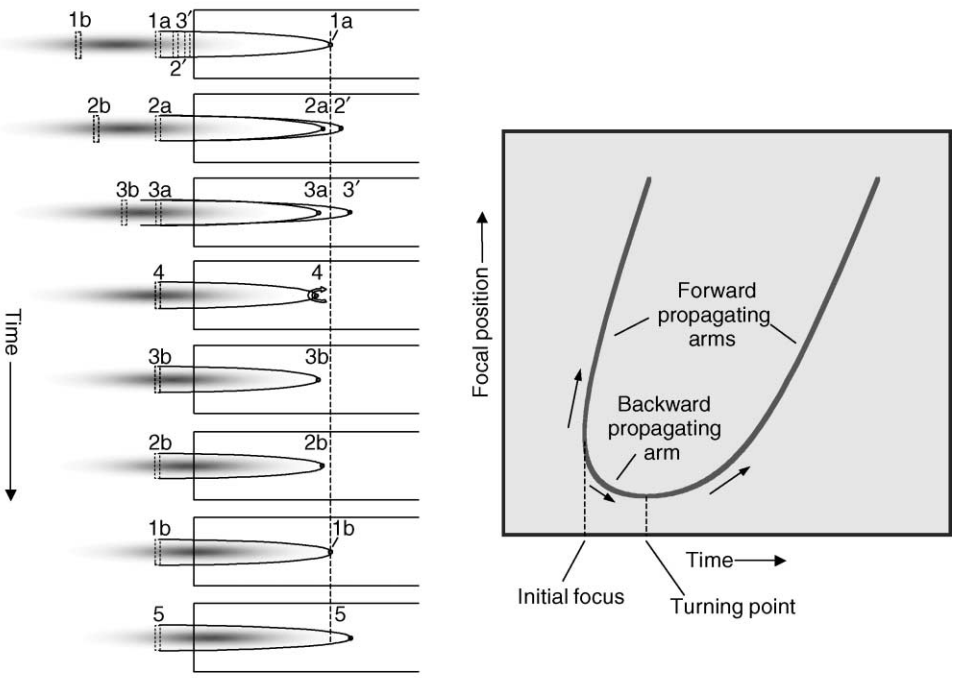

Figure 5 Moving focus model of apparent filament formation by quasi-steady-state self-focusing of a pulsed Gaussian beam. The series of snapshots on the left illustrate when and where different time slices of the pulse come to focus. The tracks of moving foci trace out the curve shown on the right.

The wave given by eqn [13] propagates along z with a constant width w along the x-axis. Such a $(1+1)$-D soliton can be formed in a slab waveguide, as illustrated in Figure 6, consisting of a nonlinear thin film deposited on a linear slab, where the wave is confined along y but can diffract along x. These types of solitons have been confirmed experimentally and shown to be quite robust. They are stable against perturbations and propagate as a self-induced waveguide. Since a soliton changes the refractive index where it propagates, it can also attract and guide other beams. The interactions or 'collisions' of solitons are an active area of current research. Intriguing potential applications include all-optical reconfigurable interconnects for telecommunications and optical computing based on the properties of soliton collisions.

Although $(2+1)$-D spatial solitons are not stable in ideal Kerr media, they can be in Kerr-like media with a saturating nonlinearity. For example, a two-level saturable absorber (e.g., an atomic vapor) at a wavelength tuned above the natural absorption frequency will exhibit a positive Kerr-like response at low intensity ($I \ll I_{sat}$), but then saturates as $(1+I/I_{sat})^{-1}$ for $I \sim I_{sat}$ or larger, where I_{sat} is the saturation intensity. This can form a stable trapped beam, as was first reported in 1974 for a cw laser in Na vapor, because as the beam self-focuses and the intensity rises, the nonlinear index levels off asymptotically until a balance between diffraction and focusing is reached. This type of situation is stable against perturbations, but may undergo almost periodic focusing–defocusing cycles.

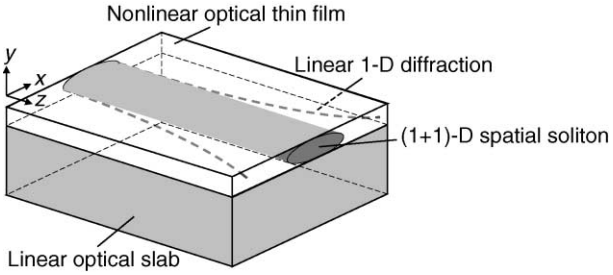

Figure 6 Spatial soliton propagation in a nonlinear slab waveguide.

Spatial solitons employing mechanisms other than the Kerr nonlinearity are also being vigorously studied. One of these is the photorefractive effect. An illustration of the generation of a slab soliton is shown in Figure 7. A Gaussian beam is focused to a line (e.g., by a cylindrical lens) and propagated as an extraordinary wave along the optic (z) axis of a uniaxial photorefractive crystal. A dc electric field is also applied along z. Charge carriers are generated in the slab beam by photo-ionization of dopant atoms and drift in the dc field. The lower resistivity in this region causes the voltage drop to be smaller and hence the field to be lower. The field induces a refractive index change by the Pockels effect ($\Delta n = -n_0^3 |r_{eff} E|/2$, where r_{eff} is the effective Pockels coefficient and n_0 is the background index). The index change is negative, but is reduced in magnitude where the field is lower. The index change depends on the local intensity, and the

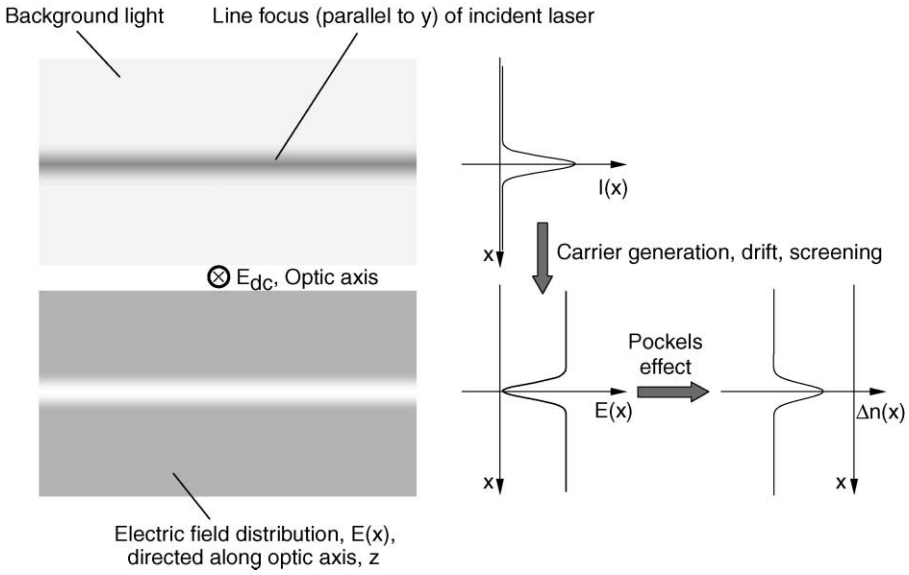

Figure 7 Mechanism of slab soliton formation in a photorefractive material.

photorefractive mechanism produces an effective saturable self-focusing nonlinearity. (There are a limited number of charge carriers, and the field cannot be reduced below zero.) This produces a waveguide that traps the slab beam, which then propagates without spreading. Thus the photorefractive soliton is stable. This effect can be observed with milliwatt-level cw lasers, but the space-charge field takes time to build up to a steady state (typically of the order of seconds). Needle (circularly symmetric) solitons have also been observed by launching a TEM_{00} Gaussian beam in a photorefractive crystal, but the theoretical description is not as simple. Other types of spatial solitons and other mechanisms have been explored using the photorefractive and photovoltaic effects. The reader is referred to the literature for a more in-depth discussion.

Another mechanism useful for soliton formation is cascaded second-order (quadratic) effects. This includes such phenomena as second-harmonic generation (SHG) and other frequency conversion processes. Consider SHG with imperfect phase matching. (The reader is referred to other articles discussing harmonic generation and phase matching.) A fundamental (F) wave generates its second harmonic (SH), but because of dispersion $n(\omega)$, the two waves travel at different phase velocities. The SH(2ω) beats with the F(ω) wave to generate, via the second-order nonlinear polarization, another wave at ω that adds to the incident F wave. This produces a net phase shift of the F wave that accumulates continuously as the waves propagate together and periodically exchange power; this is called cascading. In the nondepleted pump approximation, this phase accumulation can be expressed as

$$\Delta\varphi = -\frac{\Delta k z}{2}\left\{1 - \left[1 + \left(\frac{2\kappa\sqrt{I}}{\Delta k}\right)^2\right]^{1/2}\right\} \qquad [14]$$

$$\kappa = \frac{\omega\chi^{(2)}_{\text{eff}}}{\sqrt{2\varepsilon_0 n_0^3 c^3}}$$

where $\chi^{(2)}_{\text{eff}}$ is an effective second-order susceptibility (dependent on crystal symmetry, polarization vectors, and propagation direction), $\Delta k = 2k(\omega) - k(2\omega)$ is the phase mismatch, I is the intensity of the F wave, and n_0 is the approximate refractive index for both F and SH waves. Although not due to a refractive index change, this phase change produces a self-focusing effect for a bell-shaped intensity. For a small enough pump intensity or sufficiently large phase mismatch, an equivalent n_2 can be approximated by

$$n_2 = \frac{\omega(\chi^{(2)}_{\text{eff}})^2}{2\varepsilon_0 n_0^3 c^2 \Delta k} \qquad [15]$$

Note that the sign of n_2 depends on the sign of Δk. For $I \sim (\Delta k/2\kappa)^2$ or larger, eqn [15] is not valid and eqn [14] must be used. Note that the equivalent index change is then sublinear with respect to I, and soliton formation is stable. When pump depletion cannot be ignored, the F and SH coupled-wave equations must be solved numerically to analyze soliton dynamics. Figure 8 illustrates the difference between a beam diffracting normally and a diffractionless quadratic soliton. When an F beam is launched in a nonlinear medium, it does not immediately form a soliton, but evolves into one, shedding some energy in the process. Note that this soliton does not consist of a single frequency beam, but depends on the nonlinear coupling between the ω- and 2ω-waves that continuously exchange energy as the beams propagate. For this reason, these solitons are called simultons.

Self-Focusing in Space–Time

The moving focus model describing the self-focusing of optical pulses becomes inadequate when dispersion effects must be included. This is true in the case of ultrashort pulses (typically ~100 fs or less). To properly describe the propagation of a pulse with group velocity v_g, eqn [7] must be modified by $\partial A/\partial z \rightarrow [\partial/\partial z + (1/v_g)\partial/\partial t]A$. In addition, to include the effects of GVD, a term $-k_2 k(\partial^2 A/\partial t^2)$ is added, where $k_2 = (\partial^2 k/\partial\omega^2)$ is the GVD coefficient. For anomalous GVD, $k_2 < 0$. Taking this to be the case and defining another normalized coordinate $\tau = (t - z/v_g)/(|k_2|k)^{1/2}w$, the normalized NLSE (eqn [8]) becomes

$$i\frac{\partial\psi}{\partial\zeta} + \left(\frac{\partial^2}{\partial\xi^2} + \frac{\partial^2}{\partial\eta^2} + \frac{\partial^2}{\partial\tau^2}\right)\psi + |\psi|^2\psi = 0 \qquad [16]$$

Note the complete symmetry in eqn [16] between the transverse space (ξ, η) and time (τ) variables. There is thus a correlation between diffraction (space) and dispersion (time). The corresponding phenomenon to self-focusing is self-phase modulation (SPM). This effect denotes the additional phase retardation experienced by a pulse in a Kerr medium due to its time-dependent intensity: $\Delta\varphi(t) = -(\omega_0/c)n_2 I(t)z$, where ω_0 is the center (carrier) frequency of the pulse. SPM produces new frequencies ($d\varphi/dt$) that are red-shifted on the leading edge of the pulse and blue-shifted on the trailing edge. The frequency shifts in a self-focused filament can be quite sizeable and create a large continuum (a white light pulse) that

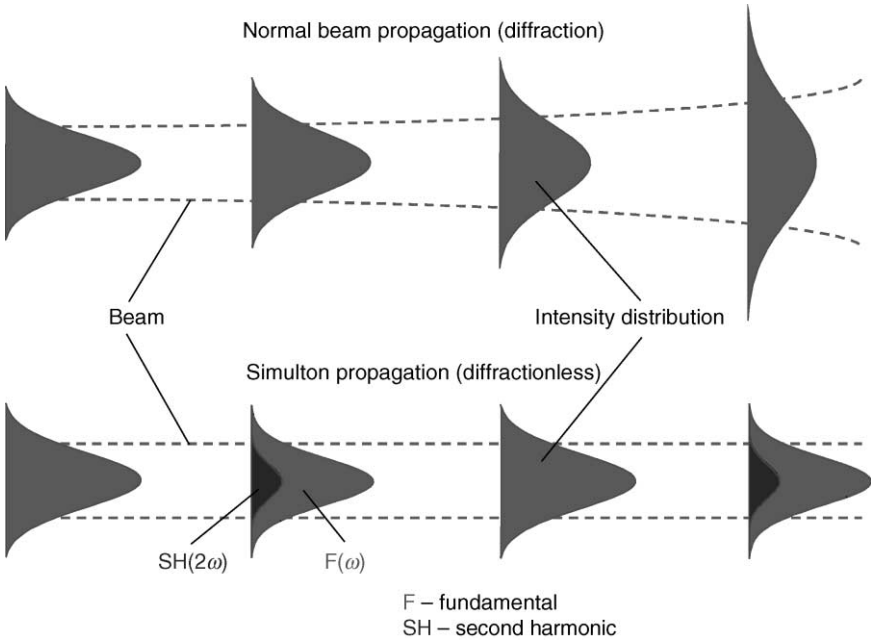

Figure 8 Comparison of normal beam propagation to simulton propagation in a quadratic nonlinear medium. In a simulton, the F and SH waves periodically exchange energy as they co-propagate in the medium.

can be used for ultrafast spectroscopy. In a medium with normal GVD the pulse spreads in time because blue frequencies in the trailing edge travel slower than red frequencies in the leading edge. However, for anomalous GVD the opposite is true, and the pulse can 'focus' or collapse in time.

The simultaneous spatiotemporal collapse of a beam of ultrashort pulses leads to the consideration of $(3 + 1)$-D soliton generation, where the third 'transverse' dimension is time. While the NLSE leads to unstable solitons for transverse dimensions >1, a saturating nonlinearity could possibly bound the collapse and lead to the formation of stable, diffractionless, dispersionless pulses. These types of pulses are called light bullets. Light bullets have a particle-like nature and display many interesting, exotic properties that could lead to ultrafast switching rates for optical digital logic systems in telecommunications and computing.

The saturable nature of self-focusing in quadratic nonlinear media makes them natural candidates in the search for light bullets, and $(2 + 1)$-D spatiotemporal simultons have been observed in crystals of lithium iodate. The drawback of ultrashort pulse simulton generation in quadratic media is the added complications of requiring anomalous GVD at both ω and 2ω, and dealing with the effects of group-velocity mismatch (GVM). The phenomenon of GVM involves the different group velocities of the F and SH pulses, which makes them walk away from one another. Without the physical overlap of these two pulses, the simulton will cease to exist. By tilting the amplitude front of the pulses with respect to their phase fronts, it is possible (over a limited distance) to compensate pulse walkoff due to GVM with spatial walkoff due to the birefringence of the quadratic medium. Accomplishing this, however, requires the beam to be in the form of a narrow stripe, and the propagation distance over which pulse overlap is good is greater for a longer stripe. This can be achieved by focusing a beam onto the medium with a cylindrical lens. The simulton then propagates without a change of width temporally or spatially (in 1-D). This is not a light bullet, however, because the confinement is not in all three dimensions.

The elliptic nature of the diffraction–dispersion operator in eqn [16] makes pulse collapse a possibility in nonlinear media with anomalous GVD. With normal GVD, the operator is hyperbolic. For such a medium, it has been predicted and observed that instead of collapsing, a self-focused pulse in a Kerr medium will split in time. Since the red-shifted frequencies generated at the front of the pulse travel faster than the blue-shifted frequencies produced at the back, the front of the pulse separates from the back part. Collapse of the pulse, as well as self-trapping, is not favored under conditions of pulse splitting.

Given this property of the NLSE, it is somewhat surprising that the reportedly first observation of light bullets was in a quadratic medium with normal GVD.

Focusing a beam of Gaussian profile in both space and time near the entrance to a lithium triborate crystal under the condition of a large positive phase mismatch, the pulses propagated without spread temporally or spatially (2D) over a distance ~20 mm (the length of the crystal). However, the pulse did not retain its shape, but evolved into a so-called 'X-wave', or X-shaped soliton. A generic X-shaped soliton (or, strictly speaking, simulton) is shown in Figure 9. The pulse has a conical (clepsydra, or hourglass-shaped) 3D structure with a central hump and slowly decaying conical tails. Interestingly, an X-shaped pulse has been shown to propagate without spreading in a linear optical medium exhibiting normal GVD. But such a pulse must be specially contrived at the input and may be impossible in many cases. In a quadratic nonlinear medium with normal GVD, the X-shaped light bullet appears to form spontaneously. The physics of this evolution lies buried in the coupled wave equations for the fundamental and second harmonic. In the strong phase-mismatched SHG process, weak perturbations in the waves at specific spatial and temporal frequencies can grow exponentially. The hyperbolic nature of the diffraction–dispersion operator with normal GVD leads to amplification of conical wave perturbations with frequencies approaching that of the X-wave. This amplification of the proper frequency components acts as a trigger that drives the evolution of the Gaussian spatiotemporal input pulse into the X-wave. This basic shape has been confirmed in experiments that outline the spatiotemporal intensity profile of the pulse exiting the rear of the crystal.

Other Related Effects (Multiphoton Nonlinearities)

At this point we should note that the susceptibility is frequency dependent. Optical waves couple principally to bound electrons, which can only occupy discrete energy levels. When the photon energy $\hbar\omega$ is nearly resonant with a difference between these energy levels, the dielectric response of the medium is enhanced. This well-known property of linear optics, accounting for absorption of light as well as normal and anomalous dispersion, is also applicable in nonlinear optics. The third-order susceptibility is actually a complex number. A sketch of its real and imaginary parts is given in Figure 10, the real part relating to n_2. The imaginary part is associated with optical loss, if positive, or gain when it is negative. In the present case the frequency dependence of the susceptibility displays a resonance (i.e., peak of the imaginary part) at a frequency $\omega = 2\omega_0$. Referring to Figure 10, when the optical frequency is significantly less than ω_0, the imaginary part of $\chi^{(3)}$ is small compared to the real part and nonlinear refraction dominates. However, when the frequency is comparable to ω_0, the resonance at $2\omega_0$ plays a major role. The real part of $\chi^{(3)}$ is resonantly enhanced, but the imaginary part signifies loss: two photons are simultaneously absorbed. This is called two-photon absorption (2PA). The intensity-dependent absorption loss per unit length is given by $\alpha_2 I$, where α_2 is called the two-photon absorption coefficient (often designated by β) and has physical units of cm W^{-1}.

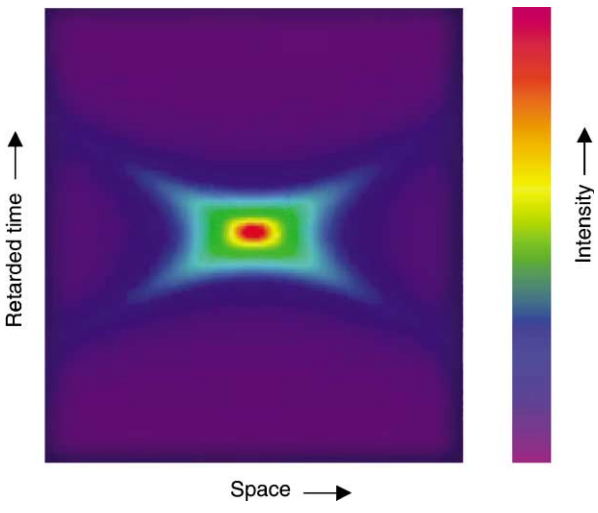

Figure 9 Generic shape of an X-wave light bullet as a function of space and retarded time ($t - z/v_g$) coordinates. The light bullet has radial symmetry.

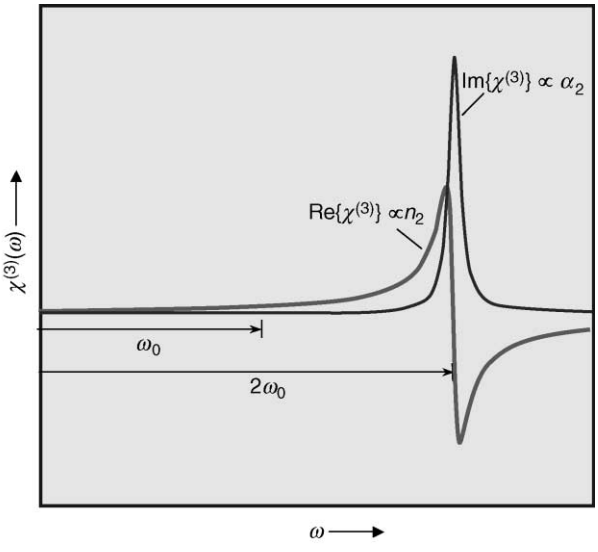

Figure 10 Sketch of the real and imaginary parts of the frequency-dependent third-order susceptibility $\chi^{(3)}$ illustrating a two-photon resonance.

In many materials at a variety of optical frequencies, 2PA will naturally accompany self-focusing. Since these two phenomena are both intensity dependent, while one decreases the intensity and the other increases it, there is an obvious interplay between the two. We illustrate the effect of 2PA in Figure 11 by comparison of the phase retardance of a Gaussian beam (in the parabolic approximation) with and without 2PA in a 'thin' medium, for which the size of an optical beam is nearly constant (diffraction ignored). Obviously, $\Delta\varphi(r)$ does not reproduce the parabolic shape when strong 2PA is present. Actually, it is possible to have multiphoton absorption (MPA) of m photons with corresponding coefficient α_m (related to $\chi^{(m)}$). The effects of 3PA and 4PA are also shown in Figure 11. 2PA, or more generally MPA, distorts the phase and modifies the focusing properties of the beam. This shows up in the Z-scan, for example, as a distortion of the dispersion-like transmittance curve: the valley is deeper and the peak is suppressed.

The reason for this phase distortion is that nonlinear absorption changes the shape of the beam: absorption is stronger where the intensity is higher. For MPA, the intensity at position z in a thin medium is

$$I(r,z) = \frac{I(r,0)}{\left[1 + (m-1)\alpha_m I^{m-1}(r,0)z\right]^{1/(m-1)}} \qquad [17]$$

The other obvious effect of MPA is that it reduces the strength of self-focusing since it robs power from the beam. The interplay of the two effects shows up more in thick media where the beam can diffract and change size. When self-focusing is dominant at the front of the medium, the intensity will start to blow up as the beam collapses, but the intensity becomes so large that MPA becomes much stronger. This robs energy from the beam and can stop or reverse the collapse. When MPA is dominant at the start, the beam will still self-focus, but MPA flattens the beam in the center causing the edges of the beam to experience dramatic diffraction effects; for example, a ring structure can develop.

The intensity of a self-focused filament can be quite high. At a level $\sim 10^{11}$ W cm^{-2} or higher, it is possible for MPA to lead to multiphoton ionization (MPI) of the medium. This is illustrated in Figure 12 where the absorption of m photons promotes an electron from the ground state to the continuum in a gas, or from the valence band to the conduction band in a solid. The ionization rate is $\sigma_m I^m$, where m depends on the optical frequency and the ionization potential of the material. For example, at a wavelength of 810 nm, $m = 11$ for nitrogen and $\sigma_{11} = 5.08 \times 10^{-144}$ s^{-1} cm^{22} W^{-11}. We note that for intensities larger than $\sim 10^{14}$ W cm^{-2}, the dominant ionization mechanism is tunneling, where a 'quivering' electron has sufficient energy to tunnel through the coulombic barrier. MPI can create a plasma whose optical properties depend on the density of free electrons. The refractive index of the plasma is nonuniform, and for $\omega > \omega_p = (N_e e^2/\varepsilon_0 m_e)^{1/2}$, the plasma frequency is <1; N_e, e, and m_e are the electron density, charge, and mass, respectively. Hence, plasma formation leads to defocusing. Consequently, self-focusing in air (which has a positive n_2) can lead to plasma formation by MPI, and the resultant defocusing can stabilize the formation of a self-trapped filament of light propagating over a distance of meters. These filaments have been called 'gas-induced solitons'. High peak power femtosecond pulses are typically used to generate these. The pulse width is short compared to the mean

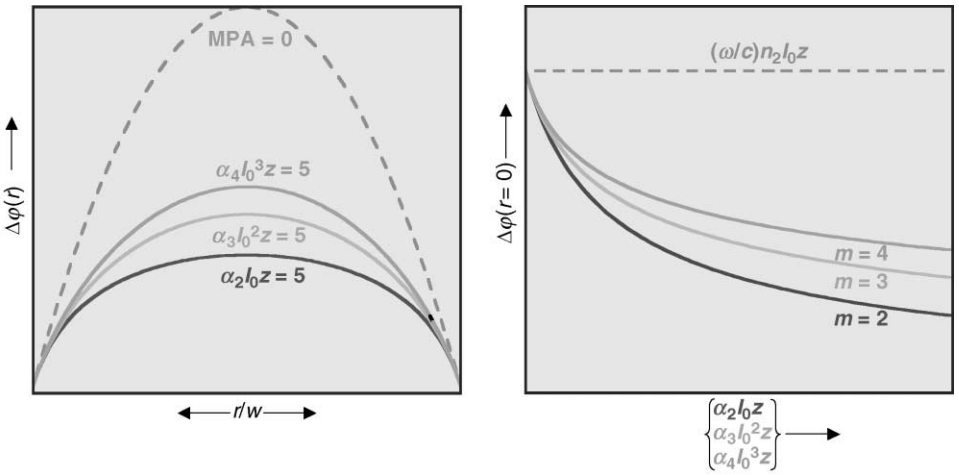

Figure 11 The effects of two-, three-, and four-photon absorption on the intensity-induced phase retardation due to a Kerr self-focusing nonlinearity. The radial dependence of $\Delta\varphi$ on MPA in the parabolic approximation is shown on the left, and the peak of $\Delta\varphi$ as a function of nonlinear absorption loss is plotted on the right.

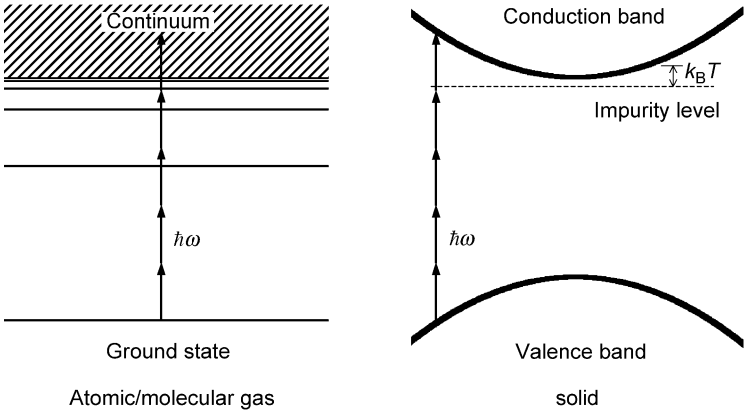

Figure 12 Multiphoton ionization in a gas (left) and a solid (right).

collision time of molecules, and the energy is low so that plasma heating is negligible.

The electron density in plasmas induced by MPI in gases is typically low enough that absorption by free electrons can be ignored. This is generally not the case in solids. MPI can provide enough 'seed' electrons to induce avalanche ionization. As illustrated in Figure 12, impurities may also supply these seed electrons by thermal ionization if they lie within an energy $\sim k_B T$ of the conduction band (k_B is the Boltzmann constant and T is the temperature). Free electrons can absorb electromagnetic energy while colliding with ions or atoms (a process called inverse bremsstrauhlung) and accelerate in a high-intensity field. They strip electrons from other atoms or molecules by impact ionization. The process multiplies free electrons and avalanche ionization ensues. A plasma forms, absorbs more energy and expands, developing a shock wave that can lead to a permanent crack in the solid. This phenomenon is called optical breakdown. Typically observed with nanosecond and picosecond pulses, permanent laser damage of the material also robs energy from the beam and generally terminates the collapse of a self-focused beam. When the electron density is sufficiently high so that $\omega_p > \omega$, the plasma absorbs and scatters light, a process that can be put to use in optical power limiters.

Many additional nonlinear phenomena play important roles when the intensity of a self-focused beam gets this large (e.g., stimulated Raman scattering, stimulated Brillouin scattering, etc.). The reader is referred to the literature on nonlinear optics for more in-depth discussions of these effects.

List of Units and Nomenclature

Critical power	[W]
Electric field	[V m^{-1}]
Four-photon absorption coefficient	[cm^5 W^{-3}]
Intensity	[W cm^{-2}]
Multiphoton (m-photon) absorption coefficient	[cm^{2m-3} W$^{-(m-1)}$]
Multiphoton (m-photon) ionization rate coefficient	[s^{-1} cm^{2m} W^{-m}]
Nonlinear refractive index coefficient	[cm^2 W^{-1}]
Pockels coefficient	[m V^{-1}]
Second-order susceptibility	[m V^{-1}]
Third-order susceptibility	[m^2 V^{-2}]
Three-photon absorption coefficient	[cm^3 W^{-2}]
Two-photon absorption coefficient	[cm W^{-1}]
Vacuum permittivity	[C V^{-1} m^{-1}]

Three-Dimensional Microfabrication

Introduction

Nonlinear optical three-dimensional microfabrication (3DM) is a photolithographic technique that enables topologically complex 3D microstructures with feature size as small as 1 μm or less to be generated in a single exposure step by nonlinear photopatterning in a material. In the broadest context, 3DM encompasses schemes based on single-beam serial patterning and parallel patterning achieved by multiple-beam interference exposure. In both cases, the photopatterning is initiated by coherent multiphoton excitation (MPE). The material may be a glass, a polymerizable resin, or even a heterogeneous composite, such as a resin containing dispersed nano-particles. The limiting resolution, or the dimensions of the smallest feature that can be generated, is determined by the optical parameters of the excitation geometry and the physical and chemical response of the material to MPE.

3DM offers great promise as a tool for generating complex microdevices, such as micro-electromechanical systems (MEMS), microfluidics, and micro-optical components. New frontiers in the technology of microdevices require that complex 3D structures can be produced in one or more materials that are optimized for a target application in terms of physical, chemical, and mechanical properties. Rapid and versatile fabrication is also essential. Extensive work has been done with conventional photolithography or electron-beam lithography, and more recently using soft-lithography approaches, such as microcontact printing. 3DM provides a new set of tools that overcomes some of the limitations inherent to other methods.

Single-Beam Three-Dimensional Microfabrication

3D Confinement

The simplest form of 3DM involves patterning a microstructure within a material using a single tightly focused laser beam that can activate the medium or one of its constituents by two-photon excitation (TPE) (Figure 1). The TPE initiates a photochemical or photophysical process (e.g., a polymerization reaction or a phase change) within the focal volume and results in an irreversible change in the material. The pattern of the target structure is impressed point by point as the focus is translated within the volume of the material. For some applications the final 3D microstructure is obtained when the unexposed material surrounding the photopatterned regions is removed. In the first report of this type of 3DM in 1990 two-photon-induced polymerization (TPIP) of an acrylate resin was used to fabricate free-standing 3D micron-scale letters on a substrate (Figure 2). The unexposed material does not have to be removed in a post-exposure process when the target structure consists of the phototransformed material supported within the matrix of the unexposed media, as in the case of 3DM of waveguide circuits embedded within a host slab.

3DM is possible because, under tight focusing, TPE and the subsequent material transformation are

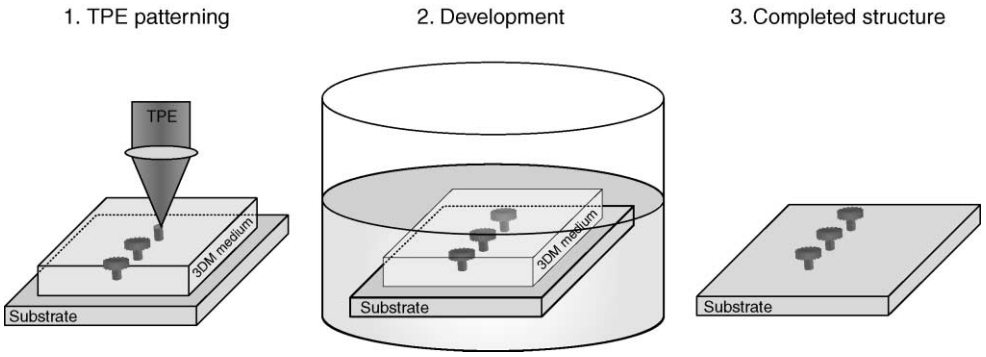

Figure 1 General scheme for single-beam 3DM based on TPE. (1. TPE patterning): The 3DM medium is supported on a substrate and translated in 3D-space relative to a tightly focused laser beam. The laser transforms the material only in the region around the focal point through a photochemical or photophysical process initiated by TPE. (2. Development): In cases where the final structure is needed free from the unexposed material, the sample is treated with a 'developer' that removes the unexposed material, for example by dissolving it in a solvent. (3. Completed structure): Following removal of the unexposed material, the final 3D structure is obtained free-standing on the substrate.

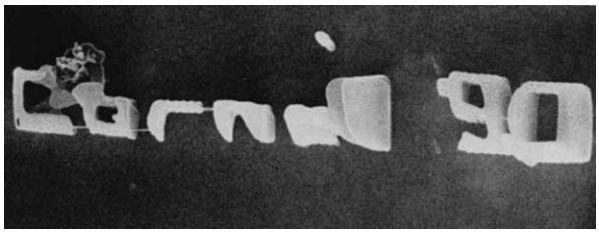

Figure 2 Scanning electron micrograph of a structure obtained by TPIP-3DM in an acrylate-ester resin. The excitation wavelength was 630 nm. The voxel dwell time was 10 ms along the letters. The thin filaments connecting some of the letters are approximately 100 nm wide. confined at the focus within a volume of $\sim(\lambda/n_0)^3$, where λ and n_0 are the vacuum wavelength of the exciting radiation and the refractive index of the material, respectively. Degenerate TPE is a resonant third-order nonlinear optical process in which a species is promoted to an excited electronic state by the simultaneous absorption of two photons of equal energy. Relative to conventional one-photon excitation (OPE), TPE is typically achieved using longer-wavelength radiation (often red or near infrared), for which the combined energy of two photons is sufficient to promote the species into one of its lower lying excited electronic states (Figure 3, left). The rate of TPE, that is the number of species excited per unit volume and time, $R_{2h\nu}$, is proportional to the square of the intensity, I. For a focused Gaussian beam, the on-axis intensity attains its maximum, I_0, at the focus and decreases with distance from the focal plane, z, approximately as $I \propto z^{-2}$. For a focused Gaussian beam, the on-axis intensity is given by $I = I_0/[1 + (z/z_R)^2]$, where z_R is the Rayleigh range of the focused wavefront. Thus, $I \propto z^{-2}$ in the limit of $z \gg z_R$. Consequently, the excitation rate decreases as $R_{2h\nu} \propto z^{-4}$. Similarly, the excitation rate decreases rapidly away from the propagation axis. This results in a region of high excitation, and thus material transformation, that is tightly confined both laterally and longitudinally in space about the focal point (Figure 3, right). This situation may be contrasted with that for OPE, for which the excitation rate, $R_{1h\nu}$, is linearly proportional to I, so $R_{1h\nu} \propto z^{-2}$. The weaker dependence of $R_{1h\nu}$ on z results in material being excited appreciably throughout the irradiation volume, with less longitudinal confinement at the focus than is achieved under TPE. Similar arguments can be used to describe 3DM involving higher-order excitation, for which the excitation is confined to an even smaller volume for a given λ.

The rate for molecular n-photon excitation, $R_{nh\nu}$, represents the average number of molecules that are excited per unit volume per unit time and is given by

$$R_{nh\nu} = \frac{1}{n(h\nu)^n}\sigma^{(n)}NI^n \qquad [1]$$

where n is the order of the excitation process, h is Planck's constant, ν is the frequency of the exciting radiation, $\sigma^{(n)}$ is a molecular n-photon absorption cross-section, which has units of $[\mathrm{cm}^{2n}\,\mathrm{s}^{n-1}\,\mathrm{photon}^{-(n-1)}]$, N is the number density of the photo-excitable species $[\mathrm{cm}^{-3}]$, and I is the intensity $[\mathrm{W\,cm}^{-2}]$. The factor of $1/n$ accounts for the fact that n photons must be absorbed to promote a single molecule to an excited state. Note that $\sigma^{(n)}$ is a

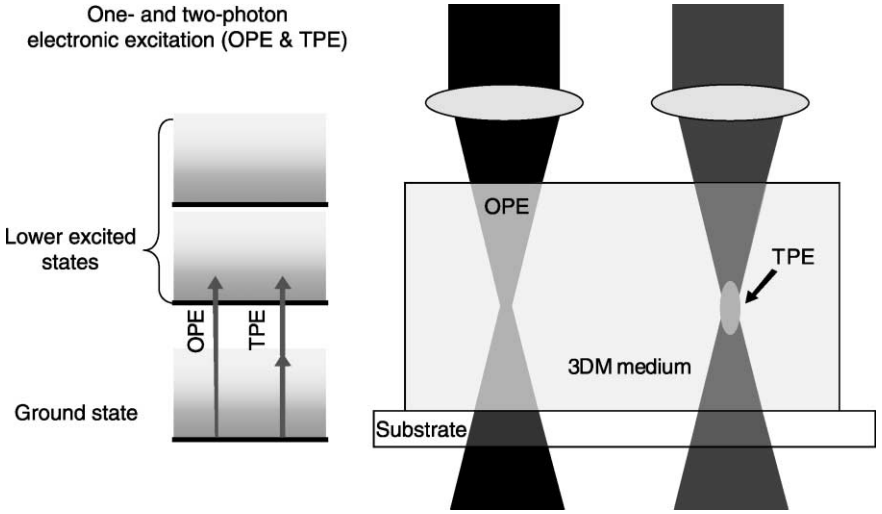

Figure 3 (Left) Jablonski representation of electronic one- and two-photon excitation (OPE and TPE, respectively). (Right) Illustration of a 3DM medium undergoing OPE and TPE using focused short- (black) and long-wavelength (dark gray) radiation, respectively. The regions that are appreciably excited are shown in light gray. Under OPE the medium is excited throughout the length of the interaction volume. Under TPE the excitation is confined in three dimensions to a small region around the focal point.

molecular parameter that is independent of the intensity. The molecular cross-sections for OPE and TPE, $\sigma^{(1)}$ and $\sigma^{(2)}$, are respectively equivalent to the parameters σ and δ that are commonly encountered in the literature.

For MPE to occur, the intensity must be sufficiently large that there is a high probability of more than one photon arriving simultaneously at the species to be excited. Typical magnitudes of the OPE and TPE cross-sections are $\sigma^{(1)} \approx 10^{-17}\,\mathrm{cm}^2$ and $\sigma^{(2)} \leq 10^{-47}\,\mathrm{cm}^4\,\mathrm{s\,photon}^{-1}$, and under conventional excitation conditions, $R_{2h\nu} \ll R_{1h\nu}$. To achieve $R2h\nu \approx R1h\nu$, $I \approx 2h\nu\sigma^{(1)}/\sigma^{(2)}$ is required. For the cross-sections given above, this condition corresponds to $I \approx 500\,\mathrm{GW\,cm}^{-2}$ at $\lambda = 800$ nm. Such peak powers can be achieved by focusing ultra-short laser pulses, so mode-locked femtosecond- or picosecond-pulse lasers are generally used for 3DM. Tight focusing in 3DM is desirable then, not only to provide a means for 3D confinement, but also to increase the intensity to a level that $R_{nh\nu}$ becomes large enough to produce a significant material change.

Opto-Mechanical Implementation

One method for implementing single-beam 3DM is illustrated in Figure 4. An excitation laser beam is directed onto a high numerical aperture (NA) objective. A beamsplitter, detector, attenuator, and shutter are placed upstream of the objective to measure and control the average power at the sample, $\langle P \rangle$. A substrate is coated with the photo-active medium and attached to a 3-axis nano/micro-positioner under the objective. The interior of the photo-active material is patterned during the exposure by translating the sample relative to the focus of the laser beam and shuttering the beam as needed. The process is automated as a computer controls the sample translation coordinates and the exposure conditions for each volume element (voxel). This configuration is well suited for patterning solid or semi-solid photo-media. An index-matching fluid must be used with high-NA objectives to achieve the smallest focal spot size. If the photo-medium is a liquid, a coverslip or other thin transparent barrier must be placed between the index matching fluid and the photomedium so that the latter does not become contaminated.

Alternatively, an inverted configuration may be used. Here, the laser is focused through the substrate into the medium. The objective and the index matching fluid are kept out of contact with the medium by the substrate. In this case, the maximum depth that can be patterned is limited by at least two conditions: (i) The working distance of high-NA objectives is small, often no more than 200 μm, so the substrate must be kept thin (~100 μm); and (ii) unless the viscosity of the medium is very high, patterning must begin at the medium/substrate interface and proceed layer by layer away from it, so that the structure remains anchored to the substrate. This could be disadvantageous, as the change in refractive index in the previously patterned layers could alter the intensity distribution

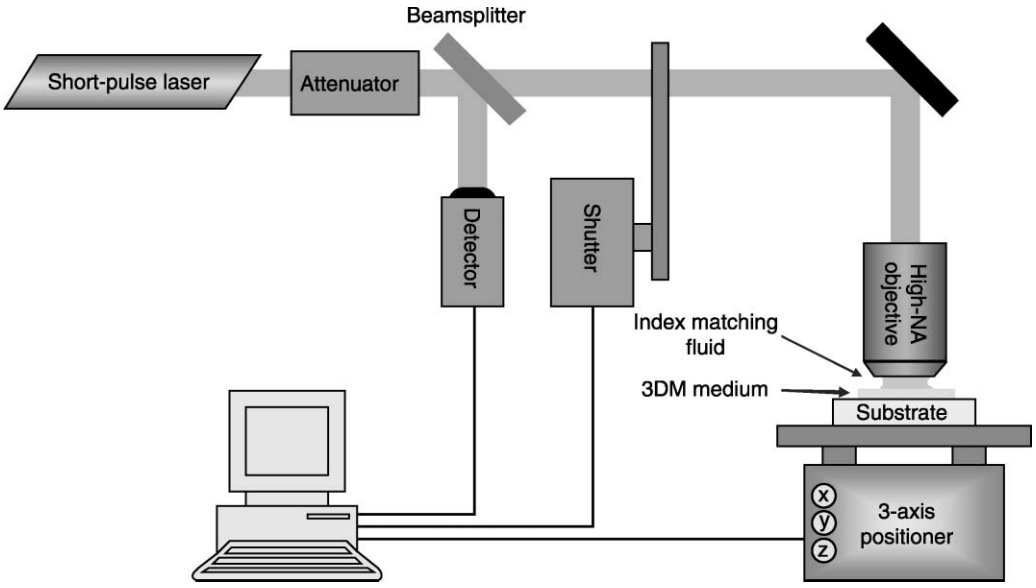

Figure 4 Optomechanical setup for single-beam 3DM.

at the focus. In all configurations, it is best to minimize the number of optical interfaces to maintain the quality of the focus.

A scanning confocal microscope system provides a convenient platform for single-beam 3DM. The nano/micro-positioner can be mounted directly on the sample stage of the microscope, and the optical components of the confocal system can be used directly for 3DM. The confocal system also enables the medium and the structure to be imaged *in situ*, using confocal reflectance or fluorescence imaging. If the material is fluorescent under MPE, a 3D image can be obtained by scanning multiphoton fluorescence microscopy. These imaging modes facilitate 3DM by providing a means for locating the focus at an absolute position within the photo-active medium.

3DM can also be realized by moving the focused beam relative to a fixed sample. One convenient implementation utilizes galvanometer-driven mirrors to scan the beam in planes parallel to the substrate (*xy*-plane). Motion in the *z*-direction is accomplished by raising and lowering the objective relative to the substrate. A galvo-based system typically enables faster fabrication, but may not afford motion as precise as that obtained using a multi-axis nano-positioner.

Excitation Sources

The most commonly used and arguably the most convenient and reliable laser for 3DM is the continuous-wave (CW) mode-locked titanium sapphire (Ti:S) laser. Ti:S lasers routinely produce sub-100 fs pulses at high repetition rates (~80 MHz) with single-pulse energies, E_p, of ~1 nJ. The Ti:S laser emission spans the range of 700–1050 nm, making it particularly well suited for two- and three-photon excitation. $\langle P \rangle$ can be as high as several watts at the peak of the gain curve ($\lambda \approx 800$ nm) with high pulse-to-pulse and time-averaged stability (RMS ≈ 1%). Such systems may also produce a nearly Gaussian TEM_{00} mode, which is helpful in achieving the tightest focus in the material. Note that focusing a 1 nJ, 100 fs pulse to a 1 μm-radius spot generates a focused average peak intensity of 320 GW cm^{-2}, as is needed to achieve photo-excitation rates of $R_{2h\nu} \approx R_{1h\nu}$.

For higher peak powers, amplified femtosecond (AFS) lasers can be used for 3DM. These systems can produce ~100 fs pulses with $E_p \approx 1$ mJ or higher at repetition rates of 1–100 kHz. Given that a continuous microfabricated structure should be generated from partly overlapping voxels, a low repetition rate reduces the speed with which the laser beam may be scanned within the material. An AFS laser can be used to pump an optical parametric generator to extend the output wavelength range.

Recently, some researchers have turned their attention toward identifying compact solid-state turn-key lasers for 3DM that could be more convenient and cheaper alternatives to the complex systems described above. A commercial Nd:YAG microlaser ($\lambda = 1064$ nm, $E_p = 5.4$ μJ, $\tau_p = 640$ ps, 13.6 kHz) and a mode-locked erbium-doped fiber laser ($\lambda = 780$ nm, $E_p \approx 0.5$ nJ, $\tau_p = 100$ fs, 50 MHz)

have both been shown to be satisfactory for 3DM in certain acrylate-based media.

Material Systems

Structural Materials

The most widely used materials for 3DM are based on acrylates that are patterned by multiphoton induced polymerization. The process begins when an initiator chromophore **C** is excited by n-photon absorption to $\mathbf{C}^*$, with an efficiency specified by the n-photon cross-section $\sigma^{(n)}$. $\mathbf{C}^*$ then generates an initiating radical **I·**. Acrylate monomers (**M**) can react with **I·** and undergo a free-radical chain reaction that leads to high molecular weight polymer. With sufficient exposure, the starting material is converted to less soluble high-molecular weight polymer chains or densely cross-linked polymer networks. The photo-patterned structure can then be 'developed' by immersing the sample into a solvent that removes the unexposed material, leaving behind a free-standing structure that is a replica of the photopattern.

Photo-polymerization starts when the MPE exposure generates enough **I·** to react with and consume all of the inhibitor in the local volume at point $\vec{r}$ within a homogeneous medium. In this discussion we assume that the local concentration of inhibitors is not changed by diffusion on the exposure timescale. The total number of **I·** generated during an exposure at $\vec{r}$ per unit volume, $N_{\mathrm{I}\cdot}(\vec{r},t)$, is obtained from the time-integrated MPE rate:

$$N_{\mathrm{I}\cdot}(\vec{r},t) = \frac{\phi_{\mathrm{c}}^{(n)}\sigma^{(n)}N_{\mathrm{C}}}{n(h\nu)^n}\int_{-\infty}^{t} I(\vec{r},t')^n \mathrm{d}t' \qquad [2]$$

Here, N_{C} is the number density of **C**, and $\phi_{\mathrm{c}}^{(n)}$ is the n-photon chemical quantum yield, defined as the number of **I·** generated divided by the number of $\mathbf{C}^*$ present after excitation. If we identify the initial number density of the inhibitors as N_{Inh}, then polymerization occurs when $N_{\mathrm{I}\cdot}(\vec{r},t) > N_{\mathrm{Inh}}$. In multiphoton-induced polymerization, $N_{\mathrm{I}\cdot}(\vec{r},t)$ is a nonlinear function of I, which generally involves a rapidly varying time envelope, as from a mode-locked ultrashort-pulse laser.

Several different commercial acrylate systems have been used successfully for 3DM, such as Nopcocure 800 (San Nopco), NOA 72 (urethane acrylate oligomer, Norland Products), and SCR 500 (blend of urethane acrylate monomers and oligomers, Japan Synthetic Rubber Co.). Researchers have also successfully developed custom formulations using blends of commercially available monomers, oligomers, and polymer additives to create resins with tailored physical, chemical, and optical properties. This aspect of acrylates, and more generally polymer-based systems, makes them one of the most attractive classes of materials for 3DM. Conventional one-photon UV- or blue-sensitive radical generators (e.g., benzil, benzoin methyl ether, 4,4′-bis(N,N′-dimethylamino)benzophenone, to name just a few) have most often been used, and these were activated by promoting the molecule into one of its low-lying electronic states by MPE over the range of 730–800 nm.

3DM based on epoxide polymerization has also been demonstrated using commercial resins including cross-linkable small molecular weight monomers (e.g., 4-vinyl-1-cyclohexene diepoxide) and epoxide oligomers (e.g., SU-8, first developed by IBM). Epoxide polymerization is most commonly initiated by molecules that, after excitation, generate a Brønsted acid, H^+. The propagating species is a carbocation, and bases present in the medium act as inhibitors. Relative to acrylates, epoxides shrink substantially less upon polymerization, leading to less distortion of the microstructure after development.

Acrylate chemistry has also been exploited for 3DM of functional composite materials. Acrylamide resin mixtures were used to fabricate bi-layer micro-cantilevers that deflect from the surface when illuminated with UV light. This type of microstructure could form the basis of a photo-activatable MEMS. 3D gratings were fabricated from an acrylate pre-polymer containing a dendrimer functionalized with cross-linkable acrylic L-phenylalanine groups. The dendrimer acts as a host encapsulation site that enables a laser dye to be loaded in the material at high weight-percent (see below). A variety of complex micro-structures have also been fabricated using 'Ormocer-I', an ORganically MOdified CERamic. Ormocer-I is an inorganic-organic hybrid polymer consisting of a Si–O–Si (siloxane) backbone that is functionalized with organic moieties, including cross-linkable methacryloxypropyl groups. Ormocers are extremely promising for 3DM because of the thermal stability and chemical inertness of the backbone and their attractive physical and optical properties.

3DM could be a powerful tool for fabricating biologically active structures and devices. In this context, hydrogels and Ormocers should be useful material systems as some formulations are known to be bio-compatible. Microstructures can also be fabricated from proteinaceous material. 3D microstructures were produced by patterned MPE of

solutions containing the dye rose bengal and the proteins bovine serum albumin or fibrinogen.

The material systems discussed thus far are 'negative-tone' media. This means that only the exposed regions of the material remain after the post-exposure development, so the final structure is a replica of the exposure pattern. In contrast, 'positive-tone' media are solid-state systems for which the exposed regions become soluble in a developer. The final structure is then the inverse of

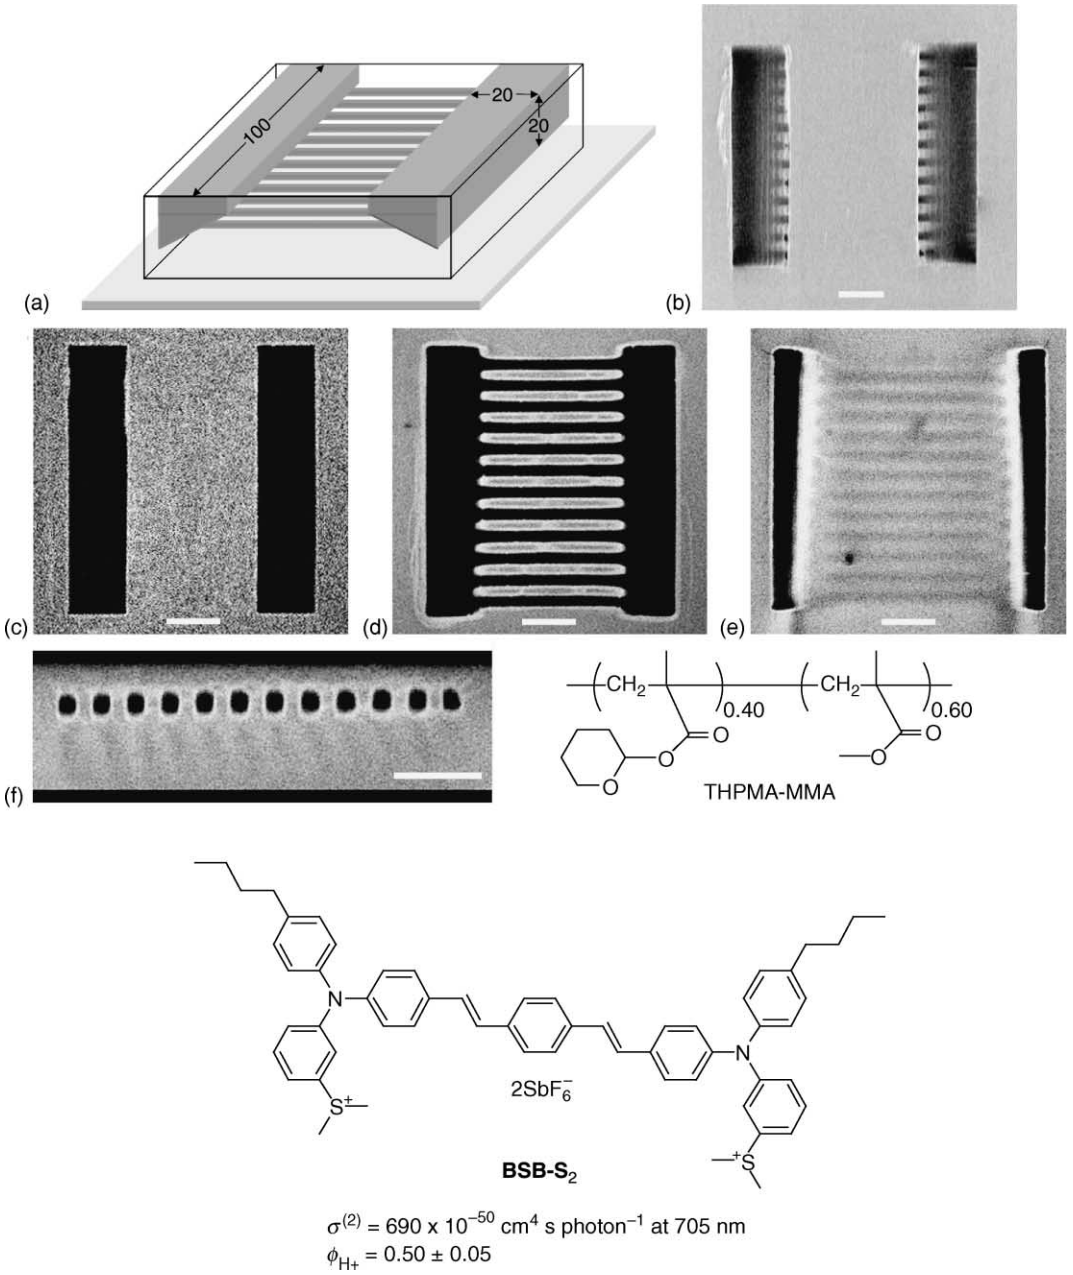

Figure 5 A 3D micro-channel structure fabricated by TPE-3DM using the positive-tone chemically amplified resist THPMA-MMA containing the two-photon PAG **BSB-S_2**. A 50 μm-thick film of the resist was exposed in the pattern of the target structure at 745 nm with tightly focused 80 fs pulses at $\langle P \rangle = 40$ μW and a linear scan speed of 50 μm s^{-1}. (a) Target structure consisting of two rectangular cavities (width: 100 μm, length: 20 μm, depth: 20 μm) with a sloped side-wall, that are connected by 12 channels (length: 50 μm; 4 μm by 4 μm cross-section) lying 10 μm below the surface and spaced apart by 8 μm (center-to-center). (b) Scanning electron micrograph of the final structure, viewed normal to the substrate. (c to e) Two-photon-fluorescence images of the final structure (viewed normal to the substrate): (c) at the surface of the film; (d) 10 μm below the surface; (e) 19 μm below the surface. the exposure pattern. Positive-tone 3DM was first demonstrated as early as 1992 with the generation of high aspect ratio trenches in thin layers of commercial photoresists. A positive-tone material system was designed for 3DM (Figure 5), is based on a chemically amplified resist and a high-sensitivity two-photon-activatable photo-acid generator (PAG) (discussed below). Using this medium, it was possible to fabricate subsurface microchannel structures and micrograting, using moderate laser scan speeds (50 $\mu m\ s^{-1}$) and exceptionally low $\langle P \rangle$ (40 μW).

Composites have been formulated that enable 3D-patterning of nanoscale metal features within a host matrix. A two-step process has been described that involves MPE of a Ag^+-containing sol–gel followed by thermal development of the latent image with a $AgClO_4$ solution. Using this system, 3D spirals of silver nano-particles embedded within the sol–gel matrix were generated. A $HAuCl_4$-doped poly(vinyl alcohol) composite was used to 3D-pattern gold nano-particles. It was shown that after TPE a particular sensitizer dye hosted in a poly(vinylcarbazole) matrix containing $AgBF_4$ and ligand-stabilized Ag nanoparticles, electron transfer from the dye to Ag^+ leads to nucleation of Ag^0 at the nanoparticles and the formation of conducting bulk metal features (Figure 6). Material systems like these should find wide application for generating micro- and nano-scale structures, having unusual and useful optical and electronic properties.

3DM in glasses is of great interest for photonic applications. Several groups have demonstrated that tightly focused infrared or visible amplified ultrashort laser pulses can be used to 3D-pattern pure and doped silica and other glasses. The patterned voxels can be generated as a result of photo-induced changes in the refractive index or extreme dielectric breakdown, resulting in pits within the material. The mechanisms for these two cases are not fully understood, but both are thought to be activated through an initial MPE event. The leading edge of the laser pulse generates a free-carrier plasma through MPE. The remainder of the pulse is increasingly absorbed by the plasma leading to avalanche ionization. The optical energy deposited into the local lattice results in cavitation, creating a pit at the focal point. Based on the electronic bandgap of silica, the process likely involves three- and six-photon absorption when 400- and 800-nm light is used, respectively. This approach has been used for the 3D-patterning fused silica and germanium doped glasses.

Multiphoton Initiators

For 3DM to develop into a widely used fabrication tool, material systems and patterning methods must be developed that enable rapid microfabrication at low cost. 'Soft materials', such as the polymer systems described above, are promising in this respect, as both the initiating species and the host resin can be engineered to optimize the multiphoton response and the physical and chemical properties of the patterned medium. It may also prove possible to create doped glasses that have physical properties close to that of neat silica and yet offer higher multiphoton sensitivity.

To develop this concept, let us consider 3DM in acrylates further. A high-sensitivity acrylate medium is one for which: (i) **C** strongly absorbs n-photons (large $\sigma^{(n)}$); (ii) $\mathbf{C}^*$ efficiently generates the initiating species $\mathbf{I}\cdot$ (large $\phi_c^{(n)}$); and (iii) $\mathbf{I}\cdot$ is an efficient initiator (high initiation rate). As criteria (i) and (ii) are predominantly determined by the molecular properties of **C**, it should be possible to engineer soft materials for 3DM by optimizing multiphoton initiators and incorporating these into pre-polymer resins that once patterned have the correct properties for the target application. The sensitivity of materials can be compared on the basis of the minimum average laser power, $\langle P\rangle_{\min}$, that is required to pattern a material using a fixed scan speed (or exposure time). Alternatively, we can use the product $\sigma(n)\phi c(n)$ as a multiphoton initiator figure-of-merit (FOM) that accounts for the strength of the multiphoton absorption and the efficiency with which $\mathbf{I}\cdot$ is generated.

The chromophores that have been used most frequently for polymerization-based 3DM do efficiently generate highly active initiating species once excited; however, they were developed for one-photon response to UV and blue radiation and generally have low multiphoton FOMs. The use of xanthene dyes was explored as initiators for free-radical polymerization of acrylamides and it was found that the multiphoton sensitivity was low. As a result, 3DM using conventional initiators requires high laser power (typically $\langle P\rangle_{\min} \approx 10-100$ mW) and slow laser scan speeds ($\sim 50\ \mu m\ s^{-1}$). Under tight-focusing conditions, the resulting peak powers are often near the damage threshold of the materials, rendering the process unreliable from a manufacturing stand-point.

A series of **D**–$\boldsymbol{\pi}$–**D** molecules was examined (Figure 7), where **D** is an electron-donating group and $\boldsymbol{\pi}$ is a conjugated π-electron bridge. This class of **D**–$\boldsymbol{\pi}$–**D** chromophores was found to have large TPE cross-sections ($\sigma^{(2)} > 200 \times 10^{-50}$ cm^4 s photon^{-1}) and to initiate the polymerization of acrylates following TPE in the visible and near infrared, with $\langle P\rangle_{\min}$ a factor of 30–50 times lower than for conventional one-photon initiators. The sensitivity achieved with **D**–$\boldsymbol{\pi}$–**D** initiators is so enhanced that TPIP-3DM was performed at laser scan-speeds as high as 9 cm s^{-1}, using $\langle P\rangle = 3$ mW, enabling a volume of 180 μm × 180 μm × 20 μm to be polymerized in 200 s.

D–$\boldsymbol{\pi}$–**A** molecules have also been examined for TPIP (Figure 7), where **A** is an electron accepting functionality. Such molecules can have large TPE cross-sections, and some have been shown to activate TPIP efficiently in acrylates at $\lambda \approx 800$ nm. A derivative of Michler's ketone was synthesized with an extended π-conjugated system (Figure 7). This molecule exhibited strong two-photon absorption over the broad range of 800–1100 nm and was also shown to be active toward acrylate polymerization at 1064 nm. A strategy was implemented for enhancing two-photon sensitivity based on up-converted fluorescence and used for 3DM of waveguide structures. The strongly two-photon-absorbing dye AF-183 was incorporated into a commercial acrylate photoresist containing a radical-generator that is activated by OPE at 315–450 nm. After AF-183 undergoes TPE at 800 nm, it fluoresces efficiently at ~465 nm. The up-converted emission then excites the one-photon initiator and radicals are generated.

The strategies discussed above are oriented toward enhancing multiphoton sensitivity by increasing $\sigma^{(2)}$ of the initiating chromophore. Little attention has been paid to the need of ensuring that the MPE couples to a mechanism for efficiently generating an active initiating species. This problem was addressed with the design of a two-photon PAG by covalently linking a **D**–$\boldsymbol{\pi}$–**D** chromophore and sulfonium moieties, which can generate H^+ when reduced by photo-induced electron transfer (**BSB-S$_2$** in Figure 5). **BSB-S$_2$** features strong two-photon absorption and its quantum yield for the generation of H^+ per photo-excited molecule (ϕ_{H^+}) exceeds that of some commercial one-photon PAGs. Based on $\langle P\rangle_{\min}$, **BSB-S$_2$** was found to be 10 to 100 times more sensitive toward multiphoton epoxide polymerization than one-photon UV/blue-sensitive PAGs.

It should be understood that this discussion of multiphoton initiators is not comprehensive of all work that has been done in the field. Rather, it is intended as a highlight of the many outstanding examples of progress in this area. The use of inexpensive low-power lasers for 3DM should become more practical as high-sensitivity

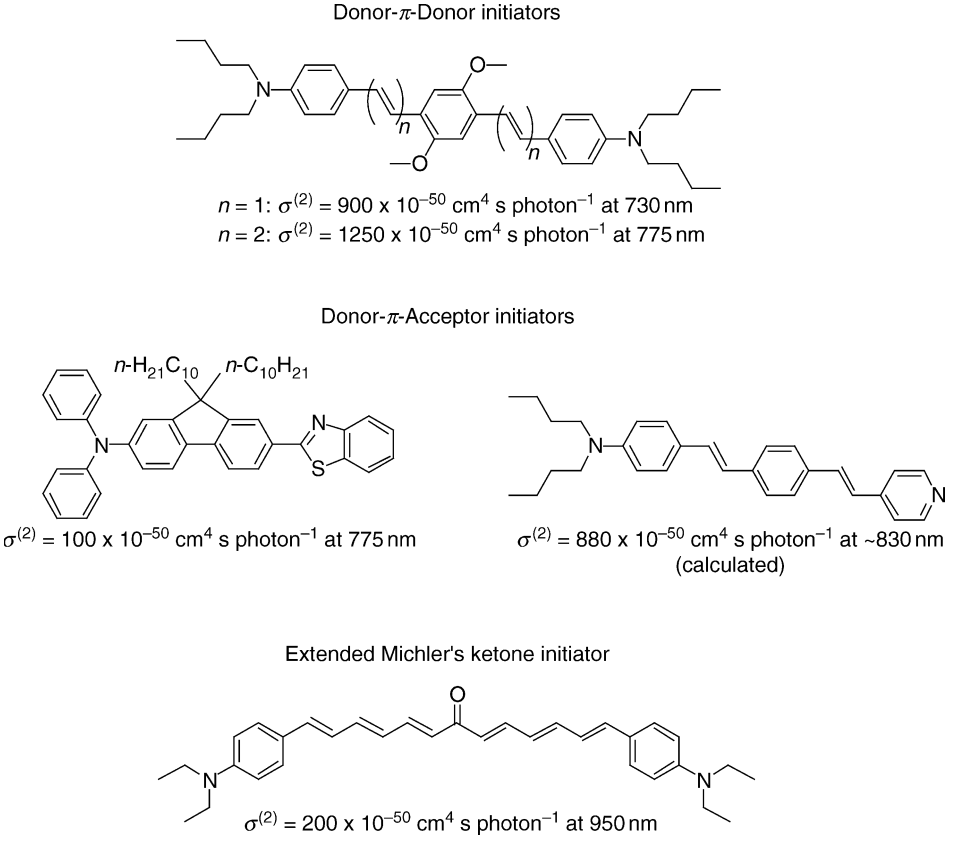

Figure 7 Examples of high-sensitivity initiators for 3DM based on TPIP of acrylates.

3DM media are developed. This should, in turn, facilitate the widespread use of 3DM as a microfabrication tool.

Resolution

The resolution of single-beam 3DM is determined by the size of the smallest voxel that can be reliably produced. Both the optical parameters and the material response under MPE affect the size of the voxel. Given the wide range of physical and chemical mechanisms that can be involved, no single set of guidelines can be outlined regarding the effect of the material response on voxel size. Additionally, this aspect of 3DM remains relatively unexplored. However, as 3DM based on TPIP of acrylates has been examined in some detail, an overview of this material response provides some valuable insight into the overall problem of resolution. The following simplified discussion is based on the local response of the material to photo-excitation.

TPIP initiated in the vicinity of the focus could, in principle, propagate throughout the entire volume of the medium, were it not for termination by inhibitors. Let us consider further the expression for $N_{\mathrm{I}\cdot}(\vec{r},t)$, expanding the intensity as:

$$I(z,r,t') = i(z,r)f(t') \qquad [3]$$

Here, $f(t')$ is a time-dependent amplitude function, $i(z,r)$ is the peak intensity, and the position vector $\vec{r}$ is expressed in cylindrical coordinates (z,r) with the origin at the focus. As before, z denotes the direction in which the beam propagates (longitudinal). The radial coordinate orthogonal to the z-axis (lateral) is denoted by r. The beam is taken to have cylindrical symmetry, so I does not depend on the angular coordinate. For a fixed exposure time $t \to \tau_{\mathrm{ex}}$, we can identify a polymerization-threshold peak intensity, I_{th}, for which $i(z,r) > I_{\mathrm{th}}$ results in $N_{\mathrm{I}\cdot}(z,r,\tau_{\mathrm{ex}}) > N_{\mathrm{Inh}}$ and polymerization occurs. The polymerized voxel consists then of all points within the volume centered at the focal point and bounded by the I_{th} isophote.

The shape of the I_{th} isophote depends upon the optical parameters of the system. The tightest focusing is achieved when the highest NA objective

is used to focus parallel incident rays that overfill the entrance aperture. This situation generates a diffraction limited intensity pattern about the focal point. Within the focal plane the lateral intensity distribution follows the Airy pattern:

$$i(0,r) = [2J_1(\rho)/\rho]^2 I_0 \qquad [4]$$

where J_1 is the first-order Bessel function:

$$\rho = 2\pi r \mathrm{NA}/\lambda \qquad [5]$$

and I_0 is the peak intensity at the origin. Near the focus, the longitudinal intensity distribution is given by

$$i(z,0) = [\sin(\zeta/4)/(\zeta/4)]^2 I_0 \qquad [6]$$

where

$$\zeta = 2\pi \mathrm{NA}^2 z/(n_0\lambda) \qquad [7]$$

Let us define the longitudinal and lateral widths of the focal spot, Z and R respectively, to be twice the distance along the corresponding z- and r-axes over which the peak intensity of the central bright fringe decreases to $I_0/2$. If $\langle P \rangle$ is adjusted so that $I_0/2 = I_{\mathrm{th}}$, then to first order we can expect the polymerization voxel to be a solid of rotation centered about the focus having a longitudinal and lateral width of Z and R, respectively. Numerical evaluation shows that the $I_0/2$-points occur at $\rho = \pm 1.6154$ and $\zeta = \pm 5.5661$. For $\lambda = 800$ nm, NA $= 1.4$, and $n_0 \approx 1.5$, we find $R = 0.29$ μm and $Z = 1.1$ μm.

Several groups have demonstrated that voxels generated under conditions similar to those discussed above do indeed have dimensions comparable to those calculated, based on diffraction limited propagation. As shown in Figure 8, voxels with lateral and longitudinal widths below the diffraction limit can be fabricated by steadily reducing τ_{ex} (or I_0) so that an increasingly smaller portion of the central bright fringe exceeds I_{th}. In this way, voxels having $R \approx 100$ nm and $Z < 800$ nm have been generated, which convincingly demonstrates the potential of this technique as a nano-fabrication tool.

Post-exposure material processing can also have a profound impact on the resolution. In the case of TPIP-3DM, material near the boundary of the I_{th} isophote may not have sufficient molecular weight or cross-linking density to resist removal in a development step. In this case, the final voxel will be smaller than the I_{th} isophote defined strictly in terms of a polymerization threshold. Additionally, a solvent-based developer can swell or otherwise distort the voxels. Overall, three important factors determine the final size of the voxel: (i) the exposure and focusing conditions; (ii) the response of the material to photo-excitation; and (iii) the behavior of the photoconverted material during the development process. It should be emphasized that 3D confinement is due to the combined effects of nonlinear photo-excitation and the nonlinearity inherent in the photoconversion and post-exposure development of the material. More advanced treatments have also attempted to address the effects of radical and inhibitor diffusion on the size of the voxel.

Previously, we assumed that the voxel is cylindrically symmetric. The intriguing result of some recent work has shown that the widths of the voxel in the transverse directions can actually differ by as much as 10% when linearly polarized radiation is used because the symmetry of the electric field vectors in the x- and y-directions is broken in high-NA focusing geometries. Cylindrically symmetric voxels can be obtained by using depolarized or circularly polarized radiation. Clearly, study of the combined effects of optical parameters and material response remains an important area for further research in this rapidly advancing field. Although this discussion has centered on TPIP, similar arguments can be developed for 3DM based on other photomaterials and higher-order processes.

Multibeam-Interference Three-Dimensional Microfabrication

Multibeam-interference (MBI) 3DM is an alternative approach to 3DM that enables large volumes of material to be simultaneously patterned into a 3D periodic structure. In MBI-3DM, multiple coherent laser beams interfere within a photo-active medium. A periodic structure results because the material undergoes photo-induced changes that occur maximally in the regions of peak intensity across the periodic interference pattern. Depending on the number of beams utilized and their reciprocal orientation, periodic structures in one, two, or three dimensions can be generated, and the periodicity is of the order of λ. This technique is often referred to as holographic lithography or recording.

MBI-3DM has most often been achieved using one-photon-induced polymerization; however, higher-order excitation may be used as well. In this discussion we will focus on multiphoton MBI-3DM, with the understanding that most of the concepts apply equally well to the case of linear photo-excitation. When the power of the incident beams is adjusted so that the intensity at the peaks of the interference pattern just exceeds I_{th}, polymerization only occurs in the local vicinity of these points, whereas the 3DM medium is not appreciably polymerized in regions where the intensity is below I_{th} and may be removed by dissolution in a solvent. The result is a periodic porous structure with highly interconnected parts, that extends over the whole volume where the beams overlapped.

Let us assume that m-beams are directed onto a photosensitive material. The intensity of light at a given point $\vec{r}$ in the region where the beams overlap is proportional to:

$$I(\vec{r}) \propto \vec{E}\cdot\vec{E}^{*} = \left(\sum_{j=1}^{m} \vec{E}_{0j}\, e^{i(\vec{K}_j\cdot\vec{r}-\omega t)}\right)\cdot\left(\sum_{l=1}^{m} \vec{E}^{*}_{0l}\, e^{-i(\vec{K}_l\cdot\vec{r}-\omega t)}\right)$$
$$\propto \sum_{j,l=1}^{m} \vec{E}_{0j}\cdot\vec{E}^{*}_{0l}\, e^{i(\vec{K}_j-\vec{K}_l)\cdot\vec{r}}$$
$$\propto \sum_{j=1}^{m} \vec{E}_{0j}\cdot\vec{E}^{*}_{0j} + \sum_{j\neq l}^{m} \vec{E}_{0j}\cdot\vec{E}^{*}_{0l}\, e^{i(\vec{K}_j-\vec{K}_l)\cdot\vec{r}} \qquad [8]$$

where $\vec{E}_{0j}$ and $\vec{K}_j$ are the electric field and wavevector of beam j, and ω is its angular frequency ($\omega = 2\pi\nu$). Equation [8] indicates that the intensity distribution depends on the difference between pairs of wavevectors of the interfering beams, $\vec{K}_j - \vec{K}_l$. This distribution is periodic in space and can be described as a crystal lattice with reciprocal lattice vectors equal to $\vec{K}_j - \vec{K}_l$ and with a unit cell structure determined by the pre-factors $\vec{E}_{0j}\cdot\vec{E}^{*}_{0l}$. By choosing the intensity of the incident beams and the exposure time appropriately, it is thus possible to generate a pattern in the medium that has the same periodicity and structure as the I_{th} isophote of the interference pattern.

The simplest implementation of MBI-3DM involves interfering two linearly polarized beams at angles $\pm\theta/2$ with respect to the normal to the film being patterned (θ is the angle between the two beams in vacuum). From eqn [8], it can be shown that the intensity is maximum if $(\vec{K}_1 - \vec{K}_2)\cdot\vec{r} = 2q\pi$, where q is an integer, or $K[\sin(\theta/2)]r' = q\pi$, where K is the magnitude of both $\vec{K}_1$ and $\vec{K}_2$, and r' is the component of $\vec{r}$ along $(\vec{K}_1 - \vec{K}_2)$. Thus, the two beams generate an interference pattern with periodicity (in one dimension) given by $\Lambda = \lambda/[2\sin(\theta/2)]$, if λ is the

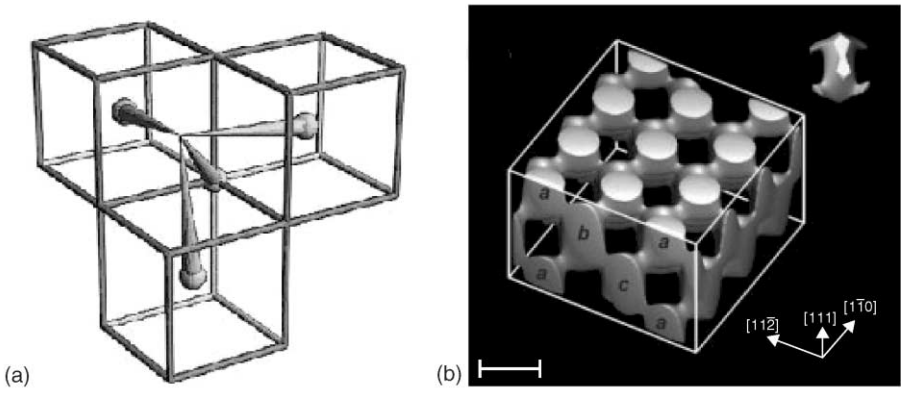

Figure 9 (a) Relative orientation of the beams in a four-beam interference scheme to obtain a face-centered cubic lattice. The beams have wave vectors along the directions [−3/2, −3/2, −3/2], [−5/2, −1/2, −1/2], [−1/2, −5/2, −1/2], and [−1/2, −1/2, −5/2]. (b) One of the isophotes generated by the interference of the four beams in (a). The inset represents the shape of the unit cell. vacuum wavelength of the exciting beam ($\lambda = 2\pi/K$). When a film of a polymerizable material is placed at the intersection of the beams, a series of ridges is generated in the resist, spaced by Λ and with a width dependent on the beam intensity. For example, if a laser beam at 800 nm is split in two components forming an angle of 30°, $\Lambda = 1.5$ μm. The periodicity becomes smaller as the angle between the beams is increased.

By interfering three beams it is possible to obtain a two-dimensional periodic structure. For example, the interference of three beams forming an angle θ with respect to the medium normal and symmetrically arranged around it was used to generate an hexagonal lattice of rods that extends parallel to the normal. At least four beams must interfere to obtain a microstructure with 3D periodicity. The beam geometry shown in Figure 9a was used to produce a microstructure with the symmetry of a face-centered cubic lattice (Figure 9b). Beam geometries for generating interference patterns having other symmetries, such as body-centered cubic and body-centered tetragonal, have also been described.

An advantage of MBI-3DM is that it enables rapid patterning of large volumes during a single exposure. In fact, the polymerization takes place, in principle, throughout the region in which the beams overlap. When the process is activated by OPE, the beams can be attenuated significantly by absorption in the material. This can limit the thickness of the fabricated structure or result in spatial variation in the filling ratio. The use of TPIP can overcome this limitation and allow for thicker media to be patterned uniformly. Structures with the same symmetry are generated if either one- or two-photon processes are exploited to induce the material transformation. However, the structures will be different for at least two reasons: (i) if the same initiator is used in both cases, the wavelength used for TPE is approximately twice that for OPE, and

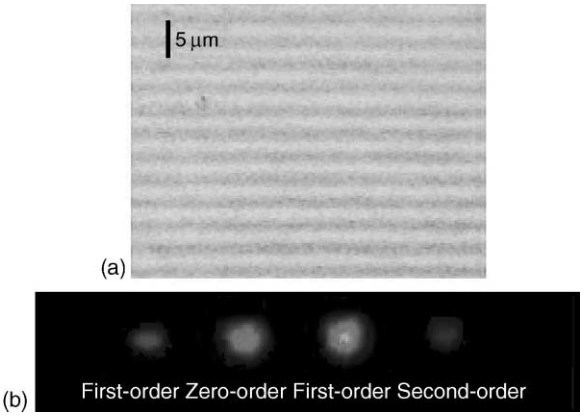

Figure 10 (a) Optical image of a diffraction grating obtained by TPIP using a two-beam interference scheme ($\lambda = 810$ nm). The spacing period is 3.4 μm and film thickness is 40 μm. The grating is made of an acrylate-based resin. (b) Diffraction pattern of the grating in (a) generated using a Helium–Neon laser (632.8 nm). The maximum diffraction efficiency was measured to be 57%. Reproduced from Guo H, *et al.* (2003) *Chemical Physics Letters* 374: 381–384. Copyright (2003), with permission from Elsevier.

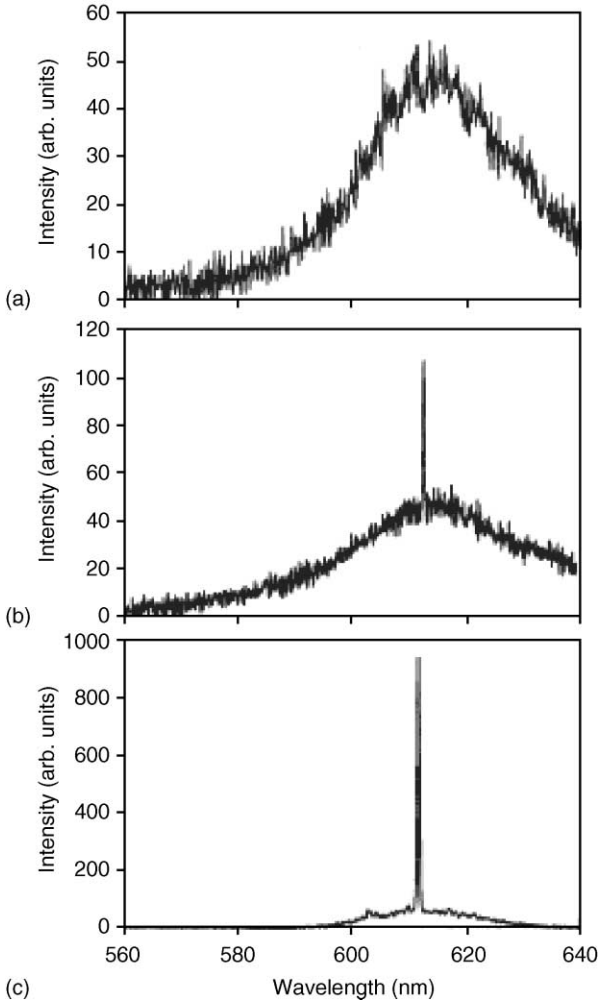

Figure 11 Emission spectra of the laser dye DCM encapsulated in a dendrimer-based resin that was patterned into a grating microstructure by single-beam 3DM. The grating was pumped at 532 nm (8 ns pulses) with excitation energies of (a) 0.03, (b) 0.05, and (c) 0.20 μJ. Starting at excitation energies as in (b), a narrow band at 612 nm appears over the spontaneous emission. The relative intensity of this lasing emission increases with excitation intensity with respect to the spontaneous emission. Reproduced from Yokoyama S, *et al.* (2003) *Thin Solid Films* 438–439: 452–456. Copyright (2003), with permission from Elsevier.

the periodicity of the structure is correspondingly different; and (ii) the I_{th} isophote, and thus the details of the polymerized structure inside each unit cell, is different under OPE and TPE because the excitation rate is proportional to I and I^2, respectively. In principle, better defined features can be obtained using two-photon or higher-order excitation because the transition between regions of low- and high-exposure is sharper than that under OPE, due to the nonlinear dependence on I. Interference fabrication techniques can enable the generation of features considerably smaller than the diffraction limit, when the beam geometry and excitation intensity are chosen appropriately.

The beams used to generate the interference pattern are usually obtained by splitting the output of a single laser source into the desired number of components. The intensity and polarization of each beam are then independently controlled. Temporal overlap of the beams at the sample can be ensured by introducing an optical delay into each of the beam paths. As fluctuations in the beam intensity can cause changes in the lattice unit cell or its filling ratio, the use of a laser with good stability is imperative in cases where exposure time extends over more than a single laser pulse.

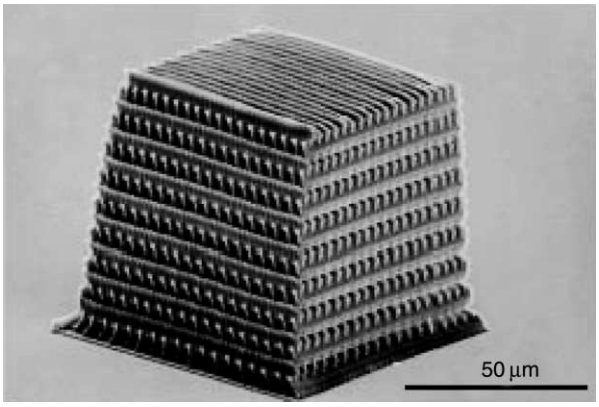

Figure 12 Example of a wood-pile PhC structure obtained by single-beam TPIP-3DM. The periodicity is 5 μm. The change in the cross-section of the structure from top to bottom, is due to shrinking of the material during development, whose effect is largest in the region farthest from the substrate. Structures and Functional Devices

The versatility of 3DM is easily appreciated by surveying the variety of microstructures that have been fabricated over the years. These may be divided into two categories: (i) structures whose characteristics lay in their form and in the interconnectivity of their parts; and (ii) structures that incorporate an active functionality that can be exploited in a specific application. Some of these microstructures are described below.

Fabricating functional micro-optical devices is a promising application of 3DM. Figure 10 shows a grating fabricated by two-beam-interference TPIP in an acrylate with a period of 3.4 μm, whose diffraction efficiency is 28% as fabricated and 57% after annealing. The same method was used to generate a surface relief grating in a resin containing a polycationic peptide. In the presence of aqueous silicic acid, the peptide catalyzes the formation of ordered arrays of silica nanospheres in

the troughs of the grating, which increases the diffraction efficiency 50-fold. 3DM was used to fabricate a grating structure in an acrylate resin containing the laser dye 4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4H-pyrane (DCM) encapsulated in a host dendrimer (see above) as an active optical medium. When pumped at 532 nm above a certain threshold, lasing emission from DCM was observed at 612 nm, with a bandwidth of 0.15 nm (Figure 11).

Several groups have explored the potential of 3DM as a tool for patterning waveguide-based optical circuitry. For example, a mixture of thermally and photocurable resins was used to generate embedded waveguides by photocross-linking within the thermally set medium. A Y-coupler was created in fused silica through the refractive index change generated by patterned MPE.

3DM provides a powerful route to 3D photonic crystals (PhC). PhCs are structures in which a basic motif, or 'unit cell', is repeated within the material with a given periodicity. PhCs have attracted great interest, because the modulation of the refractive

index between the 'filled' areas and the surrounding space provides a means for controlling the propagation of electromagnetic radiation within the structure. PhC with periodicities in the submicron and micron range exhibit their peculiar properties in the visible and near infrared spectral region. Optical wavelength PhCs can be fabricated in a straightforward way by 3DM, either by serial patterning using the single beam approach or by parallel patterning using the interference method, for which the number and orientation of the beams is dictated by the symmetry of the desired structure. Typical examples are woodpile structures (Figure 12), which consist of layers of rods of a material fabricated side by side with a fixed spacing, and alternate layers are rotated by 90° with respect to one another. If the rods in one layer are displaced by half the lattice constant with respect to the previous layer with the same orientation, the structure obtained has the symmetry of a face-center cubic lattice. PhCs with the symmetry of the diamond crystal have also been fabricated, either by inducing changes in a glass

substrate at lattice points (Figure 13), or by constructing a network of polymeric rods connecting nearest neighbor points (Figure 14). It was showed that a PhC created by TPIP-3DM does exhibit a partial bandgap in the infrared spectral region. The position of the bandgap can be tuned by fabricating the structure with the appropriate periodicity.

The ability to introduce defects in PhCs in a controlled fashion is of key importance for the application of these structures in optical circuitry, as they can act as waveguides for channeling light into preferential directions. Point, line, and plane defects can be generated easily, by locally altering the fabrication pattern in the PhC. Point-by-point MPE of a Ge-doped glass was used to pattern a cubic lattice containing systematic defects that defined a Y-shaped waveguide splitter in a [100] plane. 3DM can also be used to modify a structure that is created using another fabrication method, and additional materials can be introduced into the structure in this second fabrication step. A silica colloidal crystal was back-filled with a polymerizable material and waveguides were generated by photocross-linking channels in the medium through three-photon-excitation 3DM (Figure 15).

The full potential of single-beam 3DM can be appreciated by surveying some of the structures that have been fabricated, featuring topologically complex shape, high interconnectivity, and extreme under-cut. Examples include those of Figures 16, 17, and the diamond-lattice PhC of Figure 14. Structures with freely movable parts, like those needed for MEMS, are difficult to obtain by other fabrication techniques, but can often be made by 3DM in a single exposure step. The ability to generate structures with independent but interconnected parts is exemplified by the microchain of Figure 18. A further example is the microgear in Figure 19, which is shown to spin around its axle when the sample is flooded with a liquid. Other functional microstructures have also been reported, such as the microspring in Figure 20, fabricated in a urethane acrylate resin and characterized by a core diameter of only 300 nm. When the sample is immersed in ethanol, the pendant mass can be captured and extended with optical tweezers. When the mass is released, the spring behaves like a damped oscillator.

Promising results have also been obtained in the production of structures to be used in micro-fluidics applications. Of key importance, in this case, is the ability to pattern channels, cavities, and other hollow structures that can be used to store or transfer small amounts of fluids between different parts of a device, as needed to perform, for example, analytical processes on a femtoliter scale. Examples include the hollow microtubule (Figure 21), and the submersed channels structure fabricated in a positive-tone resist (Figure 5).

List of Units and Nomenclature

A	Electron accepting molecular fragment
AFS	Amplified femtosecond
C	Chromophore
$\mathbf{C}^*$	Excited chromophore
CW	Continuous wave
D	Electron donating molecular fragment
3D	Three-dimensional
3DM	Three-dimensional microfabrication
$\vec{E}_0$	Spatial component of the electric field vector [V m^{-1}]
E_p	Laser pulse energy [J]
$f(t)$	Normalized temporal distribution of the beam intensity [dimensionless]
FOM	Figure of merit
h	Planck's constant [J s]
$i(z, r)$	Spatial distribution of the beam intensity [W cm^{-2}]
I	Intensity of a propagating beam [W cm^{-2}]
I_0	Maximum on-axis intensity for a Gaussian beam [W cm^{-2}]
I_{th}	Threshold intensity (minimum peak intensity at which polymerization occurs for a given exposure time) [W cm^{-2}]
I·	Initiating radical
j, l, q	Integers [dimensionless]
J_1	First order Bessel function [dimensionless]
K	Amplitude of a beam wave vector ($K = 2\pi/\lambda$) [m^{-1}]
$\vec{K}$	Wave vector of a beam [m^{-1}]
m	Number of beams in a multi-beam interference configuration [dimensionless]
M	Monomer
MBI	Multi-beam interference
MEMS	Micro-electromechanical systems
MPE	Multi-photon excitation
n	Number of photons involved in MPE [dimensionless]
n_0	Linear refractive index of the medium [dimensionless]
N	Number density (concentration) of a species [cm^{-3}]
NA	Numerical aperture of a lens [dimensionless]
N_C	Number density of chromophores present [cm^{-3}]
Nd:YAG	Neodymium:Yttrium aluminum garnet
$N_{I\cdot}$	Number density of initiating radicals generated [cm^{-3}]
N_{Inh}	Number density of inhibitors present [cm^{-3}]
OPE	One-photon excitation
Ormocer	Organically modified ceramic
$\langle P \rangle$	Average laser power [W]
$\langle P \rangle_{min}$	Minimum average laser power for patterning a material [W]
	Repetition rate (number of laser pulse per unit time) [Hz]
PAG	Photo-acid generator
PhC	Photonic crystal
r	Radial coordinate (distance from optical axis) [m]
r'	Component or $\vec{r}$ along a given wave vector [m]
$\vec{r}$	Position vector in three-dimensional space [m]
R	Twice the radial coordinate of the point at which the intensity is $I_0/2$ [m]
$R_{1h\nu}$	Molecular one-photon excitation rate (number of molecules excited per unit volume and time via OPE) [$cm^{-3}\,s^{-1}$]
$R_{2h\nu}$	Molecular two-photon excitation rate (number of molecules excited per unit volume and time via TPE) [$cm^{-3}\,s^{-1}$]
$R_{nh\nu}$	Molecular n-photon excitation rate (number of molecules excited per unit volume and time via n-order MPE) [$cm^{-3}\,s^{-1}$]
RMS	Root-mean-square
t	Time [s]
TEM_{00}	Lowest order transverse electromagnetic mode of a laser
Ti:S	Titanium:sapphire
TPE	Two-photon excitation
TPIP	Two-photon induced polymerization
z	Coordinate along the beam propagation direction [m]
z_R	Rayleigh range of a Gaussian beam; axial distance between the point of minimum beam waist and the point at which the waist has increased by a factor of $\sqrt{2}$ [m]
Z	Distance between the points of intensity $I_0/2$ along the coordinate z [m]
ζ	Longitudinal optical coordinate ($\zeta = 2\pi Z\,(\mathrm{NA})^2/n_0\lambda$) [dimensionless]
θ	Angle between a beam wave vector and the normal to a substrate [rad]
λ	Wavelength (in vacuum) [m]
Λ	Period of a one-dimensional grating [m]

ν	Frequency [s^{-1}]
$\boldsymbol{\pi}$	π-conjugated molecular fragment
ρ	Transverse optical coordinate ($\rho = 2\pi r \mathrm{NA}/\lambda$) [dimensionless]
$\sigma^{(1)}$	One-photon absorption cross-section [cm^2]
$\sigma^{(2)}$	Two-photon absorption cross-section [cm^4 s $photon^{-1}$]
$\sigma^{(n)}$	n-photon absorption cross-section [cm^{2n} s^{n-1} $photon^{-(n-1)}$]
τ_{ex}	Exposure time [s]
τ_p	Laser pulse duration [s]
$\phi_c^{(n)}$	n-photon chemical quantum yield [(# of chemical species generated)/(# of n-photon-excited species)] [dimensionless]
ϕ_{H+}	Chemical yield for the generation of H^+ (number of H^+ generated per excited molecule) [dimensionless]
ω	Angular frequency ($\omega = 2\pi\nu$) [Hz]

Introduction

Historically the field of nonlinear optics has evolved along two main axes, depending on the order of the nonlinearity used. The phenomena associated with the second-order nonlinearity $\chi^{(2)}$ have dealt with frequency conversion requiring wavevector matching (i.e., momentum conservation), such as second harmonic and optical parametric generation. On the other hand, effects associated with the third-order susceptibility $\chi^{(3)}$ have focused on inherently phase-matched phenomena at a single frequency, for example an intensity-dependent refractive index or degenerate four-wave mixing.

In cascading, multiple sequential nonlinear events based on $\chi^{(2)}$ can mimic some well-known $\chi^{(3)}$ phenomena. For example, it leads to nonlinear phase shifts $\Delta\phi^{\mathrm{NL}}$ reminiscent of those obtained through self-phase modulation over a distance L, i.e.,

$$\Delta\phi^{\mathrm{NL}}(L, I) = k_0 L n_2 I \qquad [1]$$

where I is the irradiance, k_0 the vacuum wavevector, and n_2 the Kerr coefficient or nonlinear refractive index. These can be used for all-optical switching, the generation of spatio-temporal solitons, etc. Some of these cascading effects have been known from the very earliest days of nonlinear optics, but their effectiveness was not realized until recently, when it proved possible to phase match second-order interactions with usefully large nonlinearities. Note that the medium must be $\chi^{(2)}$-active, i.e., noncentrosymmetric, which usually requires crystals rather than amorphous materials (such as glass).

Here we review the basic concepts, the characteristic interactions, some of the numbers involved and, finally, a few applications.

Physics of Cascading

Nonlinear Phase Shift in Collinear Second Harmonic Generation

The most important cascading effect, the nonlinear phase shift, is rooted in the fundamentals of the parametric interaction when two or three waves of different frequencies ($\omega_3 = \omega_1 \pm \omega_2$) are coupled by the second-order susceptibility $\chi^{(2)}(-\omega_3;\ \omega_1,\ \pm\omega_2)$. The simplest case is 'Type I' second harmonic generation (SHG), in which one eigenwave at the fundamental (FF) and one at the harmonic frequency (SH) interact with $\omega_1 = \omega_2 = \frac{1}{2}\omega_3$. When the waves have different phase velocities, this process involves simultaneously up-conversion ($\omega_1 + \omega_1 \rightarrow \omega_3$) and down-conversion ($\omega_3 - \omega_1 \rightarrow \omega_1$). By the latter the FF is regenerated from the harmonic after a characteristic propagation distance called the coherence length. This phenomenon is cyclic (see Figure 1a).

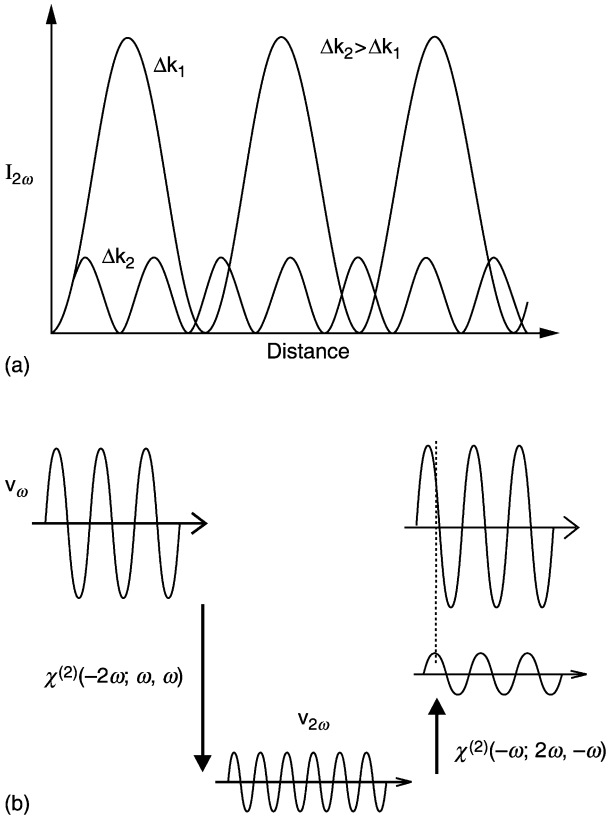

Figure 1 Phase-mismatched SHG. (a) Typical evolution of the generated second harmonic irradiance versus propagation for different mismatches. The period is twice the coherence length. (b) Intuitive picture of phase shift through cascading: the fraction of the initial energy which is first up-converted (SHG) and later down-converted (DFG), having traveled at a different phase velocity due to the wavevector mismatch, recombines with the through-FF causing an overall phase shift.

The field amplitudes in normalized form are

$$E_1(z,t) = \frac{1}{2}\sqrt{\frac{2}{c\varepsilon_0 n_1}}a_1(z)\mathrm{e}^{\mathrm{i}(\omega_1 t - k_1 z)} + \text{c.c.}$$
$$E_3(z,t) = \frac{1}{2}\sqrt{\frac{2}{c\varepsilon_0 n_3}}a_3(z)\mathrm{e}^{\mathrm{i}(\omega_3 t - k_3 z)} + \text{c.c.} \qquad [2]$$

where $|a_1|^2$ and $|a_3|^2$ are power densities, c is the speed of light in vacuum, and n_j and k_j are the refractive indices and wavevectors at angular frequencies $\omega_j\,(j = 1, 3)$, respectively. As is common in nonlinear optics, the efficiency of these processes depends on the irradiance of the different waves, and on the wavevector mismatch between them, i.e., $\Delta k = 2k_1 - k_3$ for collinear beams. Since the phase velocities of the two waves, $v_{\omega_1} = \omega_1/k_1$ and $v_{\omega_3} = \omega_3/k_3$, are generally different and $\Delta k \neq 0$, their phase fronts fall out of synchronism during propagation. This leads to a periodic oscillation with distance (coherence length $= \frac{1}{2}$period $= \pi/|\Delta k|$) in the irradiances of the fundamental and harmonic waves, conserving the total energy but giving rise to a cascading phase shift, as pictured in Figure 1b.

The equations that describe the evolution of the fields stem from coupled mode theory, and are given by

$$\frac{\mathrm{d}}{\mathrm{d}z}a_3(z) = -\mathrm{i}\Gamma a_1^2(z)\mathrm{e}^{-\mathrm{i}\Delta k z}$$
$$\frac{\mathrm{d}}{\mathrm{d}z}a_1(z) = -\mathrm{i}\Gamma a_3(z)a_1^*(z)\mathrm{e}^{\mathrm{i}\Delta k z} \qquad [3]$$

where

$$\Gamma = \frac{\omega_1 \chi^{(2)}_{\mathrm{eff}}}{\sqrt{2n^3c^3\varepsilon_0}} \qquad [4]$$

$\chi^{(2)}_{\mathrm{eff}}$ is the 'effective' nonlinearity (for a specific crystal orientation and field polarization) and we assumed $n = n_1 \cong n_3$. In the limit of a large mismatch, the energy conversion to the harmonic is negligibly small, and it is possible to find an analytical expression for an effective 'n_2', $n_{2,\mathrm{eff}}$. In this limit $|a_1(z)| = |a_1(0)| =$ constant, and, in the absence of loss, solving for the small SH wave and substituting back into the equation for $\mathrm{d}a_1(z)/\mathrm{d}z$ gives

$$\frac{\mathrm{d}}{\mathrm{d}z}a_1(z) = -\mathrm{i}\frac{\Gamma^2}{\Delta k}\Big\{1 - \cos(\Delta k z) - \mathrm{i}\sin(\Delta k z)\Big\}|a_1(0)|^2 a_1(z) \qquad [5]$$

By comparing this with the corresponding equation based on n_2 ($\propto\chi^{(3)}[-\omega;\omega,-\omega,\omega]$) and describing self-phase modulation, namely

$$\frac{\mathrm{d}}{\mathrm{d}z}a_1(z) = -\mathrm{i}n_2\frac{\omega_1}{c}|a_1(z)|^2 a_1(z) \qquad [6]$$

we can define an equivalent nonlinear refractive index

$$n_2(z) = \frac{\pi\{\chi^{(2)}_{\mathrm{eff}}\}^2}{2\varepsilon_0 c n^4 \lambda_1 \Delta k}[1 - \cos(\Delta k z)] \qquad [7]$$

which turns out to be strictly nonlocal because it relies on propagation. Since the $\cos(\Delta k z)$ term oscillates rapidly in space, the above averages to

$$n_{2,\mathrm{eff}} = \frac{\pi\{\chi^{(2)}_{\mathrm{eff}}\}^2}{2\varepsilon_0 c n^4 \lambda_1 \Delta k} \qquad [8]$$

In this so-called 'Kerr limit' cascading leads to a Kerr-like nonlinear response, with either a

self-focusing ($\Delta k > 0$, $n_{2,\text{eff}} > 0$) or a self-defocusing nonlinearity, depending on the sign of Δk.

It is worthwhile to link the above equations to the physics of cascading with a simple argument. The evolution of the waves on propagation depends on their fields (in both amplitude and phase) at the input. When only the fundamental beam at $\omega = \omega_1$ is incident (the classical case of SHG), the harmonic is initially up-converted $\pi/2$ out of phase with the input (first of eqns [3]) via $\chi^{(2)}(-2\omega; \omega, \omega)$. If $\Delta k = 0$, the phase fronts travel at the same velocity and the relative phase is locked in at $\pi/2$. Difference frequency generation (DFG, second of eqns [3]) results in a down-converted fundamental which is an additional $\pi/2$ out of phase, i.e., exactly out of phase with the original input field. This leads to the monotonic depletion of the input and the growth of the SH with distance. If $\Delta k \neq 0$, there is only partial and periodic conversion to the harmonic, the wavefronts travel at different velocities (v_ω and $v_{2\omega}$, respectively), and the relative phase between the two waves changes with distance. As a result, the down-converted FF is no longer π out of phase with the input, thereby changing the overall phase of the total input-frequency wave by a cascaded amount $\Delta\phi^{\text{NL}}$. This is the mechanism sketched in Figure 1b and buried in the better-known Maker-fringe effect represented in Figure 1a. Its magnitude depends on the irradiance and the mismatch, and its sign on that of Δk (see eqn [8]). The higher the input irradiance, the larger the harmonic conversion, and hence the larger $\Delta\phi^{\text{NL}}$.

Alternatively, with a harmonic input at high irradiance and a weak seed at the FF, parametric amplification makes the fundamental grow via down-conversion. If $\Delta k = k_3 - 2k_1 \neq 0$, self-focusing (-defocusing) is obtained on the strong harmonic for $\Delta k > 0$ ($\Delta k < 0$). These phenomena can be generalized to the nondegenerate cases of sum and difference frequency generation, keeping in mind that when using three input waves their mutual phase relationship is essential in determining the details of the interaction.

The solutions to eqns [3] can be obtained numerically or written in terms of Jacobi elliptic integrals subject to boundary conditions ($a_3(0) = 0$, $a_1(0) \neq 0$) at $z = 0$, providing additional insight into the cascading phenomenon. In contrast to the Kerr case given by eqn [1], the variation in n_2 with distance implies a staircase-like increase in $\Delta\phi^{\text{NL}}$ with distance for various detunings ΔkL, as shown in Figure 2a. This is consistent with our intuitive picture above, the increase in $\Delta\phi^{\text{NL}}$ being maximized where the fundamental is the smallest (see Figure 2b for the oscillations in the fundamental amplitude), with the step-period corresponding to twice the coherence length. Conversely, for a fixed input irradiance, the evolution of $\Delta\phi^{\text{NL}}$ exhibits two extrema with detuning ΔkL, as shown in Figure 3a. Note also that, for small ΔkL and large

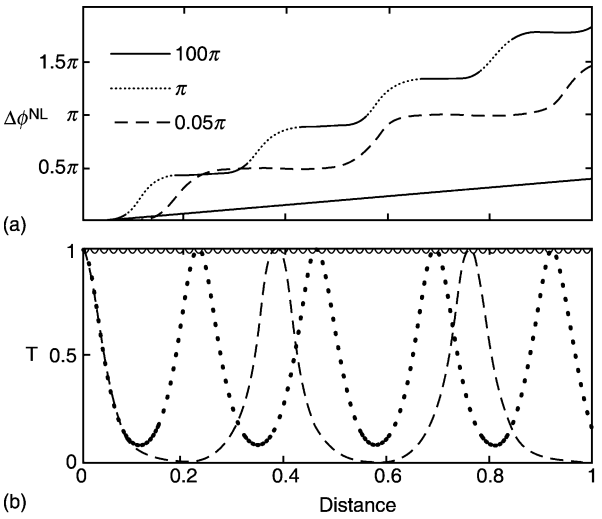

Figure 2 Calculated nonlinear phase (a) and throughput (b) of the fundamental field versus normalized propagation distance, for three values of phase mismatch.

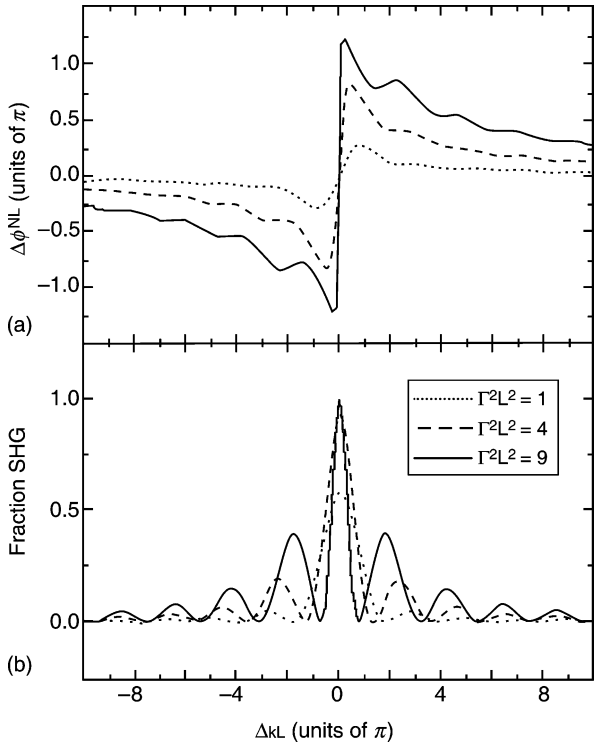

Figure 3 Calculated FF phase shift (a) and generated SH fraction (b) versus phase mismatch, i.e., the detuning curve, for three different nonlinear strengths (unitary FF irradiance).

(unrealistically high) irradiances, the increase in $\Delta\phi^{NL}$ tends to become proportional to the field amplitude, a clear indication that cascading depends on a different order of nonlinearity than $\chi^{(3)}$, namely $\chi^{(2)}$. On the other hand, for large ΔkL the growth of $\Delta\phi^{NL}$ is slower but linear with distance and irradiance, as in eqn [1].

There are trade-offs between the fundamental output and the net nonlinear phase shift. This is clearly visible in Figures 3a,b: the maxima in $\Delta\phi^{NL}$ correspond to a reduced FF throughput. Although it is possible to operate cw at the zeros of the SHG, their location changes with the irradiances required for useful phase shifts ($>\pi$), complicating the trade-offs and the response to temporal pulses (encompassing a continuous irradiance distribution). The problem can be alleviated at the expense of reducing the net phase shift for a given irradiance and propagation length, by introducing regions with a nonuniform matching condition at both ends of the sample. The goal at the input end is to first adiabatically generate the SH required for optimum $\Delta\phi^{NL}$. At the output, this harmonic is adiabatically converted back to the FF. The corresponding output for wavelengths larger than the phase-matching condition exhibits a $\Delta\phi^{NL}$ with negligible fundamental depletion. This approach has been used in temperature-tuned and quasi phase matched (QPM, where a periodic modulation of the nonlinearity provides phase matching via the additional grating momentum) lithium niobate waveguides to generate phase shifts of π with less than 10% net loss of the fundamental wave to the harmonic.

While the preceding discussion has focused on Type I SHG, it is also valid for Type II SHG (i.e., with two FF input waves), provided the two fundamental inputs have equal input energy. In fact, an input imbalance between the two fundamental polarizations could give rise to a phase shift on the weaker field even when $\Delta k = 0$, leading to all-optical modulation and transistor action, as demonstrated in potassium titanyl phosphate (KTP) crystals.

Finally, due to the nature of the quadratic nonlinearity, the phase and/or amplitude of a coherent SH seed can have a large effect on the cascaded outcome, both in the phase and amplitude of the fundamental, as shown in Figure 4 for a fixed irradiance seed 1000 times weaker than the FF input. This can be used in seed-controlled optical processors.

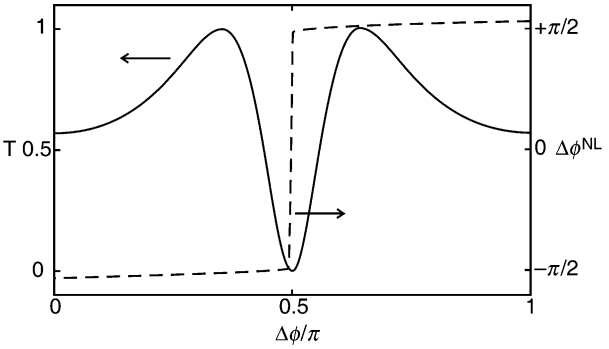

Figure 4 FF transmission (solid line) versus the relative phase of a much weaker (three orders of magnitude) SH seed. Here perfect phase matching was assumed.

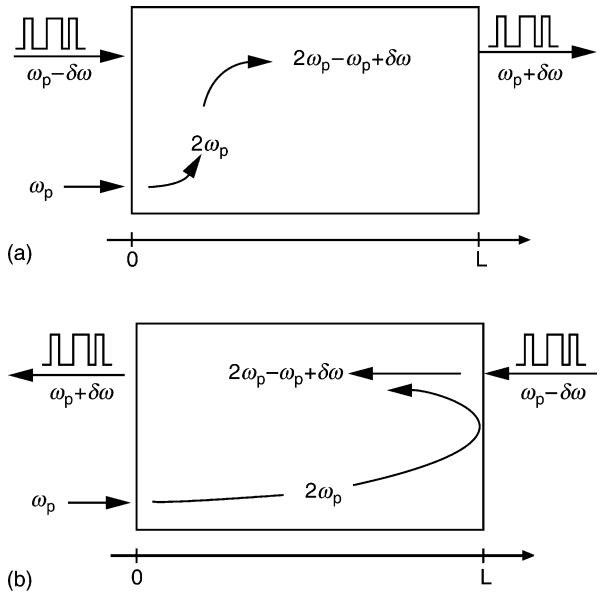

Figure 5 Wavelength shifter: (a) single-pass and (b) double-pass configurations. In (b) a dichroic mirror reflects the second harmonic of the pump.

Frequency Shifting

In the nondegenerate case of $\chi^{(2)}$ sum and difference frequency generation, two successive operations can perform the useful function of a frequency shifter (Figure 5). The idea is to shift the signal frequency ($\omega_p - \delta$) by first generating from the pump (ω_p) a second harmonic ($2\omega_p$), followed by DFG involving the latter and the signal. This leads to an output at $\omega_p + \delta$ through $\chi^{(2)}(-(\omega_p + \delta); 2\omega_p, -(\omega_p - \delta))$, i.e., a frequency shift of 2δ with an output spectrally mirror-imaged about the pump frequency. This feature is useful in WDM (wavelength division multiplexing) systems, and guarantees a protocol-insensitive wavelength shift with an additional phase conjugation useful in dispersion-compensating schemes. Notice that, since $\omega_p + \delta \cong \omega_p - \delta$ and $\delta << \omega_p$, the bandwidth is large because the interaction is near the degeneracy point.

Figure 5 shows two possible configurations for the same device length. The efficiency of the process can be increased in a double-pass geometry by using a back-propagating signal and a mirror-coated facet to reflect the SH, as sketched in Figure 5b. The best results to date were obtained at communication wavelengths with single-pass waveguides in periodically poled (QPM) $LiNbO_3$, including shift of multiple wavelength-channels with low cross-talk.

Multiple Beam Generation

Two successive $\chi^{(2)}$ processes can also be used to mimic three-wave mixing, a classic noncollinear $\chi^{(3)}$ interaction where two photons are taken out of one beam and one out of the second. In cascading, first a second harmonic is generated by one of the inputs, and then difference frequency mixing (DFM) between that SH and the second input leads to the signal of interest. In the simplest configuration, two equi-frequency (ω) beams of wavevectors $\mathbf{k}_1$ and $\mathbf{k}_2$ are incident in slightly different directions close to phase-matching and overlap inside the sample. When wave 1 is doubled (2ω) and wave 2 mixes with this harmonic via DFM, a new beam (at $2\omega - \omega \rightarrow \omega$) is generated with wavevector $2\mathbf{k}_1 - \mathbf{k}_2$. Of course the complementary output at $2\mathbf{k}_2 - \mathbf{k}_1$ is also generated via the SHG of wave 2. If these two new beams are strong enough, they can generate another pair via cascading, and so on. The generation of more than six extra beams has been demonstrated in β-barium borate with 1064 nm inputs.

This interaction can be applied to the control of the frequency chirp in pulses. For example, if wave 1 has a frequency chirp α_1 and wave 2 a chirp α_2, then the chirp of the beam scattered into the direction $2\mathbf{k}_1 - \mathbf{k}_2$ is $2\alpha_1 - \alpha_2$. This becomes especially interesting if $\alpha_2 = -\alpha_1$ so that the chirp in the new beam is $3\alpha_1$, as observed and subsequently employed in enhancing pulse compression. Note that, since a cascaded phase shift occurs on the down-conversion step back to the original fundamental (wave 1), it is not present in the scattered beam resulting in a clean transfer of the chirp.

Typical Numbers

From eqn [8] it is clear that the figure of merit (FOM) for cascaded processes is the same as for all second-order processes, namely $|\chi^{(2)}|^2/n^4$. The key is to find materials phase-matchable at the wavelengths of interest. Therefore, basically any material that is suited for frequency conversion, either SHG or parametric generation, will work. The most versatile material, which also has the largest easily usable nonlinear coefficient (18 pm/V), is lithium niobate when QPM is employed. As a reference, Table 1 gives the maximum $n_{2,\text{eff}}$ for 1-cm-long samples, obtained by extrapolating eqn [8] to the ΔkL which maximizes the nonlinear phase shift. This is not strictly valid for such small ΔkL, but it is a useful estimate.

Other Implications of Cascading

A straightforward conclusion that could be drawn is that cascading with its $n_{2,\text{eff}}$ and $\Delta\phi^{\text{NL}}$ can generally replace the Kerr n_2. This is true for self-phase modulation and the applications stemming from it, including all-optical guided-wave switches such as directional couplers, Mach–Zehnder interferometers, etc. However, this is not necessarily true for other applications, because all the waves have to be coupled through $\chi^{(2)}$ interactions (at most three at a time) and must be nearly phase-matched for efficient effects. For example, cross-phase modulation between two input FF polarization components is feasible via Type II SHG cascading, but specific wavelengths will require different crystals, or crystal cuts. The nonlinear phase shift can also be used in all-optical devices for analog processing, such as isolators, modulators, and transistors, in laser mode-locking, etc.

In the following subsections we discuss a few additional applications. Specifically, we describe a non-reciprocal device that operates as an isolator, and the cascading of beams of finite extent in space or time. The latter can counterbalance either spatial diffraction or temporal dispersion or both and gives rise to solitons of various dimensionalities.

An Optical Diode

A nonlinear response, when combined with a device structure that is asymmetric about its midpoint, can provide nonreciprocal behavior upon excitation of the structure (crystal, waveguide) from different ends.

Table 1 Figures for cascading in various materials. The effective nonlinear coefficient is estimated under optimum conditions and a 1 cm propagation length

Material L = *1 cm*	d_{ii} *(pm/V)*	d_{ij} *(pm/V)*	$n_{2,eff}$ *(cm^2/W)*
$LiNbO_3$	36		2×10^{-11}
$LiNbO_3$		5.8	5×10^{-13}
MNA(1)	165		7×10^{-10}
NPP(2)		84	2×10^{-10}
DAST(3)	600		6×10^{-9}

(1)MNA: 2-methyl-4-nitroaniline
(2)NPP: N-(4-nitrophenyl)-(L)-prolinol
(3)DAST: dimethyl amino stilbazolium tosylate

In analogy to the standard electronic element, we can refer to such device as a power-dependent optical diode. Dealing with quadratically nonlinear waveguides, simple ways to induce a directional asymmetry are variations in wavevector mismatch, or in QPM periodicity. A mismatch profile which depends on distance from one end, or a localized defect (i.e., an isolated domain in a QPM grating), will give rise to different throughputs when the waveguide is excited from opposite sides, up to complete FF depletion in one direction, and complete transmission in the opposite one. This can be explained by the fact that the output depends on the evolution and interaction of the FF field with its harmonic. The amount and phase of the latter, however, do depend on the details of the propagation path and can substantially change the FF throughput as in the case of seeded SHG.

The sketch of an all-optical diode in a QPM waveguide with its calculated response is shown in Figure 6a,b. Clearly, total depletion is obtained via SHG in backward propagation, whereas unity FF transmission is recovered by the insertion of a phase discontinuity (and seeded interaction) in the forward path. As demonstrated at 1.55 μm in lithium niobate, different degrees of isolation are available at various excitations, with a large extinction ratio at a given power when launching FF waves from opposite ends.

Quadratic Solitons

When beams propagate in a two- (planar waveguides) or three-dimensional (bulk) medium with a quadratic response, cascading induces a nonlinear phase-front distortion which, coupled to the inherent parametric gain, can effectively counteract diffraction and lead to diffractionless propagation or 'spatial solitons' (Figure 7). In contrast to the Kerr case, such solitons are multifrequency solutions or 'simultons' with field components (FF and SH in the degenerate SHG process) bound together in propagation despite possible walk-off or transverse velocity mismatch. Moreover, since the second-order nonlinearity is inherently saturable, the solitons are stable and robust even in bulk media, and provide 'clean' filtered beam profiles at FF and SH frequencies, as has been demonstrated in KTP. Just like other cascading phenomena, quadratic solitons can be controlled by a weak seed, by polarization imbalance at the input (Type II SHG), by direction of propagation (due to birefringence), by phase mismatch, etc. Employing quadratic spatial solitons, phenomena such as collisions, soliton fusion, spatial reshaping, and transverse light localization and instabilities have been studied and constitute an active field of investigation.

When employing pulses, the cascaded phase shift can balance dispersion (material, chromatic, or photonics bandgap) leading to temporal simultons with frequency components locked together despite their individual group-velocity differences and dispersion. This feature can also substantially broaden the bandwidth available for parametric generation. Finally, in analogy to the cubic case, a combination of space and time effects is expected to lead to the formation of 'light bullets' in (3 + 1) dimensions.

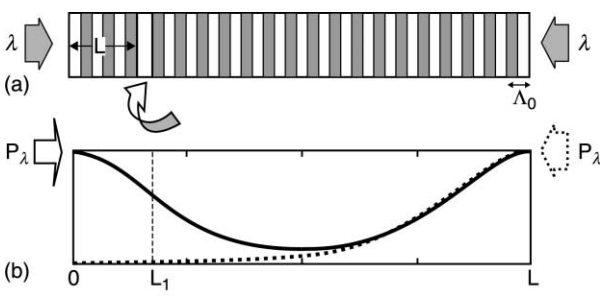

Figure 6 All-optical diode: (a) sketch of implementation with an engineered 'defect' in a QPM grating (*z*-cut periodically poled lithium niobate), and (b) example of FF transmittance *T* versus propagation for forward (solid line) and backward (dashed line) FF excitation of power P_λ.

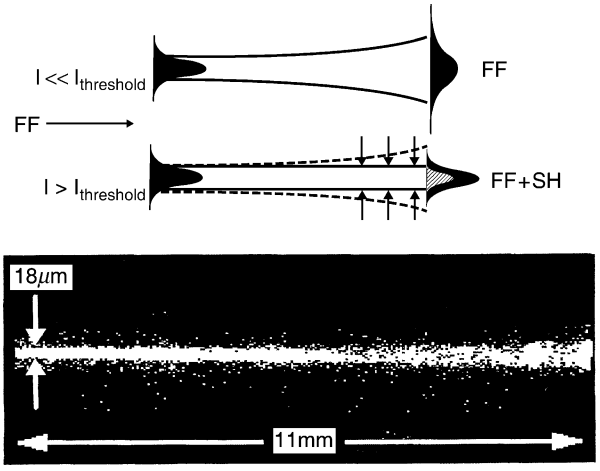

Figure 7 Top: sketch of a quadratic spatial soliton excited by an FF input: when the irradiance is high enough, linear diffraction is overcome by parametric self-trapping and a two-color simulton is obtained. Bottom: sample photograph (top view) of a quadratic soliton experimentally observed in a potassium niobate crystal excited by a 1064-nm laser beam.

$\chi^{(2)}$–Harmonic Generation

R C Eckardt, Cleveland Crystals, Inc., Highland Heights, OH, USA

Introduction

Optical harmonic generation is nonlinear conversion of laser output to light, of a frequency that is an integer multiple of that of the fundamental. It is used over a wide range of applications, from battery-operated, pencil-sized pointers emitting less than a milliwatt of light to installations that occupy large buildings and generate thousands of Joules of ultraviolet energy in nanosecond-duration pulses. The applications also range from frequency-stable continuous-wave light to generation of pulses a few femtoseconds in duration. Laser output with specific properties may only be available in narrow spectral regions, and harmonic generation is a method to convert the laser output to spectral regions of shorter wavelength. It is customary to call light of twice the frequency of the fundamental the second harmonic; three times the third harmonic, and so on.

The conversion of light by harmonic generation is a process that is driven by the nonlinear electric polarization. The total polarization $\mathbf{P}(t)$, including the linear term, is a vector quantity related to the electric field $\mathbf{E}(t)$ by the susceptibility tensors

χ of a material:

$$\mathbf{P}(t) = \varepsilon_0 \chi^{(1)} : \mathbf{E}(t) + \varepsilon_0 \chi^{(2)} : \mathbf{E}(t)\mathbf{E}(t) + \varepsilon_0 \chi^{(3)} : \mathbf{E}(t)\mathbf{E}(t)\mathbf{E}(t) + \ldots, \quad [1]$$

where $\varepsilon_0 \cong 8.854 \times 10^{-12}$ C/N·m^2 is the permittivity of free space. The first-order tensor describes linear optical properties on the material. The second-order tensor $\chi^{(2)}$ describes second-harmonic generation and sum- and difference-frequency generation. This is the term that is of interest here. The second-order nonlinear optical tensor, equal to half the second-order susceptibility, is used widely instead of the susceptibility:

$$d_{ijk} = \chi^{(2)}_{ijk}/2 \quad [2]$$

In calculations of harmonic generation and sum- and difference-frequency generation, the coefficient is usually reduced to a scalar quantity d_{eff}, the effective nonlinear coefficient that expresses the relationship between only the specific vector components involved in an interaction. The second-order optical nonlinearity, when present, is usually significantly larger than higher-order optical nonlinearities. When optical frequency conversion is possible, using the second-order nonlinearity, it is generally preferred. Any material that has inversion symmetry, however, will have vanishing second-order nonlinearity. Although there is continuing interest in developing other materials, such as poled polymers for future applications, materials for current practical applications are restricted to noncentrosymmetric crystals.

This article will provide a description of the process of optical harmonic generation and discuss some of the concerns in the design of harmonic generation systems. In many cases, harmonic generation can be modeled accurately by analytic or numerical techniques. Some of the theoretical development that is the basis for this modeling will be presented along with examples. There are several essential considerations that must be made in selecting a harmonic generation process. These involve both material properties and conditioning of the fundamental radiation.

General Considerations

The nonlinear optical material must be highly transmitting at the fundamental and harmonic wavelengths and must have a laser-induced-damage threshold high enough to allow optical intensities that will provide adequate conversion efficiency. Phase matching must be possible in the material. Other material characteristics must be considered for specific applications. The harmonic generation process requires that the phase velocities of the fundamental and harmonic radiation be matched. Without phase matching, power converted to the harmonic is back converted to the fundamental in a rapid oscillation, and harmonic conversion remains at low levels. The material also needs to be of good optical quality to provide optical transmission without distortion, which would destroy the phase relationship. Continuous-wave harmonic generation may involve local intensities of the order of 1 megawatt per square cm (1 MW/cm^2). Pulsed applications with Q-switched laser output of a few nanoseconds duration typically employ intensities of several hundred MW/cm^2, and harmonic-generation applications with mode-locked lasers may involve pulse durations of tens of femtoseconds with peak intensities of tens of gigawatts per square cm. Many other properties are desirable, but it is necessary to work within the limitations of available materials.

Phase matching is an essential requirement. When harmonic and fundamental waves of different eigen polarizations are coupled through the nonlinear optical tensor, it may be possible to use crystal birefringence to provide phase matching. The birefringence, if large enough, can compensate dispersion. The fundamental wave is introduced into the crystal with the polarization of the larger refractive index, and the harmonic is generated in the polarization of the smaller index. This is a description of type-I birefringent phase matching. Phase matching is achieved by selecting the direction of propagation in the crystal or by changing the temperature of the crystal. Type-II phase matching with the fundamental wave resolved into the two eigen polarizations is possible with large birefringence. Quasi phase matching involves periodically structuring the nonlinear material in a way that spatial modulation of the optical nonlinearity compensates for dispersion. Quasi phase matching is tuned by selection of the modulation period, and temperature control may provide a fine tuning. Periodic poling, one method of quasi phase matching, involves changing the orientation of ferroelectric domains after each coherence length of the harmonic generation process. These methods of phase matching are sketched in Figure 1.

The physical arrangement of the harmonic generation process depends on properties of the available fundamental light and the properties of the selected nonlinear material. The single-pass techniques, shown in Figure 1, may have the advantage of simplicity, but expanding or focusing the fundamental beam may be required. Crystal length and clear

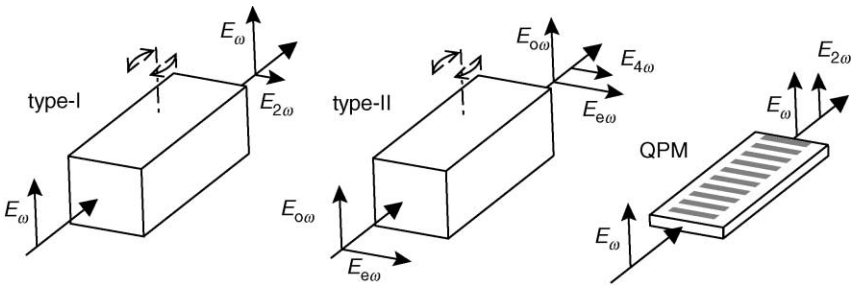

Figure 1 Different methods of phase matching optical harmonic generation are illustrated. The arrows indicate the directions of electric-field polarization and directions of propagation.

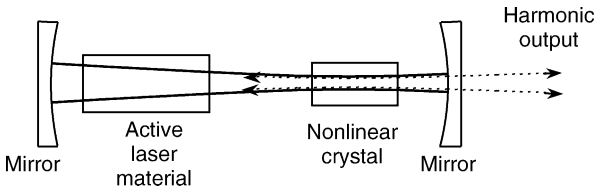

Figure 2 Placing a harmonic-generation crystal inside a laser cavity with mirrors highly reflecting at the laser wavelength is one technique of increasing the intensity of the fundamental beam.

aperture need to be selected. Intracavity harmonic generation (Figure 2), or external-resonant-cavity harmonic generation, may provide advantages in other cases. Analysis of harmonic generation provides the means to select among the options.

Basic Equations

Much of the analysis of second-harmonic generation follows from the differential equations that describe the interaction between the fundamental and harmonic fields, and it is appropriate to describe the development of these coupled equations. The wave equation:

$$\nabla^2\mathbf{E}(\mathbf{r},t) - \mu_0\sigma\frac{\partial\mathbf{E}(\mathbf{r},t)}{\partial t} - \mu_0\varepsilon_0\frac{\partial^2\mathbf{E}(\mathbf{r},t)}{\partial t^2} = \mu_0\frac{\partial^2\mathbf{P}(\mathbf{r},t)}{\partial t^2} \quad [3]$$

is obtained from Maxwell's equations. Here $\mu_0 = 4\pi\times10^{-7}$ is the permeability of free space, and σ is the conductivity, which later will be incorporated into the optical absorption coefficient $\alpha = \mu_0\sigma c/2$, and $(\varepsilon_0\mu_0)^{-1/2} = c \cong 2.998\times10^8$ m/s is the speed of light in vacuum. The electric field of a planewave, at angular frequency ω, is expressed in complex notation as the product of a slowly varying complex amplitude and a carrier wave:

$$\mathbf{E}_\omega(\mathbf{r},t) = (1/2)\{\mathbf{E}_\omega \exp i(\mathbf{k}_\omega\cdot\mathbf{r} - \omega t) + \text{c.c.}\} \quad [4]$$

The intensity of this plane wave is

$$I_\omega = (nc\varepsilon_0/2)|E_\omega|^2 \quad [5]$$

Here n is the index of refraction of the material in which E is specified. The nonlinear polarization resulting from the second-order susceptibility driven by the plane wave $\mathbf{E}_\omega(\mathbf{r},t)$ is expressed as

$$\mathbf{P}^{\text{NL}}_{2\omega}(\mathbf{r},t) = (1/2)\{\mathbf{P}^{\text{NL}}_{2\omega} \exp i(2\mathbf{k}_\omega\cdot\mathbf{r} - 2\omega t) + \text{c.c.}\} \quad [6]$$

The individual components of the polarization amplitude vector are

$$P^{\text{NL}}_{2\omega,i} = \varepsilon_0\sum_{j,k} d_{ijk}(-2\omega;\omega,\omega)E_{\omega,j}E_{\omega,k} \quad [7]$$

If the nonlinear polarization is produced by two distinguishable waves, such as for sum-frequency generation of the third harmonic by the second harmonic and the fundamental, the nonlinear polarization is

$$\mathbf{P}^{\text{NL}}_3(\mathbf{r},t) = (1/2)\{\mathbf{P}^{\text{NL}}_3 \exp i[(\mathbf{k}_1+\mathbf{k}_2)\cdot\mathbf{r} - (\omega_1+\omega_2)t] + \text{c.c.}\} \quad [8]$$

where

$$P^{\text{NL}}_{3,i} = 2\varepsilon_0\sum_{j,k} d_{ijk}(-\omega_3;\omega_1,\omega_2)E_{1,j}E_{2,k} \quad [9]$$

and

$$\omega_3 = \omega_1 + \omega_2 \quad [10]$$

A number of simplifications are used to arrive at the coupled equations for harmonic generation with monochromatic plane waves. All waves are assumed to be propagating collinearly in the z direction. Only the vector components involved in the

interaction are retained, and the nonlinear optical tensor is replaced by the scalar effective nonlinear coefficient d_{eff}. Finally, the slowly varying envelope approximation is invoked and the higher-order derivatives of the amplitudes are ignored, as are time derivatives of the envelopes. The wave equation simplifies to

$$\frac{\mathrm{d}E(z)}{\mathrm{d}z} + \alpha E(z) = \mathrm{i}\frac{\mu_0 c\omega}{2n} P(z) \qquad [11]$$

where n is the index of refraction.

With three distinguishable waves, as with sum-frequency generation and type-II second-harmonic generation, there are three coupled equations:

$$\frac{\mathrm{d}E_3(z)}{\mathrm{d}z} + \alpha_3 E_3(z) = \mathrm{i}\frac{\omega_3 d_{\text{eff}}}{n_3 c} E_1(z)E_2(z)\exp(-\mathrm{i}\Delta k z) \qquad [12]$$

$$\frac{\mathrm{d}E_1(z)}{\mathrm{d}z} + \alpha_1 E_1(z) = \mathrm{i}\frac{\omega_1 d_{\text{eff}}}{n_1 c} E_3(z)E_2^*(z)\exp(\mathrm{i}\Delta k z) \qquad [13]$$

$$\frac{\mathrm{d}E_2(z)}{\mathrm{d}z} + \alpha_2 E_2(z) = \mathrm{i}\frac{\omega_2 d_{\text{eff}}}{n_2 c} E_3(z)E_1^*(z)\exp(\mathrm{i}\Delta k z) \qquad [14]$$

Here the wave vector mismatch is

$$\Delta k = k_3 - k_1 - k_2 \qquad [15]$$

and

$$\omega_3 = \omega_1 + \omega_2 \qquad [16]$$

with the convention of $\omega_1 \leq \omega_2 < \omega_3$. The indices of refraction of the three waves are n_1, n_2, and n_3, respectively, and α_1, α_2, and α_3 are the respective amplitude absorption coefficients.

With type-I second-harmonic generation, the fundamental field consists of only a single eigen polarization, and there are two coupled equations:

$$\frac{\mathrm{d}E_{2\omega}(z)}{\mathrm{d}z} + \alpha_{2\omega} E_{2\omega}(z) = \mathrm{i}\frac{\omega d_{\text{eff}}}{n_{2\omega} c} E_\omega(z)E_\omega(z)\exp(-\mathrm{i}\Delta k z) \qquad [17]$$

$$\frac{\mathrm{d}E_\omega(z)}{\mathrm{d}z} + \alpha_\omega E_\omega(z) = \mathrm{i}\frac{\omega d_{\text{eff}}}{n_\omega c} E_\omega(z)E_\omega^*(z)\exp(\mathrm{i}\Delta k z) \qquad [18]$$

Indices of refraction at the harmonic and fundamental are $n_{2\omega}$ and n_ω respectively; $\alpha_{2\omega}$ and α_ω are the respective absorption coefficients; and the wavevector mismatch is

$$\Delta k = k_{2\omega} - 2k_\omega \qquad [19]$$

The equations for type-II second-harmonic generation, where $\omega_1 = \omega_2$ and $\omega_3 = 2\omega_1$, become equivalent for those for type-I second-harmonic generation, providing intensities of the two fundamental polarizations are equal, $I_1 = I_2$ and $\alpha_\omega = \alpha_{2\omega}$.

Steady-State Solutions

Three monochromatic planewave solutions for type-I second-harmonic generation are discussed. These solutions address type-I harmonic generation; first for low levels of conversion with arbitrary phase mismatch; next for high levels of conversion with perfect phase matching; and last for arbitrary levels of conversion with arbitrary amounts of phase mismatch. Near-field and focused-beam approximations also exist. Beyond that, numerical techniques, such as split-step Fourier transform methods can handle more complicated conditions. The simple approximations of monochromatic planewaves, or steady-state solutions, however, yield useful information.

The coupled equations for type-I second-harmonic generation can be solved by simple integration for low levels of fundamental depletion, where $E_\omega(z)$ is treated as constant and there is insignificant absorption. Initial conditions are $I_\omega(0)$, incident on the crystal and $I_{2\omega}(0) = 0$. Integration of the equation for the harmonic electric field yields an expression for electric field after propagating a distance of l in the crystal:

$$E_{2\omega}(l) = \frac{\omega d_{\text{eff}} E_\omega^2(0)}{n_{2\omega} c}\frac{1}{\Delta k}\left\{\exp\mathrm{i}(k_{2\omega} l) - \exp\mathrm{i}(2k_\omega l)\right\} \qquad [20]$$

Expressed as intensity the solution is

$$I_{2\omega}(l) = I_\omega(0)\Gamma^2 l^2 \,\mathrm{sinc}^2(\Delta k l/2) \qquad [21]$$

where $\mathrm{sinc}(x) = \sin(x)/x$ and

$$\Gamma^2 = 2\omega^2 d_{\text{eff}}^2 I_\omega(0)/(n_{2\omega} n_\omega^2 c^3 \varepsilon_0) \qquad [22]$$

When $\Delta k = 0$ and $\alpha_\omega = \alpha_{2\omega} = 0$, conditions of perfect phase matching and no absorption, the coupled equations for type-I second-harmonic generation can be combined into a single equation. This is done using conservation of energy, which requires $E_\omega^2(z) + E_{2\omega}^2(z) = E_\omega^2(0)$, in this case with no initial harmonic intensity. The equation can then be manipulated into a standard integral that yields the

inverse hyperbolic tangent. Rewritten and expressed in terms of intensity the result is

$$I_{2\omega}(l) = I_{\omega}(0)\tanh^2(\Gamma l) \qquad [23]$$

The two solutions for $I_{2\omega}(l)$ given above serve well for a number of applications. The $\mathrm{sinc}^2(\Delta k \cdot l/2)$ function is widely used to determine phase-matching acceptances. The $\tanh^2(\Gamma l)$ function is a good approximation for local conversion with large, well-collimated fundamental beams.

An exact solution to the coupled equations, however, gives insight to conditions such as high initial fundamental intensity with small amounts of phase mismatch. After extensive algebraic manipulation, a solution in the form of a Jacobian elliptic function $\mathrm{sn}(u|m)$ is obtained:

$$I_{2\omega}(l) = I_{\omega}(0)\nu_{\mathrm{b}}^2 \mathrm{sn}^2\left(\frac{\Gamma l}{\nu_{\mathrm{b}}}\middle|\nu_{\mathrm{b}}^4\right) \qquad [24]$$

where

$$1/\nu_{\mathrm{b}} = \Delta s/4 + \sqrt{1 + (\Delta s/4)^2} \qquad [25]$$

$$\Delta s = \Delta k/\Gamma$$

and Δk and Γ retain the earlier definitions. This solution can be extended to provide the phase of the fundamental and harmonic as the conversion process evolves. Expressing the complex harmonic and fundamental field amplitudes as the product of a real amplitude and a complex exponential:

$$E(z) = A(z)\exp \mathrm{i}\phi(z) \qquad [26]$$

the harmonic phase is

$$\phi_{2\omega}(z) = (\pi - \Delta k z)/2 \qquad [27]$$

The fundamental phase, however, is found to be dependent on the conversion process:

$$\phi_{\omega}(z) = (1/2)\arccos[A_{2\omega}(z)\Delta k/(2\kappa A_{\omega}^2(z))] - (\pi - \Delta k z)/z \qquad [28]$$

where $\kappa = \omega d_{\mathrm{eff}}/(n_{\omega} c)$. Small amounts of phase mismatch significantly change the phase of the fundamental at high levels of conversion. This phase change is used for switching applications in waveguide interferometers. It also makes phase-matching requirements more stringent at high levels of conversion. The three planewave solutions are illustrated in Figure 3. The narrowing of phase matching at higher conversion is illustrated in Figure 4.

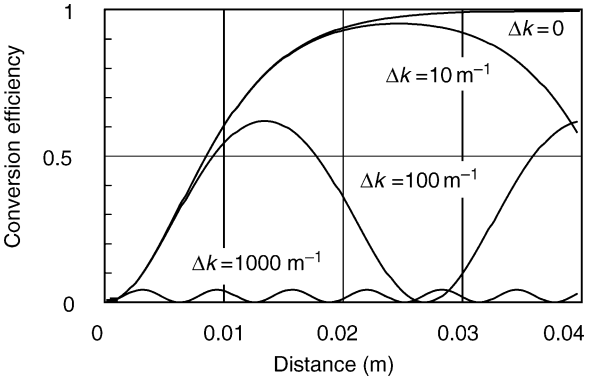

Figure 3 Monochromatic plane-wave solutions of the coupled equations for second-harmonic generation are illustrated for different amounts of wavevector mismatch. The solution takes the form $\tanh^2(\Gamma l)$ when $\Delta k = 0$ and $(\Gamma l)^2\mathrm{sinc}^2(\Delta k l/2)$ when conversion is small.

There is a Jacobian elliptic function solution for intensities with the coupled waves of type-II second-harmonic generation and sum-frequency generation. The phases of the individual waves can be recovered with elliptic integrals of the third kind. Both sets of equations, the two coupled equations for type-I phase matching and the three coupled equations for type-II phase matching, are amenable to numerical solution by Runge–Kutta methods.

Phase Matching

Phase matching is achieved in birefringent materials by balancing the dispersion of the material with the difference between the indices of refraction of the fast and slow waves. With adequate birefringence it may be possible to obtain phase matching by selecting the direction of propagation in the crystal. Equations describing the dispersion and birefringence of nonlinear crystals, necessary for calculating phase matching, along with the nonlinear optical coefficients and expressions for the effective nonlinear optical coefficients, are tabulated in handbooks. Values for a few examples are given here.

The negative uniaxial crystal potassium dihydrogen phosphate (KH_2PO_4 or KDP) is used as an illustrative example. The harmonic wave is chosen to have extraordinary polarization with the smaller index of refraction in this crystal with negative birefringence. With type-I phase matching, the fundamental consists of only an ordinary polarized wave. To have phase matching, $\Delta k = 0$, it is necessary to choose a direction of propagation that makes an angle θ with the optic axis that satisfies:

$$n_{\mathrm{e},2\omega}(\theta) = n_{\mathrm{o},\omega} \qquad [29]$$

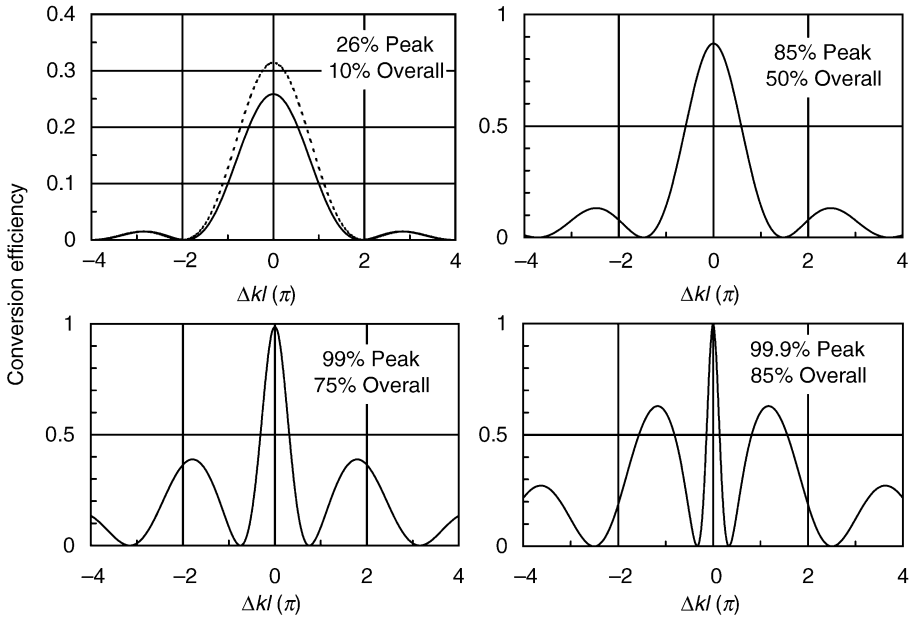

Figure 4 High levels of overall second-harmonic conversion require higher levels of conversion at peak pulse intensity. Phase-matching bandwidths narrow at the higher levels of peak conversion. The broken curve is the $(\Gamma l)^2\text{sinc}^2(\Delta kl/2)$ small conversion approximation.

The extraordinary index for propagation at an angle of θ to the optical axis in a uniaxial crystal $n_e(\theta)$ is given by

$$\frac{1}{n_e^2(\theta)} = \frac{\cos^2\theta}{n_o^2} + \frac{\sin^2\theta}{n_e^2} \qquad [30]$$

where n_o is the ordinary index and n_e is the extraordinary index for propagation at 90° to the optic axis. The phase-matching angle is obtained by using the identity $\cos^2\theta = 1 - \sin^2\theta$ and solving for θ:

$$\theta_{PM} = \sin^{-1}\left\{\frac{n_{e,2\omega}^2(n_{o,2\omega}^2 - n_{o,\omega}^2)}{n_{o,\omega}^2(n_{o,2\omega}^2 - n_{e,\omega}^2)}\right\}^{1/2} \qquad [31]$$

where the subscripts refer to ordinary and extraordinary indices at the fundamental and second-harmonic frequencies.

The effective nonlinear coefficient is determined by crystal symmetry, the type of phase matching, the birefringence of the crystal, and the direction of propagation. For crystals of point group $\bar{4}2m$ with negative birefringence, such as KDP, the effective nonlinear coefficient for type-I phase matching is given by

$$d_{eff} = -d_{36}\sin\theta\sin 2\phi \qquad [32]$$

The azimuthal angle ϕ is measured from the crystal x-axis. The x-axis and y-axis are specified by X-ray diffraction and piezoelectric coefficients and can be determined from the growth morphology. The azimuthal orientation of a finished crystal, however, is not obvious, and requires X-ray orientation, piezoelectric characterization, or nonlinear optical measurements, if the record of crystal orientation is lost. The nonlinear coefficient d_{36} is an abbreviation for the d_{312} and d_{321} tensor components, which are equal. For harmonic generation with a 1064 nm fundamental in KDP, $d_{36} = 0.39 \times 10^{-12}$ m/V. The unit of 10^{-12} m/V is usually expressed as picometers per volt (pm/V). The effective nonlinear coefficient for type-II phase matching for this class of crystals is

$$d_{eff} = d_{36}\sin 2\theta\cos 2\phi \qquad [33]$$

Type-I and type-II crystals cut from the same material are not interchangeable. The type-II phase-matching angle for KDP can be found by iterative solution of the equation:

$$n_{e,2\omega}(\theta) = \{n_{o,\omega} + n_{e,\omega}(\theta)\}/2 \qquad [34]$$

The birefringent walkoff angle, that is the angle the Poynting vector of an extraordinary wave makes with the wavevector, is another consideration for birefringent phase matching. There will be no further harmonic generation when the extraordinary and ordinary fundamental beams of type-II phase matching no longer overlap. For type-I phase matching, birefringent walkoff can limit the interaction length, but there can be several interaction lengths

in a crystal. The birefringent walkoff of an extraordinary wave propagating at an angle θ to the optic axis in a uniaxial crystal is given by

$$\rho = \tan^{-1}\left\{\frac{n_e^2(\theta)}{2}\left[\frac{1}{n_e^2} - \frac{1}{n_o^2}\right]\sin(2\theta)\right\} \qquad [35]$$

Refractive indices for 1064 nm to 532 nm second-harmonic generation in KDP are $n_{e,2\omega} = 1.4709$, $n_{o,2\omega} = 1.5129, n_{e,\omega} = 1.4603$, and $n_{o,\omega} = 1.4944$. The dispersion of KDP and indices at the phase-matching angles are shown in Figure 5. For type-I phase matching $d_{\text{eff}} = 0.26$ pm/V, $\theta_{\text{PM}} = 41.2°$, and $\rho_{2\omega} = 28$ milliradians (mr), and for type-II phase matching $d_{\text{eff}} = 0.34$ pm/V, $\theta_{\text{PM}} = 59.1°, \rho_{\omega} = 20$ mr, and $\rho_{2\omega} = 25$ mr. Type-II phase matching in KDP for this application offers an advantage of larger effective nonlinear coefficient. Also the angular acceptance is larger for type-II phase matching.

The angular acceptance is calculated from dispersion equations by first evaluating the derivative $\partial\Delta k/\partial\theta$ and then finding the value of $\Delta\theta$ corresponding to the full width at half maximum (FWHM) of the $\text{sinc}^2(\Delta k \cdot l/2)$ function:

$$\frac{\partial\Delta k}{\partial\theta}\Delta\theta_{\text{FWHM}} \cong 4 \times 1.39 \text{ radians}/l \qquad [36]$$

When θ is 0° or 90° for uniaxial crystals, or for propagation along one of the refractive index principal axes in a biaxial crystals, the first derivative $\partial\Delta k/\partial\theta$ becomes zero, and the angular acceptance must be calculated from the second derivative $\partial^2\Delta k/\partial\theta^2$. This case is called noncritical phase matching (NCPM), and the case for θ between 0° and 90° is called critical phase matching.

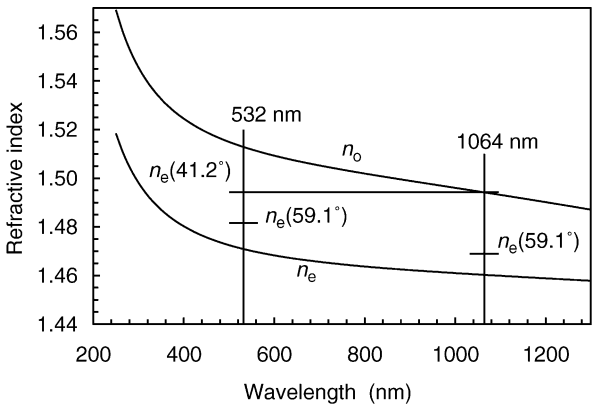

Figure 5 Dispersion of the birefringent nonlinear material KH_2PO_4 with refractive indices indicated for type-I and type-II 1064 nm to 532 nm second-harmonic generation. (Adapted from Byer RL (1977) Parametric oscillators and nonlinear materials. In: Harper PG and Wherrett BS (eds) *Nonlinear Optics*, pp. 47–159. San Francisco, CA: Academic Press.)

Second-harmonic generation of 1064 nm fundamental radiation in the crystal lithium triborate (LBO or LiB_3O_5) is an example of NCPM. At 149°C, this crystal will phase match for type-I SHG for propagation along the x-axis in the xyz frame determined by the indices of refraction of this biaxial crystal $n_x < n_y < n_z$. The following are calculated from dispersion equations for this case: $\partial\Delta k/\partial\theta = 0$; $\partial^2\Delta k/\partial\theta^2 = 2.04 \times 10^4$ (rad/cm)/rad^2; $\partial\Delta k/\partial\phi = 0$; and $\partial^2\Delta k/\partial\phi^2 = 6.45 \times 10^3$ (rad/cm)/rad^2. The FWHM angular acceptances for a 1.5 cm-long LBO crystal are $\Delta\theta_{\text{FWHM}} = 1.09°$ and $\Delta\phi_{\text{FWHM}} = 1.94°$. Angle-tuned CPM at 23°C in LBO occurs at $\theta = 90°$ and $\phi = 11°.5$. For this case $\partial\Delta k/\partial\phi = 1.32 \times 10^4$ (rad/cm)/rad, and the azimuthal angular acceptance decreases to $\Delta\phi_{\text{FWHM}} = 0.16°$. Also there is a birefringent walkoff angle of $\rho_{2\omega} = 19$ mr, which results in a displacement of 0.29 mm of the extraordinary-like harmonic beam for a 1.5 cm-long crystal. Both the larger angular acceptance and the absence of birefringent walkoff are advantages for harmonic generation. The effective nonlinear coefficient of LBO is reported as 0.85 pm/V and 1.04 pm/V by different sources.

Quasi phase matching offers the possibility, in principle, of noncritical phase matching at any wavelength in the transmission range of a material. However, it may be difficult producing the periodic structure that is required for phase matching in a particular application. The ferroelectric crystals lithium niobate ($LiNbO_3$), lithium tantalate ($LiTaO_3$), and potassium titanyl phosphate ($KTiOPO_4$ or KTP) can be processed by electric-field poling to produce domains of alternating polarity. Lithography techniques are used to apply a patterned electrode structure on the surface of a wafer or thin slab. Domains are reversed by the application of a carefully monitored and controlled electric field. Thicknesses of several mm have been achieved in periodically poled KTP (PPKTP). The higher coercive field of 21 kV/mm has limited the thicknesses that can be achieved in periodically poled lithium niobate (PPLN), particularly at shorter wavelengths for which poling periods become small. Progress is now being made with zincblende materials such as gallium arsenide. These materials have large linearity and good transmission in the infrared, but they are not birefringent. Epitaxial growth on patterned substrates is now being used to produce periodically structured GaAs on a research basis, and bonded stacks of wafers of alternating orientation also have been used. Harmonic conversion with quasi phase matching is compared with conventional phase matching and nonphase-matched harmonic generation in Figure 6.

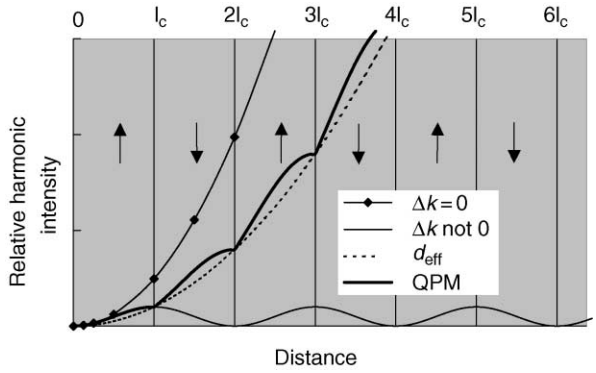

Figure 6 The growth of harmonic intensity is illustrated schematically for a quasi-phase-matched process in which the polarity of the nonlinearity is reversed after each coherence length. Conversion for $\Delta k = 0$, $\Delta k \neq 0$, and a uniform effective nonlinear coefficient are shown for comparison. (Adapted from Fejer MM (1992) Quasi-phase-matched second harmonic generation: tuning and tolerances. *IEEE Journal of Quantum Electronics* 28: 2631–2654.)

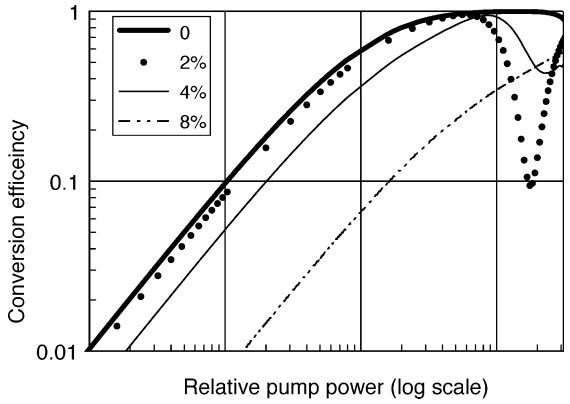

Figure 7 Random variations in domain length will lower harmonic conversion efficiency and have effect on back conversion. RMS variations in domain length are indicated in the legend for this specific example.

Quasi phase matching also provides access to tensor components that are not accessible with birefringent phase matching. This is the case for lithium niobate; the largest tensor component is $d_{333} = d_{33}$, which has a value of 25 pm/V. The effective nonlinear coefficient is the relevant Fourier component of the modulated nonlinearity:

$$d_{\text{eff}} = (2/\pi)d_{33} \approx 16 \text{ pm/V} \qquad [37]$$

This is a larger effective nonlinearity than is available with common birefringently phase matched materials in the visible and near-infrared. A more accurate treatment of second-harmonic generation involves application of the Jacobian-elliptic-function solution to each domain. After nearly complete conversion is reached, the phase perturbations on the individual domains have effect, and back conversion takes over (Figure 7). Conversion is lower and back conversion can set in sooner with random differences in the domain length. There is some experimental evidence that this type of back conversion has been observed in guided-wave harmonic conversion devices. Guided-wave nonlinear optical interaction can have long interaction lengths not limited by diffraction. Quasi phase matching is particularly useful in waveguide second-harmonic generation because the direction of propagation is fixed.

Gaussian Beams and Pulses

A radially symmetric Gaussian light beam has transverse intensity of

$$I(r) = I_0 \exp(-2r^2/w^2) \qquad [38]$$

where r is the radial coordinate and w is called the spot size. Harmonic generation in the low-conversion limit by a Gaussian beam, with a focus of spot size w_0 at the center of a crystal with optimized phase matching, is described by

$$p_{2\omega}(l)/p_{\omega}(0) = 2\omega^2 d_{\text{eff}}^2 p_{\omega}(0) l k h(B, \xi)/(\pi n^3 \varepsilon_0 c^3) \qquad [39]$$

The harmonic power after propagating distance l in the crystal is $p_{2\omega}(l)$, and $p_{\omega}(0)$ is the incident fundamental power. The function $h(B, \xi)$ is the Boyd and Kleinman focusing factor. It is a function of the walkoff parameter:

$$B = \rho\sqrt{lk}/2 \qquad [40]$$

and the focusing parameter:

$$\xi = l/(kw_0^2) \qquad [41]$$

The spot size w_0 of the fundamental beam at its waist is used to described the fundamental intensity distribution at the focus at the center of the crystal:

$$I_{\omega}(r) = (2p_{\omega}(0)/(\pi w_0^2))\exp(-2r^2/w_0^2) \qquad [42]$$

Values of the focusing factor for arbitrary focusing and walkoff are usually displayed in the form of a graph (Figure 8). In the case of weak focusing $\xi \ll 1$ and relatively small walkoff $w_0 > \rho l$, the focusing factor is given by

$$h(B, \xi) \approx \xi(1 - t^2/12 + t^4/120 - t^6/1344 + \ldots) \qquad [43]$$

where $t = 2B(2\xi)^{1/2}$.

An example of continuous-wave second harmonic generation is used. This calculation models a conversion experiment published in the literature. External-resonant-cavity second-harmonic generation of 6.5 W of 532 nm radiation was reported. The 1064 nm fundamental radiation with 378 W of circulating power in a resonant cavity external to the laser was focused to a 32 μm spot size in the center of a 6 mm-long LBO crystal (Figure 9). This corresponds to a focusing factor of $\xi = 0.62$ in the index $n = 1.6053$ material. The value of the focusing parameter is $h(0, 0.62) = 0.58$. The nonlinear optical coefficient for this process is reported as 0.85 pm/V and 1.04 pm/V by different sources. When these values are inserted into the earlier equation for $p_{2\omega}(l)/p_{\omega}(0)$, the higher coefficient yields a conversion efficiency of 0.0273 and 10.3 W of 532 nm output, whereas the lower coefficient yields a conversion efficiency of 0.0182 and 6.9 W of 532 nm radiation. Differences in published values of nonlinear optical coefficients are common. The reported precision of the experiment and the measured values tend to support the lower value. Practical applications are useful to check the accuracy of parameter values. With many variables and the added complication of operation at high intensity there is uncertainty that demands caution in accepting the derived parameter values. It is interesting to note that the power and beam size of the example result in a maximum intensity of 17 MW/cm^2 at the surface of this crystal. Many vendors will warranty antireflection coatings for only 1 MW/cm^2 maximum continuous-wave intensity.

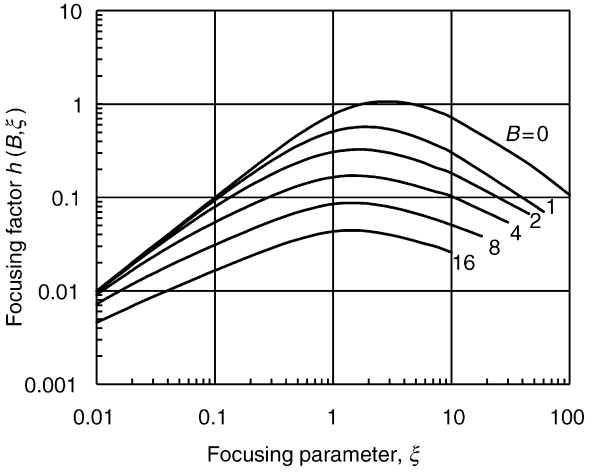

Figure 8 The Boyd and Kleinman focusing factor $h(B,\xi)$ for type-I second-harmonic generation is shown as a function of the focusing parameter ξ for different values of the walkoff parameter B. The curves shown were generated with a split-step Fourier transform calculation. (Adapted from Boyd GD (1968) Parametric interactions of focused Gaussian light beams. *Journal of Applied Physics* 39: 3597–3639.)

For a pulsed fundamental with temporal shape $p_{\omega}(t) = p_{\omega}(0)\exp(-t^2/\tau^2)$, integration over time gives a calculated energy conversion efficiency of:

$$\eta_{\text{calc}} = U_{2\omega}(l)/U_{\omega}(0)$$
$$= \sqrt{2}\omega^2 d_{\text{eff}}^2 U_{\omega}(0) l k h(B,\xi)/(\tau\sqrt{\pi^3} n^3 \varepsilon_0 c^3) \quad [44]$$

where $U_{2\omega}(l)$ is the harmonic energy generated after propagation distance l in the crystal and $U_{\omega}(0)$ is the incident fundamental energy. This is still a low conversion approximation. An estimate of conversion efficient at arbitrary levels of depletion η_{est} is obtained with the empirical expression:

$$\eta_{\text{est}} = \eta_{\text{calc}}/(1 + \eta_{\text{calc}}) \quad [45]$$

Returning to the example 1.064 nm to 532 nm, type-II SHG in KDP and using $l = 3$ cm, $U_{\omega}(0) = 0.3$ J, and $\tau = 3.6$ ns for a 6 ns FWHM pulse duration, the above two relationships predict a conversion efficiency of 50%. These parameters give a peak intensity of 330 MW/cm^2, a value typical for efficient harmonic conversion, while avoiding laser-induced damage in a long-term, repetitive-pulse application using KDP. Single-shot laser-induced-damage thresholds for KDP are about 10 times higher.

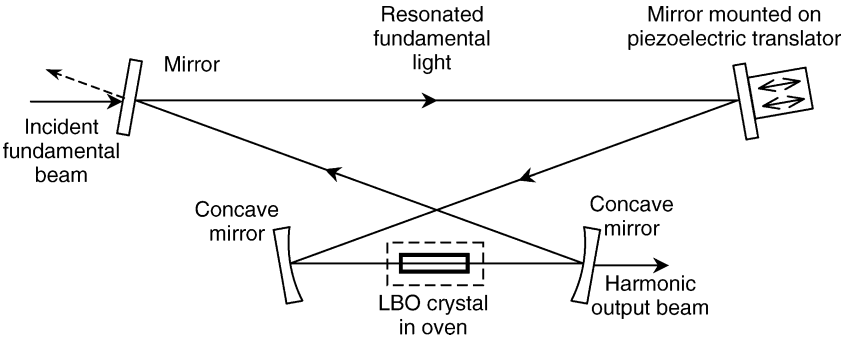

Figure 9 A bow-tie cavity for externally resonant second-harmonic generation is illustrated. The reflected fundamental beam is used to develop an error signal to drive the piezoelectric translator and hold the cavity in resonance.

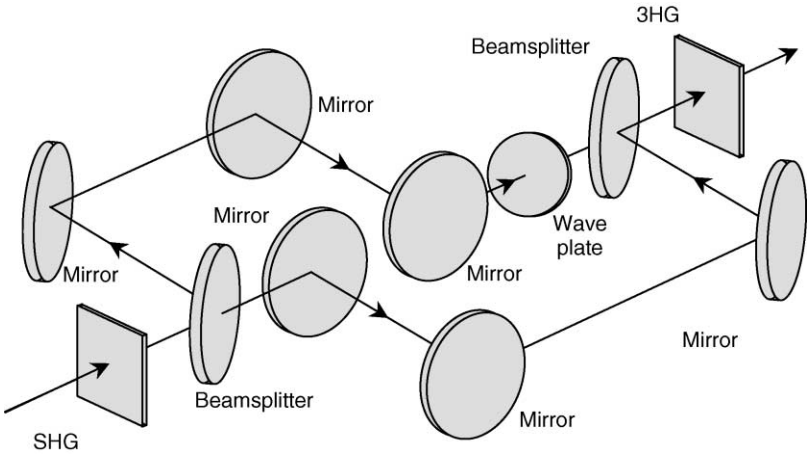

Figure 10 Short crystals less than 1 mm in length are typically used for second-harmonic generation with fundamental pulses that are only ten's of femtoseconds in duration. It is necessary to separate fundamental and second-harmonic pulses and recombine them with appropriate delay to compensate for group-velocity mismatch before sum-frequency generation to the third harmonic.

As a final example, consider second-harmonic generation of a 100 fs ($1\,\text{fs} = 10^{-15}$ s) duration pulse from a mode-locked Ti:Al_2O_3 laser operating at 800 nm. Typical laser output might consist of 10 nJ (10×10^{-9} Joule) pulses at 80 MHz repetition rate. Group velocity walkoff is a concern for this short pulse duration (Figure 10). Barium borate (BaB_2O_4 or BBO) is a common crystal for this application. The group velocity walkoff rate between the ordinary-polarization 800 nm fundamental pulse and the extraordinary-polarization 400 nm harmonic pulse is 190 fs/cm. A crystal length no longer than 0.5 mm is needed to avoid lengthening the harmonic pulse in time. Fortunately, the laser-induced-damage-threshold intensity increases approximately as the inverse of the square root of the pulse length between roughly 10 ns and 1 ps, and it is possible to focus the beam to achieve higher intensity without crystal damage and compensate for the short crystal length. However, the 68-milliradian birefringent walkoff of the harmonic will limit the size of the focus. A 20 μm spot size will allow an interaction length that roughly matches the crystal length and provides a peak fundamental intensity around 16 GW/cm^2 and a conversion efficiency of nearly 30%. Now suppose the 100 fs pulse is amplified to 100 mJ in a large chirped-pulse regenerative amplifier. A larger diameter crystal is required, and KDP is an appropriate choice. The group velocity walkoff rate in KDP is 78 fs/mm, and a crystal of 1.5 mm thickness could be used. With the beam spot size increased to 30 mm, the peak intensity will be 71 GW/cm^2, and the conversion efficiency will be about 40%. Material availability, such as the large sizes possible with KDP, often determines a choice.

Conclusion

Basic techniques for describing and modeling second-harmonic generation have been discussed. Birefringent phase matching and quasi phase matching were reviewed. Three examples were used to illustrate considerations for implementing harmonic-generation systems. There are many more parameters to be considered for other applications and for more detailed analysis. The examples presented illustrate the demands nonlinear optical frequency conversion places on materials. A few materials have been established as primary choices in common applications. But for many applications, available materials or laser system performance are limiting and it is necessary to use the materials and systems that are available. The importance of using the analysis methods is stressed. It is possible to sacrifice performance by improperly specifying a crystal. Choosing the best crystal for a harmonic-generation application with an appropriate optical design will optimize harmonic conversion.

Introduction

The invention of the ruby laser, in 1960, provided a revolutionary new light source, which emits an intense, highly collimated polarized beam of light. The new source opened the way for developments that have enabled new technologies, thus profoundly changing our way of life. One of these new frontiers opened by the laser was the field of nonlinear optics. In 1961, Franken *et al.* were the first to report the observation of second-harmonic generation from a quartz crystal, using ruby laser light. Third-harmonic generation (THG) was soon discovered by Terhune and co-workers in 1962.

THG has found applications as a spectroscopic tool to probe optical properties of materials, but recently it has been developed as a microscopy tool and a pulse measurement technique. More efficient THG is possible by engineering the materials; for instance, one way to improve conversion efficiency is to use periodic structured dielectric materials, called photonic bandgap structures.

Polarization and the Third-Order Susceptibility

THG is a nonlinear optical phenomenon, where light of angular frequency ω is converted into light at an angular frequency 3ω that is three times higher. Light is made of particles called photons and the nonlinear medium enables the process whereby three photons of frequency ω are annihilated to create one photon of frequency 3ω. The nonlinear interactions are strongly dependent on the polarization or the dipole moment per unit volume, which is written as a series

$$P(t) = \chi^{(1)} \times E(t) + \chi^{(2)} : E^2(t) + \chi^{(3)} \vdots E^3(t) + \cdots \quad [1]$$

where χ is the susceptibility of the optical material, the superscript of χ in parentheses denotes the order of nonlinearity, t is the time variable, and E is the electric field. Both the electric field and the polarization are vectors; therefore the susceptibilities are tensors. The first-order or linear susceptibility $\chi^{(1)}_{ij}$ is a second-order tensor. This term constitutes the linear polarization of the medium denoted a P^{L}. It has nine elements, but only up to three independent elements depending on the symmetry of the lattice. The other terms represent an expansion for the nonlinear polarization of the medium, P^{NL}. Note that the superscripts 'L' and 'NL' denote linear and nonlinear polarization contributions, respectively. The third-order susceptibility $\chi^{(3)}_{ijkl}$ is a four-rank tensor, which usually has 81 elements ($3 \times 3 \times 3 \times 3 = 81$). In asymmetric crystalline solids, all 81 elements can be of nonzero value and independent. With a higher degree of symmetry in other optical materials, the 81 elements are no longer all independent, and thus the number of independent elements can be reduced to a lower number. For example, isotropic material such as glass, liquid, or vapor has only three independent elements. For illustration, we consider a general case where the applied frequencies ω are arbitrary, and the third-susceptibility is given as

$$\chi_{ijkl} \equiv \chi^{(3)}_{ijkl}(\omega_4 = \omega_1 + \omega_2 + \omega_3) \quad [2]$$

Note that the superscript has been removed. In the isotropic material, the coordinate axes must be

equivalent. Thus, the susceptibility has symmetry given by

$$\chi_{1111} = \chi_{2222} = \chi_{3333} \quad [3a]$$

$$\chi_{1122} = \chi_{1133} = \chi_{2211} = \chi_{2233} = \chi_{3311} = \chi_{3322} \quad [3b]$$

$$\chi_{1212} = \chi_{1313} = \chi_{2323} = \chi_{2121} = \chi_{3131} = \chi_{3232} \quad [3c]$$

$$\chi_{1221} = \chi_{1331} = \chi_{2112} = \chi_{2332} = \chi_{3113} = \chi_{3223} \quad [3d]$$

For the isotropic material, there are only 21 nonzero elements, as given in eqns [3a]–[3d], because these elements have a Cartesian index (1, 2, or 3) that appears an even number of times. The reason for nonexistence of the elements with an index appearing an odd number of times is because, for example, χ_{1222} would give a response in the $\hat{x}_1$ direction due to a field applied in the $\hat{x}_2$ direction. This response must vanish in an isotropic material, because there is no reason why the response should be in the $+\hat{x}_1$ direction rather than in the $-\hat{x}_1$ direction. In summary, the elements in the third-order susceptibility of the isotropic material have the relationship given by

$$\chi_{ijkl} = \chi_{1122}\delta_{ij}\delta_{kl} + \chi_{1212}\delta_{ik}\delta_{jl} + \chi_{1221}\delta_{il}\delta_{jk} \quad [4]$$

where δ is the Kronecker delta function; it has a unit value, $\delta_{ij} = 1$, if and only if $i = j$, otherwise, it is zero, $\delta_{ij} = 0$. Thus, we see from eqn [4] that there are only three independent elements in the isotropic material. Crystalline materials have more independent components and they have been determined for the 32 crystals classes. The relationships between the elements for these crystalline classes are tabulated in books by Boyd and by Butcher and Cotter.

A block diagram of a material illustrates THG and its corresponding energy-level diagram is depicted in Figure 1. Figure 1a shows that fields of frequency ω excite the χ^3 optical material to generate the third-harmonic field with the residual of the fundamental harmonic field. Figure 1b shows that three photons of frequency ω are destroyed to generate a photon of frequency 3ω in the third-harmonic generation.

For third-harmonic generation, the frequency dependence of the susceptibility is expressed as $\chi_{ijkl}(3\omega = \omega + \omega + \omega)$. With the intrinsic permutation symmetry of the nonlinear susceptibility, the elements of the susceptibility tensor has a relationship such that $\chi_{1122} = \chi_{1212} = \chi_{1221}$. So we can further reduce eqn [4] for the third-harmonic generation as

$$\chi_{ijkl}(3\omega = \omega + \omega + \omega) = \chi_{1122}(3\omega = \omega + \omega + \omega) \times (\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) \quad [5]$$

Therefore, we see that the third-harmonic susceptibility tensor has only one independent element.

Wave Equation for χ^3 Third-Harmonic Generation

Theoretically, we have to use the wave equation to observe how an intense laser field interacts with the nonlinear material, so that the polarization of the medium could develop new frequency components that are not present in the incident field. Thus, these new frequency components of the polarization become the sources of the new frequency components of the electromagnetic field.

To formally describe THG, we begin with Maxwell's equations (in Gaussian units), and we have

$$\nabla \times D = 4\pi\rho \quad [6a]$$

$$\nabla \times B = 0 \quad [6b]$$

$$\nabla \times E = \frac{-1}{c}\frac{\partial B}{\partial t} \quad [6c]$$

$$\nabla \times H = \frac{-1}{c}\frac{\partial D}{\partial t} + \frac{4\pi}{c}J \quad [6d]$$

where H is the magnetic field, B is the magnetic flux density, D is the electric flux density, ρ is the charge density, and J is the current density. The desired solution is in the region of space in the nonlinear material that has no free charge ($\rho = 0$), and therefore, there is no free current ($J = 0$). We assume

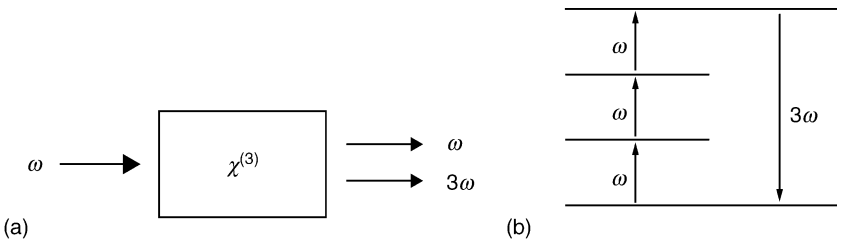

Figure 1 The third-harmonic (a) block diagram; and (b) energy level description.

that the nonlinear material is nonmagnetic, so that $B = \mu H = H$, where $\mu = 1$ in a nonmagnetic environment. In nonlinear material, the electric flux is defined as

$$D = E + 4\pi P \quad [7]$$

so that the polarization depends nonlinearly on the strength of E. Using eqns [6c] and [6d], we have

$$\nabla \times \nabla \times E + \frac{1}{c^2}\frac{\partial^2 D}{\partial t^2} = 0 \quad [8]$$

Substituting eqn [7] into [8], we have

$$\nabla \times \nabla \times E + \frac{1}{c^2}\frac{\partial^2 E}{\partial t^2} = \frac{-4\pi}{c^2}\frac{\partial^2 P}{\partial t^2} \quad [9]$$

Using an identity from the vector calculus, we have

$$\nabla \times \nabla \times E = \nabla(\nabla \times E) - \nabla^2 E \quad [10]$$

In linear optics, we see from eqn [6a] that when there is no free charge in source-free isotropic material, $\nabla \times D = \nabla \times E = 0$. Thus, the first term on the right-hand side of eqn [10] has no effect. Whereas in nonlinear optics, $\nabla \times E \neq 0$ in isotropic material, but the contribution from the first term on the right-hand side of eqn [10] is negligible, therefore, we can ignore it. Thus, eqn [9] can be simplified as

$$\nabla^2 E - \frac{1}{c^2}\frac{\partial^2 E}{\partial t^2} = \frac{4\pi}{c^2}\frac{\partial^2 P}{\partial t^2} \quad [11]$$

For distinction of the linear and nonlinear contributions, we modified eqn [7] to get

$$D = E + 4\pi P^{\mathrm{L}} + 4\pi P^{\mathrm{NL}}$$

where $P = P^{\mathrm{L}} + P^{\mathrm{NL}}$. Let $D^{\mathrm{L}} = E + 4\pi P^{\mathrm{L}}$, and we rewrite eqn [11] as

$$\nabla^2 E - \frac{1}{c^2}\frac{\partial^2 D^{\mathrm{L}}}{\partial t^2} = \frac{4\pi}{c^2}\frac{\partial^2 P^{\mathrm{NL}}}{\partial t^2} \quad [12]$$

Equation [12] is the most general form of the wave equation seen in nonlinear optics, and could be used as our starting point for our study of third-harmonic generation.

Methods of Third-Harmonic Generation

Since nonlinear optics is a popular research topic, there are a handful of existing methods that can be used for third-harmonic generation, and possibly new methods may be developed in the future. Here, we will discuss three methods using χ^3 material: (i) photonic crystal; (ii) defect mode using photonic crystal; and (iii) homogeneous nonlinear crystal.

Photonic Crystal

After the invention of electronic bandgap structure, the optical scientists and engineers saw the possibility to extend the operating waveband into the visible, and thus we have the photonic bandgap structure. The geometry and material choices of the photonic bandgap structure create a unique bandgap in frequency spectrum that has potential applications in laser optics, telecommunication, medical imaging, optical limiting, etc. A photonic bandgap structure is also commonly known as the photonic crystal. For a one-dimensional photonic crystal, two materials of certain thicknesses each, repeat themselves a number of times. For example, the first and second materials are of thickness 'a' and 'b', respectively, so that their combined thickness is 'd', and have a periodicity of 10. The schematic of such a one-dimensional photonic crystal, with its corresponding dielectric function as a function of axial distance z, is depicted in Figure 2.

By using χ^3 materials for photonic crystal, and using method of multiple scales (MMS), we have the nonlinear polarization given as

$$P^{\mathrm{NL}} = \lambda \chi^{(3)} E^3 \quad [13]$$

where λ is the perturbation parameter. With reference to Figure 2, assume that 'a' is equal to 'b' so that $d = 2a$, then the Fourier expansion of the dielectric

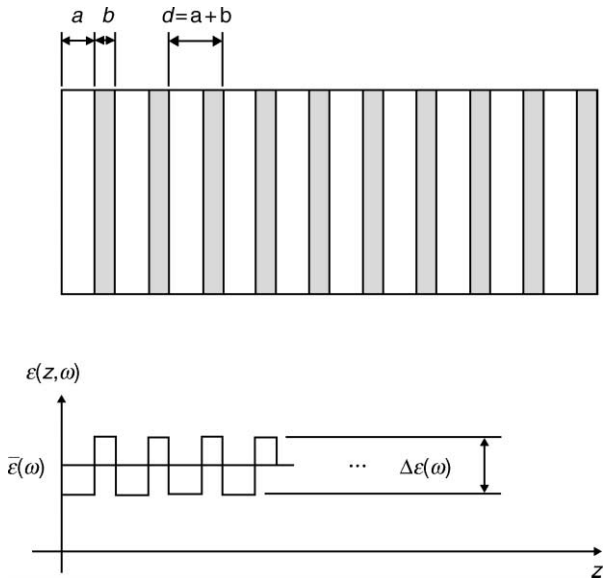

Figure 2 The schematic of the one-dimensional photonic crystal.

function is given as

$$\varepsilon(z,\omega) = \bar{\varepsilon}(\omega) + \lambda\Delta\varepsilon(\omega)\cos(2\pi z/d) - \frac{1}{3}\lambda\Delta\varepsilon(\omega)\cos(6\pi z/d) + \cdots \quad [14]$$

where $\bar{\varepsilon}(\omega)$ is the zeroth-order coefficient, and $\Delta\varepsilon(\omega)$ is first-order coefficient of the Fourier series expansion. Without going through the mathematics of MMS, we use eqns [12] and [13] to obtain the solution of the wave equation and two sets of coupled mode equations. The solution to the wave equation in eqn [12] is given by

$$E_0 = \left(\frac{1}{\sqrt{k_1}}A_{f1}(z_1,t_1)e^{ik_1z_0} + \frac{1}{\sqrt{k_1}}A_{b1}(z_1,t_1)e^{-ik_1z_0}\right)e^{-i\omega t_0} + \left(\frac{1}{\sqrt{k_3}}A_{f3}(z_1,t_1)e^{ik_3z_0} + \frac{1}{\sqrt{k_3}}A_{b3}(z_1,t_1)e^{-ik_3z_0}\right)e^{-3i\omega t_0} + \text{c.c.} \quad [15]$$

where A is the amplitude of the field, k is the wavenumber such that $k_1^2=\omega^2\varepsilon(\omega)/c^2$, and $k_3^2=(3\omega)^2\varepsilon(3\omega)/c^2$ where c is the speed of light, and 'c.c.' refers to the complex conjugate. Note that the subscript 'f' and 'b' refer to the forward and backward modes, respectively. Also, the subscript '0' refers to the slowest scale, and '3' refers to the fastest scale chosen in the analysis using MMS. Let $a_{f1}=NA_{f1}e^{i\pi\delta_1 z_1/d}$, $a_{b1}=NA_{b1}e^{-i\pi\delta_1 z_1/d}$, $a_{f3}=NA_{f3}e^{i\pi\delta_3 z_1/d}$, and $a_{b3}=NA_{b3}e^{-i\pi\delta_3 z_1/d}$, such that

$$N^2=\frac{2d\sqrt{3k_3}(3\omega)^2\chi^{(3)}}{k_3c^2k_1\sqrt{k_1}}$$

The coupled mode equations for the fundamental field are given as

$$\frac{\partial a_{f1}}{\partial z_1}+\frac{d}{\pi v_{g1}}\frac{\partial a_{f1}}{\partial t_1}=\frac{id}{2\pi k_1}\nabla_\perp^2 a_{f1}+i\delta_1 a_{f1}-i\kappa_1 a_{b1} -\frac{\alpha_1}{2}a_{f1}+ia_{f1}[2|a_{b1}|^2+|a_{f1}|^2] +ia_{f1}^{*2}a_{f3} \quad [16a]$$

$$\frac{-\partial a_{b1}}{\partial z_1}+\frac{d}{\pi v_{g1}}\frac{\partial a_{b1}}{\partial t_1}=\frac{id}{2\pi k_1}\nabla_\perp^2 a_{b1}+i\delta_1 a_{b1}-i\kappa_1 a_{f1} -\frac{\alpha_1}{2}a_{b1}+ia_{b1}[2|a_{f1}|^2+|a_{b1}|^2] +ia_{b1}^{*2}a_{b3} \quad [16b]$$

where, at the fundamental harmonic, v_{g1} is the group velocity of the homogeneous medium, δ_1 is the laser detuning, κ_1 is the coupling coefficient, α_1 is the absorption coefficient, $\nabla_\perp^2$ is the transverse Laplacian and the whole term ($\nabla_\perp^2 a_{f1}$ and $\nabla_\perp^2 a_{b1}$) accounts for diffraction effects, and '$*$' denote the complex conjugate of the corresponding term. Similarly, the coupled mode equations for the third-harmonic field are given as

$$\frac{\partial a_{f3}}{\partial z_1}+\frac{d}{\pi v_{g3}}\frac{\partial a_{f3}}{\partial t_1}=\frac{id}{2\pi k_3}\nabla_\perp^2 a_{f3} +ia_{f3}\left[\delta_3+6\sqrt{\frac{3k_1}{k_3}}(|a_{f1}|^2+|a_{b1}|^2)\right] -i\kappa_3 a_{b3}-\frac{\alpha_3}{2}a_{f3}+ia_{f1}^3 \quad [17a]$$

$$-\frac{\partial a_{b3}}{\partial z_1}+\frac{d}{\pi v_{g3}}\frac{\partial a_{b3}}{\partial t_1}=\frac{id}{2\pi k_3}\nabla_\perp^2 a_{b3} +ia_{b3}\left[\delta_3+6\sqrt{\frac{3k_1}{k_3}}(|a_{b1}|^2+|a_{f1}|^2)\right] -i\kappa_3 a_{f3}-\frac{\alpha_3}{2}a_{b3}+ia_{b1}^3 \quad [17b]$$

where at the third harmonic, v_{g3} is the group velocity of the homogeneous medium, δ_3 is the laser detuning, κ_3 is the coupling coefficient, and α_3 is the absorption coefficient. Note that in the limit when $k_3\approx 3k_1$, the coupling coefficient between the fundamental and third harmonics are related by

$$\kappa_3=3\left(\frac{d}{\pi}\right)\frac{\Delta\varepsilon\omega_0^2}{2k_3c^2}+3\delta_1=\kappa_1 \quad [18]$$

Also, note that the laser detuning between the fundamental and third harmonics are expressed as

$$\delta_3=\left(\frac{d}{\pi}\right)\Delta k+3\delta_1 \quad [19]$$

where $\Delta k=k_3-3k_1\times$ Equation [19] described the phase matching condition, which determines the efficiency of the third-harmonic generation. When the phase is completely matched ($\Delta k=0$), then we can achieved the most efficienct in third-harmonic generation when $\delta_3=3\delta_1$. Equations [16] and [17] are useful equations which are commonly used for numerically simulation of beam propagation.

Defect Mode Using Photonic Crystal

A defect mode can be generated in the photonic crystal if we introduce a defect in the geometry of the photonic crystal. The schematic of the photonic crystal with a defect of length d_d located at the center of the photonic crystal, where the subscript 'd' denotes defect, is depicted in Figure 3. For the convenience of the analysis, we divide the entire photonic crystal into three regions: (i) Region I; (ii) Region II; and (iii) Region III. Since we arbitrarily

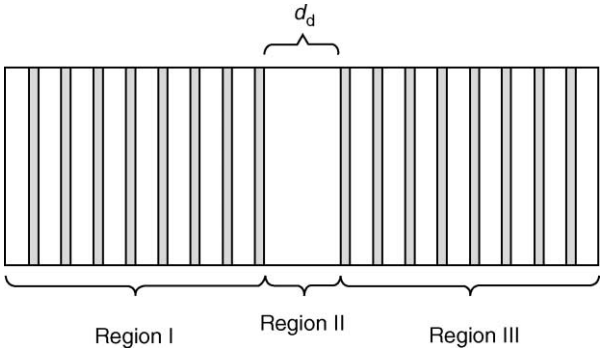

Figure 3 The schematic of the photonic crystal with a defect of length d_d.

put the defect in the center of the photonic crystal, Region I and II will be identical, thus it will be easier for us in our analysis. The strategy of our analysis is to solve the wave equation for Region I of the photonic crystal, and apply the result to the Region II analysis. Similarly, we apply the corresponding result of Region II to Region III. Thus, by breaking up the entire photonic crystal into three regions, we can then easily analyze the propagation of a field through the entire photonic crystal.

Assume that Region I and II are each of length $L/2$. Using the coupled mode equations without considering the effect of absorption, the fundamental fields in the forward and backward modes in Region I is given as

$$a_{f1(REG)}(z_1) = \left(\cos(\Delta_1 z_1) - \frac{i\delta_1}{\Delta_1}\sin(\Delta_1 z_1)\right)a_{f1(REG)}(0) + \frac{i\kappa}{\Delta_1}\sin(\Delta_1 z_1)a_{b1(REG)}(0) \quad [20a]$$

$$a_{b1(REG)}(z_1) = \left(\cos(\Delta_1 z_1) + \frac{i\delta_1}{\Delta_1}\sin(\Delta_1 z_1)\right)a_{b1(REG)}(0) - \frac{i\kappa}{\Delta_1}\sin(\Delta_1 z_1)a_{f1(REG)}(0) \quad [20b]$$

where

$$\Delta_1 = \sqrt{\delta_1^2 - \kappa^2}, \qquad \kappa = \frac{d\omega_0^2\Delta\varepsilon(\omega)}{2\pi k_1 c^2}$$

and the subscript '(REG)' denotes solution in either Region I, II, or III. The boundary conditions for the fundamental harmonic field, at the interface between Region I and II, are given as

$$a_{f1(II)}(d_d) = e^{ikd_d}a_{f1(I)}(L/2) \quad [21a]$$

$$a_{b1(II)}(d_d) = e^{-ikd_d}a_{b1(I)}(L/2) \quad [21b]$$

where $k = n\omega/c$. The field that propagates through Region II can be determined using eqns [20] and [21]. Also, the boundary conditions at the front and end faces of the Region III of the photonic crystal are given as

$$a_{f1(III)}(0) = a_{f1(II)}(d_d) \quad [22a]$$

$$a_{b1(III)}(L/2) = 0 \quad [22b]$$

Using eqns [20] and [22], we can determine the field that propagates through Region III. Similarly, we can use the same approach to analyze the third-harmonic field.

Homogeneous Nonlinear Crystal

If we examine Figure 2, we see that when $\Delta\varepsilon(\omega) = 0$, the photonic crystal becomes a homogeneous nonlinear crystal. In another word, $\kappa_3 = 0$ when we set the laser detuning to zero, thus there is no more coupling between the layers, and we are left with only the forward mode. Without going through the mathematics of four-wave mixing to describe the THG in a homogeneous nonlinear crystal, we can obtain the fundamental and third-harmonic coupled mode equations from eqns [16] and [17]. This will make it easier to make comparisons between the photonic crystal and the homogeneous nonlinear crystal, rather than comparing the coupled mode equation with the four-wave mixing equations among them. Since no backward wave is generated in the homogeneous nonlinear crystal when there is no coupling between the forward and backward modes, eqn [16] can remove the coupling term and the backward mode equation, and the modification is given as

$$\frac{\partial a_{f1}}{\partial z_1} + \frac{d}{\pi v_{g1}}\frac{\partial a_{f1}}{\partial t_1} = \frac{id}{2\pi k_1}\nabla_\perp^2 a_{f1} + i\delta_1 a_{f1} - \frac{\alpha_1}{2}a_{f1} + ia_{f1}|a_{f1}|^2 + ia_{f1}^{*2}a_{f3} \quad [23]$$

$$\frac{\partial a_{f3}}{\partial z_1} + \frac{d}{\pi v_{g3}}\frac{\partial a_{f3}}{\partial t_1} = \frac{id}{2\pi k_3}\nabla_\perp^2 a_{f3} + ia_{f3}\left[\delta_3 + 6\sqrt{\frac{3k_1}{k_3}}|a_{f1}|^2\right] - \frac{\alpha_3}{2}a_{f3} + ia_{f1}^3 \quad [24]$$

for the fundamental and third-harmonic fields, respectively.

Applications

Generation of short wavelength radiation is possible using THG. Therefore, it becomes less expensive to generate green, blue, or ultraviolet light with the

infrared and the red light. In order to improve THG conversion efficiency, a beam with a tight focus is used, which results in an electric field of highest intensity, and has the highest possible χ^3 polarization effect. Normally, due to the phenomenon of the Gouy phase shift at a tight focal point of the beam, third-harmonic generation is suppressed. However, in the presence of an interface within the focal volume, the phase is disturbed and a third-harmonic signal is generated. This phenomenon has been used to image cells in *in vivo* microscopy on a femtosecond time-scale. The ultrashort pulses have little energy and therefore little heat is deposited in the material. The cells can be continuously imaged without damage.

Introduction

Light waves propagate along straight lines in a vacuum and in materials. However, their amplitude and phase can only be affected by the intrinsic properties of the sample, such as absorption and refraction index. Experimental work from the early 1960s, has deviated from this simple approach, mainly through propagating intense light beams in crystals and glasses. Among many puzzling new effects, frequency conversion and beam coupling have triggered intense studies and opened a whole new field, theoretically and experimentally. These various phenomena have been classified according to the order of their optical nonlinearity. The second order mainly occurs in frequency generation and has already been discussed in previous articles of this encyclopedia. Therefore, this article will be devoted to the higher order, in which self focusing, coupling, and mixing of light beams will be explained. We will illustrate some simple ideas with a convenient model before describing a few applications.

The framework of electromagnetic wave interaction with matter is embedded in the Lorentz force. The oscillating electric field drives the components, ions, and electrons, but due to the large mass differences, only the electron movement is strongly perturbed. In dielectric media, these carriers are connected with static bonds such that the applied electric field modulates the spatial position of equilibrium of the charges. As a result, a dipolar moment is created and oscillates quasi-adiabatically at very high frequencies (between 10^{14} and 10^{17} Hz) for an applied optical wave. These collective oscillations of the induced dipoles compose the so-called matter polarization, proportional to the driving electric field amplitude. Magnetic field interaction is usually much weaker and so can be neglected in nonmagnetic media.

As an electromagnetic wave, lasers are a coherent source of very high intensity, i.e., large electric fields. For example, in standard pulsed

lasers focused on a target, the light intensity can easily reach 10 Tw/cm^2, corresponding to an electric field of the order of magnitude of the internal bonding field (10^{10} V/m). At this level of interaction, dipolar moments are no longer strictly proportional to the applied electric field, as depicted in Figure 1. In the weak field regime, the simple perturbation approach displaces the carriers in a power series of the applied electric field. The polarization is thus developed in series, in respect to this electric field.

Formalism

Relation Between Field and Polarization: The Response Function

Although numerous works have been published with a frequency description of the material polarization, we will discuss here the study of nonlinearity in the time domain in order to follow the physical reality. In most processes, both spaces are equal and can be selected at will, as long as the entire requirements are fully understood; the electromagnetic field is classically described.

In the time domain, the polarization can be developed as

$$P(r,t) = P_{\text{Linear}}(r,t) + P_{\text{Nonlinear}}(r,t) \qquad [1]$$

where the linear part of the polarization can be written as

$$P_{\text{Linear}}(r,t) = \varepsilon_0 \int_{R^3} \int_{-\infty}^{\infty} R^{(1)}(r_1,t_1) \times E(r-r_1,t-t_1)\mathrm{d}t_1\,\mathrm{d}r_1 \qquad [2]$$

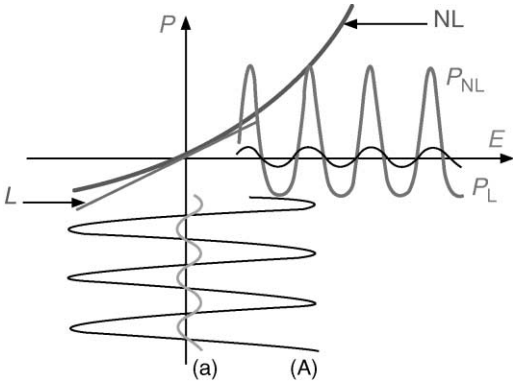

Figure 1 Polarization for various field amplitude: (a) Weak field case, linear response. (A) Strong field, distortion and nonlinearity.

This general expression is rather complex but shows that the polarization, due to collective movement of carriers in a macroscopic volume (thousands of dipoles) centered at position r, always depends on the applied electric field. This expression is also nonlocal as dipoles–dipoles interactions play an important role.

In general, for the nonlinear (NL) part of the polarization, an approximation of the local interaction is described for simplicity. For a second-order interaction, one can write:

$$P^{(2)}_{\text{NL}}(r,t) = \varepsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(2)}(t_1,t_2) \times E(r,t-t_2)E(r,t-t_2-t_1)\mathrm{d}t_1\,\mathrm{d}t_2 \qquad [3]$$

For the other series expansion – at third order, one obtains

$$P^{(3)}_{\text{NL}}(r,t) = \varepsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(3)}(t_1,t_2,t_3)E(r,t-t_3) \times E(r,t-t_3-t_2)E(r,t-t_3-t_2-t_1)\mathrm{d}t_1\,\mathrm{d}t_2\,\mathrm{d}t_3 \qquad [4]$$

This third-order polarization already combines three electric fields. This nonlinear polarization also radiates a fourth wave and is therefore the adopted framework for describing four-wave mixing experiments (Figure 2).

As the physical properties of materials depend only on time intervals between the different pulse interactions, eqn (4) can be rearranged as

$$P^{(3)}_{\text{NL}}(r,t) = \varepsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(3)}(t-\tau_1,t-\tau_2,t-\tau_3) \times E(r,\tau_1)E(r,\tau_2)E(r,\tau_3)\mathrm{d}\tau_1\,\mathrm{d}\tau_2\,\mathrm{d}\tau_3 \qquad [5]$$

If the sample response time is much shorter than pulse duration, the so-called adiabatic limit (as for electronic cloud deformation excited distant from

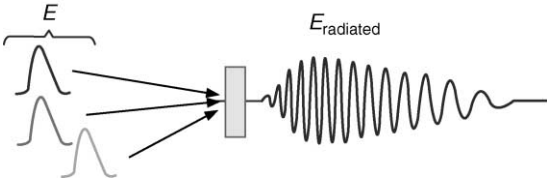

Figure 2 Three incoming beams E_1, E_2, E_3 create a polarization (nonlinear). The sample responds while radiating a fourth field E_4.

resonance) the polarization is written as

$$P_{\mathrm{NL}}^{(3)}(r,t)=\varepsilon_0\sigma^{(3)}E(r,t)E(r,t)E(r,t) \qquad [6]$$

We will see later how this expression is useful for third-harmonic generation and optical Kerr effects, etc. This expression is accurate for materials excited at a distance from resonances and care must be taken to reserve such a model for corresponding processes. In this case, the frequency approach is quite simple too and both spaces, time or Fourier, can be chosen at will.

For very long response time, such as orientational or structural molecular reorganization, one can use the Born–Oppenheimer approximation and present the nonlinear polarization as

$$P_{\mathrm{NL}}^{(3)}(r,t)=\varepsilon_0E(r,t)R'(t) \qquad [7]$$

Similar is linear polarization, where the response function takes into account the changes of the molecular structure under the light intensity stress:

$$R'(t)=\int_{-\infty}^{+\infty}d^{(3)}(t-t_1)E(r,t_1)E(r,t_1)\mathrm{d}t_1 \qquad [8]$$

The material response will then be mostly driven by the field amplitude rather than the frequency.

Properties of Nonlinear Susceptibilities

The third-order nonlinear susceptibility $\chi^{(3)}$ is the Fourier transform of the response function R and has proved to be a most practical tool in optical nonlinear theory. The symmetry properties of the material lead to simplification on the tensor of rank 4 (fourth rank tensor), involved in four-wave mixing:

$$P_i^{(3)}(\omega_m)=\varepsilon_0\sum_{n_1,\ldots,n_p}\sum_{i_1,\ldots,i_p}\chi_{i,i_1,\ldots,i_p}^{(3)}(\omega_m;\omega_{n_1},\ldots,\omega_{n_p})\times E_{i_1}(\omega_{n_1})\cdots E_{i_p}(\omega_{n_p}) \qquad [9]$$

The nonlinear susceptibility tensor must account for all the spatial and symmetrical order of the sample. This will eventually reduce the number of independent elements from a possible 81.

Wave Equation in Nonlinear Regime

From Maxwell's equations, with a sample without free carriers and current, one can deduce the wave equation in the time domain, as:

$$\Delta E-\frac{1}{c^2}\frac{\partial^2E}{\partial t^2}-\frac{1}{c^2}\frac{\partial^2P_{\mathrm{L}}}{\partial t^2}=\frac{1}{c^2}\frac{\partial^2P_{\mathrm{NL}}}{\partial t^2} \qquad [10]$$

In the frequency domain, this equation reduces to

$$\Delta\tilde{E}(r,\omega)+k(\omega)^2\tilde{E}(r,\omega)=-\mu_0\omega^2\tilde{P}_{\mathrm{NL}}(r,\omega) \qquad [11]$$

In order to solve these (coupled) wave equations in relation to four-wave mixing, we must develop the electric field and the polarization in a slowly varying envelope approximation, using the following conventions:

$$E_i(r,t)=\frac{1}{2}\left(A_i(r,t)\mathrm{e}^{\mathrm{i}(\omega_it-k(\omega_i)z)}+\bar{A}_i(r,t)\mathrm{e}^{-\mathrm{i}(\omega_it-k(\omega_i)z)}\right) \qquad [12]$$

$$P_{\mathrm{NL}}(r,t)=\frac{1}{2}\left(p_{\mathrm{nl}}(r,t)\mathrm{e}^{\mathrm{i}(\omega t-k(\omega)z)}+\bar{p}_{\mathrm{nl}}(r,t)\mathrm{e}^{-\mathrm{i}(\omega t-k(\omega)z)}\right) \qquad [13]$$

Within the framework of small perturbations, diffraction can be neglected and the wave equation can be easily reduced to one dimension:

$$\frac{\partial A}{\partial z}=\frac{\mathrm{i}\omega}{2n(\omega)\varepsilon oc}p^{\mathrm{NL}}(z,\omega)\exp(-\mathrm{i}k(\omega)z) \qquad [14]$$

where ω represents the sum or difference permutations over all the frequencies ω_i, thus reflecting the law of energy conservation.

In the case of four-wave mixing, one has to solve four coupled equations for the four interacting waves. Using the polarization eqn [13], one gets:

$$\frac{\partial A_j}{\partial z}=\frac{\mathrm{i}\omega_j}{2n(\omega_j)c}\chi^3A_1^{(*)}A_2^{(*)}A_3^{(*)}\times\exp\left(\sum_{i=1,2,3}\exp(\pm\mathrm{i}k_i(\omega_i)z)\right)\exp(-\mathrm{i}k(\omega_j)z) \qquad [15]$$

This set of generic equations respectively represent indifferently, either the three incoming beams ($j=1,2,3$), or the radiated field E_4 at ω. The algebra used here associates at each complex conjugate field (*) with the counter propagating wave ($-k$). The amplitude variation of the j field at frequency ω_j is due to the coupling of the three other fields within the sample. The accumulated field is nevertheless always strongly dependent of the phase term and will vanish except when this phase term is zero. This is known as the phase matching condition which has to be fulfilled to ensure an efficient energy conversion. A more general approach of this condition can be found in the corresponding article of this encyclopedia.

Example and Selected Applications

When inserting the full material polarization (linear and nonlinear) into the propagation equation, even

restricted at third order, a whole set of processes must be considered. All of them are described by the generic equation already presented, but only a few very important processes – with increasing complexity – will be described here.

Optical Kerr Effect

We consider one single beam incident at frequency ω on a sample. The non-linear polarization is given by

$$P_{\mathrm{NL}}^{(3)}(r,t)=\frac{\varepsilon_0}{8}\chi^{(3)}\left(E(r,t)^3+E^*(r,t)^3+3E(r,t)^2E^*(r,t)+3E(r,t)E^*(r,t)^2\right) \quad [16]$$

The polarization at frequency ω reduces to

$$P_{\mathrm{NL}}^{(3)}(r,t)=\frac{3\varepsilon_0}{4}\chi^{(3)}|E(r,t)|^2E(r,t) \quad [17]$$

This term has the same phase as the incident beam and, therefore, the phase matching is automatic. Using eqns [12] and [13], one can rewrite the wave equation for the optical Kerr effect in the thin sample approximation:

$$\frac{\partial A}{\partial z}=\frac{3\mathrm{i}\omega}{8nc}\chi^{(3)}|A|^2A \quad [18]$$

The solution of this equation is

$$A(z)=A(0)\exp\left(\frac{3\mathrm{i}}{8nc}\chi^{(3)}|A(0)|^2z\right) \quad [19]$$

Along the beam, the amplitude of the input pulse stays constant for this process but its phase is affected by a nonlinear shift proportional to power density I.

In literature, one can find the concept of n_2, the sample nonlinear index, in the following formula:

$$\psi_{\mathrm{NL}}(z)=\frac{\omega}{c}n_2Iz \quad [20]$$

In this way of describing the total phase along the beam, the index of refraction in the nonlinear regime can be expressed more conveniently as

$$n=n_0+n_2I \quad [21]$$

One of the most significant demonstrations of this effect is the self-focusing phenomenon. The usual Gaussian transverse structure of a laser beam presents high intensity at the center of the beam, therefore creating an index variation in the isotropic sample due to this optical Kerr effect. An induced lens can then be applied to this refractive index gradient, following the field distribution. As a result, the beam focuses itself along the propagation and can result in a complete breakdown.

Third Harmonic Generation

In the third harmonic generation, i.e., the third-order nonlinear process where the frequency of the generated wave is three times the frequency of the input wave at ω, only two waves are in the sample (at ω and 3ω). For the nonlinear wave, the master equation is then:

$$\frac{\partial A_{3\omega}}{\partial z}=\frac{3\mathrm{i}\omega}{8n(3\omega)c}\chi^{(3)}A_\omega^3\exp((3\mathrm{i}k(\omega)-\mathrm{i}k(3\omega))z) \quad [22]$$

Here, propagation effects have to be carefully considered as theses waves do travel at different velocities and will eventually be out of phase. Obviously this discrepancy of phase velocities precludes the co-propagation and strongly affects the global efficiency. The only way to ensure a coherent generation of the harmonic wave throughout the material is to fulfill the relation:

$$k(3\omega)=3k(\omega) \quad [23]$$

This is the so-called phase matching condition. Although difficult because the usual dispersion of materials is very large for such a frequency difference, this can be satisfied using either geometrical arrangement or, if possible, using the birefringent properties of the material. The efficiency of this method is poor and a better approach is implemented when two $\chi^{(2)}$ processes are cascaded (doubling and sum frequency mixing).

Degenerate Four-Wave Mixing and Phase Conjugation

One of the most popular and intriguing interactions is depicted in Figure 3. Where the sample is excited by three fields at the same frequency ω in this particular geometry: two-waves, named pump beams E_1 and E_2, are exactly counter-propagating with opposite wave vectors of $+k_1$ and $k_2=-k_1$, while the third wave (E_3) arrives at the sample with a given wave vector of k_3.

Of possible couplings, one contribution E_4 corresponds to a re-emitted beam along $k_4=-k_3$, i.e., opposite to the E_3 wave.

The third-order nonlinear polarization is given here by

$$P_{\mathrm{NL}}^{(3)}(r,t) = \frac{\varepsilon_0}{8}\chi^{(3)}(E_1(r,t) + E_1^*(r,t) + E_2(r,t) + E_2^*(r,t) + E_3(r,t) + E_3^*(r,t))^3 \quad [24]$$

This E_4 wave (along $-k_3$) originates in this product from source terms including:

$$E_1(r,t)E_2(r,t)E_3^*(r,t) \quad [25]$$

and thus present an evolution driven by:

$$\frac{\partial A_4}{\partial z} = \frac{3\mathrm{i}\omega}{4n(\omega)c}\chi^{(3)}A_1A_2A_3^* \quad [26]$$

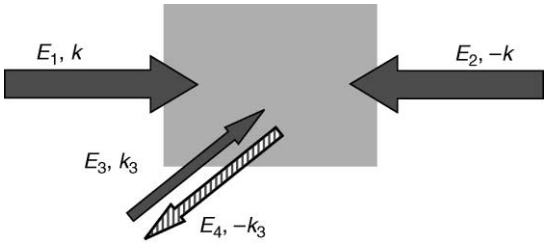

Figure 3 Two counter-propagating fields (E_1, E_2) and the third field E_3 create a polarization (nonlinear). The sample responds while radiating a fourth field E_4 opposite to the E_3 wave.

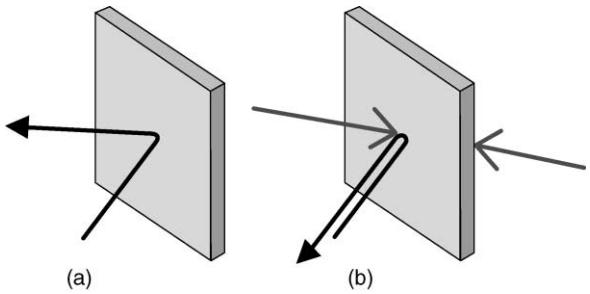

Figure 4 (a) Snell refraction in a conventional mirror; (b) Phase conjugate mirror.

where the phase matching condition is automatically fulfilled. Interesting facts can be described using this expression. First, the radiated amplitude is proportional to the complex conjugate of the E_3 field. This nonlinear process is not only able to reverse the direction of propagation but also the whole phase of an arbitrary incoming beam of light. This 'phase conjugator' can be considered as a kind of mirror with very unusual reflection properties. Unlike a conventional mirror, where a ray is redirected according to the ordinary law of reflection, a phase-conjugate mirror (PCM) retro-reflects all incoming rays back to their origin (Figure 4).

Second, the reflectivity of this mirror depends on the susceptibility and the amplitude of the first two fields, usually called pump beams. This will allow reflectivity that is much higher than the unity, unlike with conventional mirrors.

The remarkable reflection properties of the PCM have found many important applications. The most useful undoubtedly is related to distortion correction. If the image information has been distorted by the transmitting medium on its way to the PCM, then these aberrations will be corrected when the reflected signal retraces its original path through the medium. Through this amazing 'healing' property of optical phase conjugation, a high-quality optical beam can be double passed through a distorting medium, such as an imperfect imaging device or a turbulent atmosphere, without any loss of beam quality. Figure 5 shows the basic two-pass geometry for imaging and aberration correction using a PCM.

The spherical wave from the object point P is aberrated by the distorting medium. The wave-front is reversed by the PCM and a second passage through the same distorting path restores the initial field. The resulting spherical wave converges to the image point P', separated from P by the beamsplitter.

Numerous other applications for PCM and the various underlying nonlinear optical interactions have been proposed. These include effects as diverse

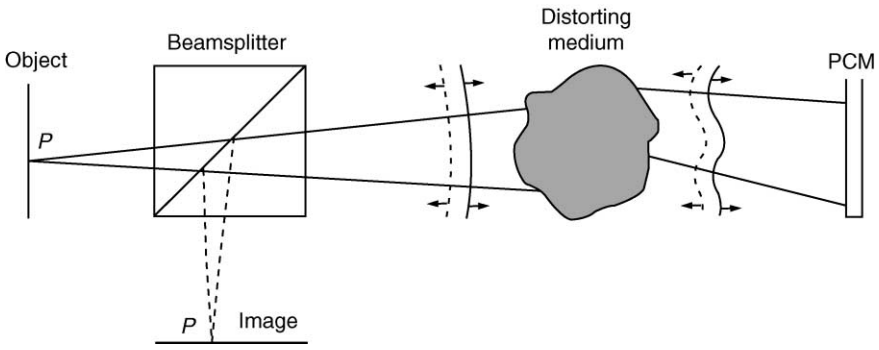

Figure 5 A basic two-pass system for imaging and distortion compensation using optical phase conjugation.

as parametric oscillation, optical tracking and pointing, spatial and temporal image processing, optical computing, optical filtering, etc. The PCM is also successfully implemented for aberration correction in high-power laser resonators.

Nondegenerate Four-Wave Mixing

If the frequencies of the impinging fields build a nonlinear polarization with an oscillating term close to absorption (or emission) frequencies of the sample, the nonlinear susceptibility increases tremendously. The radiated field amplitude changes by orders of magnitude and allows spectroscopic studies of the sample. The most popular process used to perform gas spectroscopy is CARS, an acronym for coherent anti-Stokes Raman scattering (or spectroscopy). In this case, the three incoming beams have different frequencies and the phase matching condition is eventually fulfilled in the 3D space.

Usually, two beams at the same frequency ω_P (pump beams), are mixed with a third beam at a tunable frequency ω_S, according to the energy scheme in Figure 6. As the radiated frequency ω_{CARS} is higher, the Raman spectroscopic notation is used and the subscripts 'S' hold for 'Stokes' and 'P' for 'anti-Stokes'.

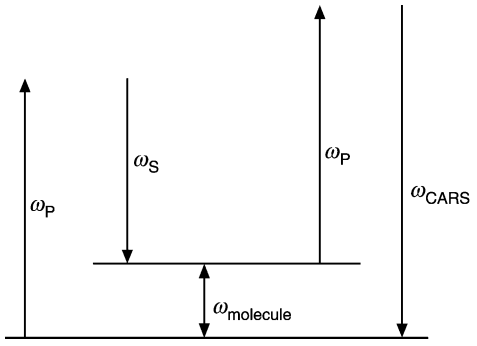

Figure 6 Energy diagram for a CARS experiment. Four-wave mixing efficiency increases when the frequency difference $\omega_P - \omega_S$ is close to a resonant frequency of the sample, $\omega_{molecule}$.

Whenever $\omega_P - \omega_S = \omega_{molecule}$, then an increase of the CARS intensity by many orders of magnitude is observed. Therefore, a Raman spectrum can be obtained by continuously changing, the Stokes laser and simultaneously recording the intensity of the CARS beam. This procedure is called scanning CARS, an interesting technique insofar as it allows taking high-resolution spectra, as well as measuring temperature of the sample while scanning over the Boltzmann distribution of the electronic ground state.

Figure 7 displays a classical geometrical arrangement where the phase matching condition fully determines the directionality of the radiated field at ω_{CARS}. Although the alignment of the setup can become tedious, this technique has been widely used, even in hostile industrial environments. The coherent aspect of this four-wave mixing process, imbedded in the phase matching condition, has a huge benefit over classical spectroscopic techniques and thus isotropic techniques, such as laser-induced fluorescence or Raman spectroscopy.

The CARS process is an interference process comparable to diffraction of a grating. The two fields at ω_P and ω_S form a laser-induced moving grating and the third field, at ω_P, undergoes a Doppler shift at ω_{CARS}. This scattered field undergoes a coherent amplitude addition in the Bragg direction.

Conclusion

In this article, we have discussed a set of optical nonlinear processes occurring at the third order of the development in series of the material polarization. At this order, wave mixing obviously shows most

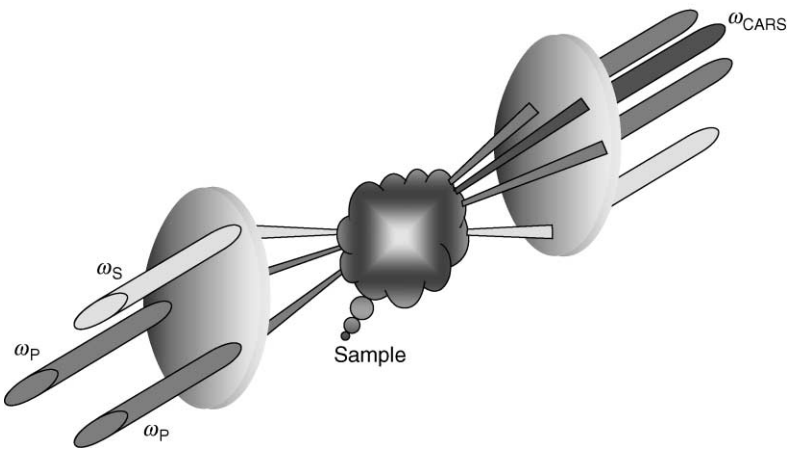

Figure 7 Layout of the CARS beams near a sample (a flame here). This particular arrangement is called folded (or 3D) Boxcars.

significant behavior and has been extensively studied and applied in many scientific areas. The general framework presented here can be further investigated using some books listed in Further Reading below.

Kramers–Krönig Relations in Nonlinear Optics

M Sheik-Bahae, The University of New Mexico, Albuquerque, NM, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Since their introduction nearly 75 years ago, the Kramers–Krönig (KK) dispersion relations have been widely appreciated and applied in the analysis of linear optical systems. Because they are a consequence of strict causality, the KK relations apply not only to optical systems, but also to any linear, causal system such as electrical networks and particle scattering. In this article, we review the formulation and application of these relations in nonlinear optical systems. Simple logical arguments are used to derive dispersion relations that relate the nonlinear absorption coefficient to the nonlinear refraction coefficient. More general formalisms are then derived that apply to all nonlinear susceptibilities including the harmonic generating cases. Examples of recent successful application of these dispersion relations in analyzing various nonlinear materials will be presented.

The mathematical formalism of the KK dispersion relations in nonlinear optics was studied in the formative days of the field. The great usefulness of these relations was appreciated only recently, however, when they were used to derive the dispersion of the optical Kerr effect in solids from the corresponding nonlinear absorption coefficients, including two-photon absorption.

Before examining the details of KK relations in nonlinear optical systems, it is instructive to revisit the linear dispersion relations and their derivation based on the logic of causality. We will begin this task by introducing the definition of the linear as well as nonlinear susceptibilities $\chi^{(n)}$. In most nonlinear optics texts, the total material polarization (P) that

drives the wave equation for the electric field (E) is expressed as

$$\begin{aligned}P_i(t) = \varepsilon_0 \int_{-\infty}^{\infty} R_{ij}^{(1)}(t-t_1)E_j(t_1)\mathrm{d}t_1 + \varepsilon_0 \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \\ \times R_{ijk}^{(2)}(t-t_1,t-t_2)E_j(t_1)E_k(t_2)\mathrm{d}t_1\,\mathrm{d}t_2 \\ + \varepsilon_0 \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} R_{ijkl}^{(3)}(t-t_1,t-t_2,t-t_3) \\ \times E_j(t_1)E_k(t_2)E_l(t_3)\mathrm{d}t_1\,\mathrm{d}t_2\,\mathrm{d}t_3 + \cdots \end{aligned} \quad [1]$$

where $R^{(n)}$ is defined as the nth-order, time-dependent response function or time-dependent susceptibility. The subscripts are polarization indices indicating, in general, the tensor nature of the interactions. The summation over the various indices $j, k, l, \ldots$ is implied for the various tensor elements of $R^{(n)}$. Upon Fourier transformation, we obtain:

$$\begin{aligned}\vec{P}_i(\omega) = \varepsilon_0 \int_{\infty}^{-\infty} \mathrm{d}\omega_1\, \chi_{ij}^{(1)}(\omega_1)\vec{E}_j(\omega_1)\delta(\omega-\omega_1) \\ + \varepsilon_0 \int_{\infty}^{-\infty} \mathrm{d}\omega_1 \int_{\infty}^{-\infty} \mathrm{d}\omega_2 \\ \times \chi_{ijk}^{(2)}(\omega_1,\omega_2)\vec{E}_j(\omega_1)\vec{E}_k(\omega_2)\delta(\omega-\omega_1-\omega_2) \\ + \varepsilon_0 \int_{\infty}^{-\infty} \mathrm{d}\omega_1 \int_{\infty}^{-\infty} \mathrm{d}\omega_2 \int_{\infty}^{-\infty} \mathrm{d}\omega_3 \\ \times \chi_{ijkl}^{(3)}(\omega_1,\omega_2,\omega_3)\vec{E}_j(\omega_1)\vec{E}_k(\omega_2)\vec{E}_l(\omega_3) \\ \times \delta(\omega-\omega_1-\omega_2-\omega_3), \cdots \end{aligned} \quad [2]$$

where δ is the Dirac delta-function. Here the $E(\omega)$ are Fourier transforms of the corresponding electric field. The nth-order susceptibility is defined as the Fourier transform of the nth-order response function:

$$\begin{aligned}\chi_{ijk\ldots n}^{(n)}(\omega_1,\omega_2,\ldots,\omega_m) = \int_{-\infty}^{+\infty} \mathrm{d}\tau_1 \int_{-\infty}^{+\infty} \mathrm{d}\tau_2 \cdots \int_{-\infty}^{+\infty} \\ \times \mathrm{d}\tau_n R_{ijk\ldots m}^{(n)}(\tau_1,\tau_2,\ldots,\tau_m)\mathrm{e}^{\mathrm{i}(\omega_1\tau_1+\omega_2\tau_2+\cdots+\omega_m\tau_m)} \end{aligned} \quad [3]$$

For simplicity, we drop the polarization indices $i, j, \ldots$, and thus ignore the tensor properties of $\chi^{(n)}$ as well as the vector nature of the electric fields.

Let us for the moment concentrate on the linear polarization alone and derive the linear KK relations for the first-order susceptibility $\chi^{(1)}(\omega)$. For this, we rewrite eqn [3] for $n = 1$:

$$\chi^{(1)}(\omega) = \int_{-\infty}^{\infty} R^{(1)}(\tau)\mathrm{e}^{-\mathrm{i}\omega\tau}\,\mathrm{d}\tau \quad [4]$$

(As defined above, $\chi^{(1)}(\omega)$ and $R^{(1)}(\tau)$ are not a strict Fourier transform pair because of a missing factor of 2π.) Causality means that the effect cannot precede the cause. This can be restated mathematically as:

$$R^{(1)}(t) = R^{(1)}(t)\Theta(t) \quad [5]$$

i.e., the response to an impulse at $t = 0$ must be zero for $t < 0$. Here $\Theta(t)$ is the Heaviside step function defined as $\Theta(t) = 1$ for $t > 0$ and $\Theta(t) = 0$ for $t < 0$. Upon Fourier transforming this equation, the product in the time domain becomes a convolution integral in frequency space

$$\begin{aligned}\chi^{(1)}(\omega) &= \chi^{(1)}(\omega)\left[\frac{\delta(\omega)}{2} + \frac{\mathrm{i}}{2\pi\omega}\right] \\ &= \frac{\chi^{(1)}(\omega)}{2} + \frac{\mathrm{i}}{2\pi}\wp\int_{-\infty}^{\infty}\frac{\chi^{(1)}(\omega')}{\omega-\omega'}\mathrm{d}\omega' \\ &= \frac{1}{\mathrm{i}\pi}\wp\int_{-\infty}^{\infty}\frac{\chi^{(1)}(\omega')}{\omega'-\omega}\mathrm{d}\omega' \end{aligned} \quad [6]$$

which is the KK relation for the linear optical susceptibility. The symbol $\wp$ stands for the Cauchy principal value of the integral. The KK relation is thus a restatement of the causality condition [5] in the frequency domain. Taking the real part we have,

$$\Re e\{\chi^{(1)}(\omega)\} = \frac{1}{\pi}\wp\int_{-\infty}^{\infty}\frac{\Im m\{\chi^{(1)}(\omega')\}}{\omega'-\omega}\mathrm{d}\omega' \quad [7]$$

Taking the imaginary part of eqn [6] leads to a similar relation relating the imaginary part to an integral involving the real part. It is conventional to write the optical dispersion relations in terms of the more familiar quantities of refractive index, $n(\omega)$, and absorption coefficient, $\alpha(\omega)$. For $|\chi^{(1)}| \ll 1$ then $n - 1 = \Re e\{\chi^{(1)}\}/2$ and $\alpha = \omega\Im m\{\chi^{(1)}\}/c$, and eqn [7] is transformed into

$$n(\omega) - 1 = \frac{c}{\pi}\wp\int_{0}^{\infty}\frac{\alpha(\omega')}{\omega' 2 - \omega^2}\mathrm{d}\omega' \quad [8]$$

where we additionally used the reality conditions of $n(\omega) = n(-\omega)$, and $\alpha(\omega) = \alpha(-\omega)$ to change the lower integral limit to 0. More rigorous analysis shows that eqn [8] is general and valid for any value of $|\chi^{(1)}|$. Although the KK dispersion relations and the extent of their applications in linear optics are well understood, some confusion sometimes exists about their applications to nonlinear optics. Causality clearly holds for both linear and nonlinear systems. The question is: what form do the resulting dispersion relations take in a nonlinear system? The linear Kramers–Krönig relations were derived from linear system theory, so it would appear to be impossible to apply the same logic to a nonlinear system. The key insight is that one can linearize the system. This is illustrated in Figure 1 where a linear

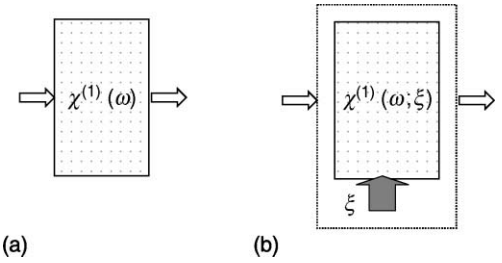

Figure 1 (a) A causal linear system obeying KK relations. (b) The system in (a) when externally perturbed by ξ. The dotted box now represents our new linear causal system whose altered $\chi^{(1)}$ obeys the KK relations.

(and of course, causal) optical material is transformed into a 'new' linear system that now contains the material and an external perturbation denoted by ξ. Although we are interested in perturbations of an optical nature, this formalism is general under any type of perturbation. It is important to appreciate the fact that our new system is causal even in the presence of the perturbation. This allows us to write down a modified form of the Kramers–Krönig relation linking the index of refraction to the absorption:

$$[n(\omega)+\Delta n(\omega;\zeta)]-1 = \frac{c}{\pi}\wp\int_0^\infty \frac{\alpha(\omega')+\Delta\alpha(\omega';\zeta)}{\omega' 2-\omega^2}\mathrm{d}\omega' \qquad [9]$$

which, after subtracting the linear relation between n and α leaves a relation between the changes in index and absorption:

$$\Delta n(\omega;\zeta)=\frac{c}{\pi}\wp\int_0^\infty \frac{\Delta\alpha(\omega';\zeta)}{\omega' 2-\omega^2}\mathrm{d}\omega' \qquad [10]$$

where ζ denotes a general perturbation. An equivalent relation also exists whereby the change in absorption coefficient can be calculated from the change in the refractive index. It is essential that the perturbation be independent of frequency of observation, ω', in the integral (i.e., the excitation ζ must be held constant as ω' is varied).

Equation [10] has been used to determine refractive changes due to 'real' excitations such as thermal and free-carrier nonlinearities in semiconductors. In those cases, ζ denotes either ΔT (change of temperature) or ΔN (change of free-carrier density), respectively. In the former case, one calculates the refractive index change resulting from a thermally excited electron–hole plasma and the temperature shift of the band edge. For cases where an electron–hole plasma is injected (e.g., optically), the change of absorption gives the plasma contribution to the refractive index. In this case, the ζ parameter in eqn [10] is taken as the change in plasma density regardless of the mechanism of generation or the optical frequency.

Let us now extend this formalism to the case where the perturbation is virtual, occurring at an excitation frequency Ω that is below any material resonance. To the lowest order in the excitation irradiance I_Ω, we write

$$\Delta\alpha(\omega;\zeta)=\Delta\alpha(\omega;\Omega)=2\alpha_2(\omega;\Omega)I_\Omega \qquad [11]$$

and

$$\Delta n(\omega;\zeta)=\Delta n(\omega;\Omega)=2n_2(\omega;\Omega)I_\Omega \qquad [12]$$

where n_2 and α_2 are the nonlinear refractive index and absorption coefficients of the material, respectively. By definition, these coefficients are related to the third-order nonlinear susceptibility $\chi^{(3)}(\omega_1,\omega_2,\omega_3)$ via (*see* **Nonlinear Optics, Basics**: Nomenclature and Units)

$$n_2(\omega;\Omega)=\frac{3}{4\varepsilon_0 n_0(\omega)n_0(\Omega)c}\Re e\{\chi^{(3)}(\omega,-\Omega,\Omega)\} \qquad [13]$$

and

$$\alpha_2(\omega;\Omega)=\frac{3\omega_a}{2\varepsilon_0 n_0(\omega)n_0(\Omega)c^2}\Im m\{\chi^{(3)}(\omega,-\Omega,\Omega)\} \qquad [14]$$

We can therefore write the dispersion relations between α_2 and n_2:

$$n_2(\omega;\Omega)=\frac{c}{\pi}\wp\int_0^\infty \frac{\alpha_2(\omega';\Omega)}{\omega' 2-\Omega^2}\mathrm{d}\omega' \qquad [15]$$

Note that even when the degenerate $n_2(\omega)=n_2(\omega;\omega)$ is desired (at a given ω), the dispersion relation requires that we should know the nondegenerate absorption spectrum $\alpha_2(\omega';\omega)$ at all frequencies ω'.

Let us pause here and discuss some physical mechanisms that can be involved for a given system of interest. Consider a material characterized by an optical resonance occurring at, say ω_0 (i.e., a degenerate two-level system). For a solid, this resonance can be regarded as that of the fundamental energy gap; $\omega_0=\omega_g=E_g/\hbar$ in a two-band system. Now, let us examine how the presence of an optical excitation at $\Omega<\omega_0$ can alter the absorption spectrum (at a variable probe ω'). In the quantum mechanical picture, this gives rise to a 'new' material whose perturbed wave functions are 'dressed' by the intensity and frequency of the applied optical field.

The lowest-order correction to the absorption is given by $\alpha_2(\omega';\Omega)$ which involves three major physical processes. Recalling that $\Omega < \omega_0$, these processes include (1) two-photon absorption (2PA) when $\omega' + \Omega \rightarrow \omega_0$ and (2) Raman-induced absorption when $\omega' - \Omega \rightarrow \omega_0$, both implying an absorption of a photon at the probe frequency ω' (i.e., $\alpha_2 > 0$). The third process can be identified as resulting from the blue-shift (for $\Omega < \omega_0$) of the resonance (known as the quadratic optical Stark effect) caused by the excitation field. For our two-level system, the latter results in a decrease followed by an increase in absorption in the vicinity of ω_0. An example of the overall absorption changes due to such processes is shown in Figure 2 where $\alpha_2(\omega';\Omega)$ is qualitatively plotted for a degenerate two-level system. We should note that the relative magnitude of each contribution as well as the width and shape of the resonances are chosen arbitrarily for the purpose of illustration. Using the KK relation in eqn [15], we can now arrive at the nonlinear index coefficient $n_2(\omega;\Omega)$. The result of this transformation is also given in Figure 2. The above simple example elucidates the key concepts involving the relationship between nonlinear absorption and refraction in materials for third-order processes. These concepts, when applied more rigorously to semiconductors, have been successful in predicting the sign, magnitude, and dispersion of n_2 due to the anharmonic motion of bound electrons. This will be briefly discussed later. Returning to the mathematical foundation of KK relations, we use eqns [13] and [14] to write eqn [15] in terms of the nonlinear susceptibility $\chi^{(3)}$:

$$\Re e\{\chi^{(3)}(\omega_1, \omega_2, -\omega_2)\} = \frac{1}{\pi}\wp\int_{-\infty}^{\infty} \frac{\Im m\{\chi^{(3)}(\omega', \omega_2, \omega_2)\}}{\omega' - \omega_1}\, d\omega' \qquad [16]$$

The above dispersion relation for $\chi^{(3)}$ was obtained using the physical and intuitive arguments that followed the linearization scheme depicted in Figure 1. General dispersion relations can be formulated following a mathematical procedure that is similar to the derivation of the linear KK relations. In this case we apply the causality condition directly to the nth-order nonlinear response $R^{(n)}$. For example, without loss of generality, we can write

$$R^{(n)}(\tau_1, \tau_2, \ldots, \tau_n) = R^{(n)}(\tau_1, \tau_2, \ldots, \tau_n)\Theta(\tau_j) \qquad [17]$$

and then calculate the Fourier transform of this equation. Here j can apply to any one of the indices $1, 2, \ldots, n$. Following the same procedure as for a linear response, we obtain

$$\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega_j, \ldots, \omega_n) = \frac{-i}{\pi}\wp\int_{-\infty}^{\infty} \frac{\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega', \ldots, \omega_n)}{\omega_j - \omega'} d\omega' \qquad [18]$$

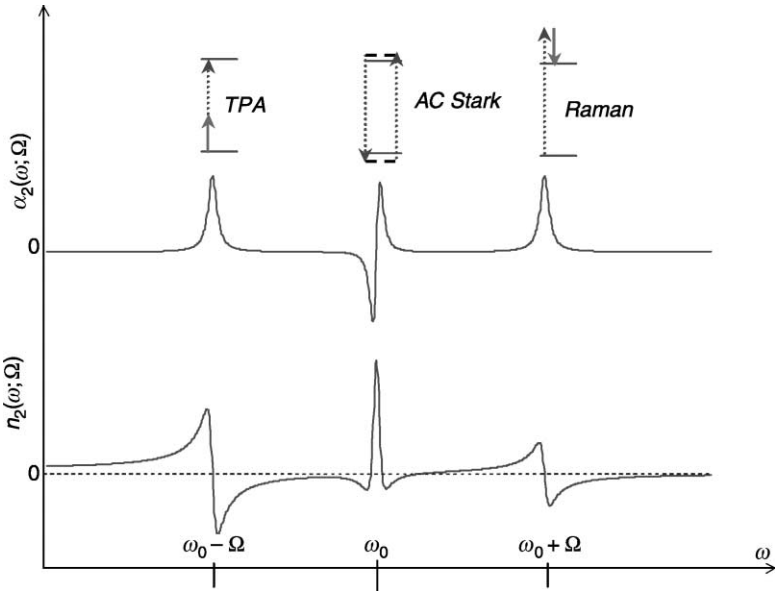

Figure 2 Upper trace: the nonlinear absorption coefficient in a fictitious 'degenerate' two-level system. Lower trace: the resulting nonlinear refractive index obtained using the KK relations. The insets show the three possible physical mechanisms involved.

By separating the real and imaginary parts of this equation, we get the generalized Kramers–Krönig relation pairs for a nondegenerate, nth-order nonlinear susceptibility:

$$\Re e\{\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega_j, \ldots, \omega_n)\} = \frac{1}{\pi}\wp\int_{-\infty}^{\infty}\frac{\Im m\{\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega', \ldots, \omega_n)\}}{\omega' - \omega_j}\mathrm{d}\omega' \quad [19]$$

and

$$\Im m\{\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega_j, \ldots, \omega_n)\} = -\frac{1}{\pi}\wp\int_{-\infty}^{\infty}\frac{\Re e\{\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega', \ldots, \omega_n)\}}{\omega' - \omega_j}\mathrm{d}\omega' \quad [20]$$

In particular, for $\chi^{(3)}$ processes having $\omega_1 = \omega_a, \omega_2\omega_b$, and ${}_3b$, this becomes identical to eqn [16].

Note that in describing the nonlinear susceptibilities, no special attention was given to the harmonic generating susceptibility $\chi^{(N)}(N\omega) \equiv \chi^{(N)}(\omega, \omega, \ldots\omega)$, i.e., the susceptibility generating the Nth harmonic at $N\omega$. It turns out that in addition to the KK relations given by eqns [19] and [20], the real and imaginary parts of $\chi^{(N)}(N\omega)$ can also be related in different sets of dispersion integrals that involve only the degenerate forms of the susceptibilities. A more general yet simple analysis gives the most general form of KK relations for any type of $\chi^{(n)}$:

$$\chi^{(n)}(\omega_1 + p_1\omega, \omega_2 + p_2\omega, \ldots, \omega_m + p_m\omega) = \frac{1}{\mathrm{i}\pi}\wp\int_{-\infty}^{\infty}\frac{\chi^{(n)}(\omega_1 + p_1\Omega, \omega_2 + p_2\Omega, \ldots, \omega_m + p_m\Omega)}{\Omega - \omega}\mathrm{d}\Omega \quad [21]$$

for all $p_1, p_2, \ldots, p_m \geq 0$. Setting $\omega_1 = \omega_2 = \cdots = \omega_m \equiv 0$, and $p_1 = p_2 = \cdots = p_m = 1$ in eqn [21] yields an interesting form of the KK relations for the Nth-harmonic susceptibilities:

$$\Re e\{\chi^{(N)}(N\omega)\} = \frac{1}{\pi}\wp\int_{-\infty}^{\infty}\frac{\Im m\{\chi^{(N)}(N\omega')\}}{\omega' - \omega}\mathrm{d}\omega' \quad [22]$$

These dispersion relations have allowed calculations of $\chi^{(2)}(2\omega)$ and $\chi^{(3)}(3\omega)$ in semiconductors using full band structures.

At the beginning of this article, it was noted that all the KK relations for nonlinear optics were known in the early days of the field. Their application in unifying nonlinear absorption (in particular two-photon absorption) and the optical Kerr effect (n_2) in solids came only much later. More recent work demonstrated that the KK relations are a powerful analytical tool in nonlinear optics. Following the picture of a degenerate two-level system shown in Figure 2, a simple two-band model has been used to calculate the nonlinear absorption coefficient, $\alpha_2(\omega_1; \omega_2)$, resulting from three mechanisms: 2PA, the Raman absorption process, and the ac Stark effect. The optical Kerr coefficient $n_2(\omega_1; \omega_2)$ was then calculated using eqn [15]. Of particular practical interest is the degenerate case ($\omega_1 = \omega_2 = \omega$), from which the 2PA coefficient $\beta(\omega) = \alpha_2(\omega; \omega)$ can be extracted. Figure 3 depicts the calculated dispersion of n_2 and β as a function of $\hbar\omega/E_g$ where E_g is the bandgap energy of the solid. The dispersion of n_2 and its sign reversal shown in Figure 3 has been observed experimentally in many optical solids.

Finally, let us discuss a related implication of causality in nonlinear optics. The KK dispersion relations are traditionally derived in terms of internal material parameters such as susceptibility, absorption coefficient, and refractive index. Similar to the case of electrical circuits, one can obtain dispersion relations that apply to an external transfer function of the system that relates an input signal to an output signal. In this case, the dispersion of the transfer function includes system structure as well as the intrinsic dispersion of the material. As an optical (and linear) example, consider a Fabry–Perot etalon. The optical transmission of this system has well-known spectral

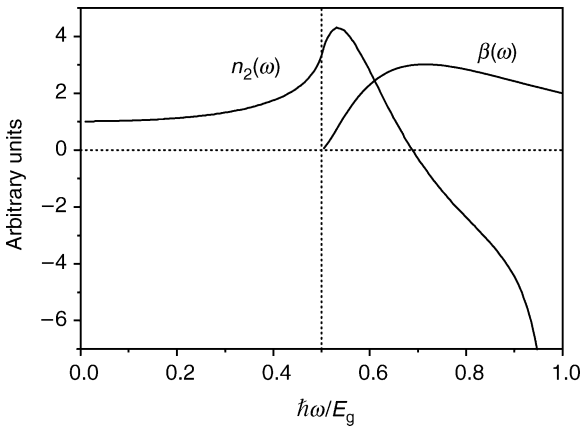

Figure 3 The two-photon absorption coefficient in semiconductors (β) calculated for a two-band model. The resultant nonlinear refractive index (n_2) obtained using a KK transformation of the calculated nondegenerate nonlinear absorption coefficient includes all major mechanisms.

features that are primarily caused by structural dispersion (i.e., interference) in addition to the intrinsic dispersion of the material. Causality still demands that the transmitted signal has a phase variation whose value and dispersion can be determined using a KK relation linking the real and imaginary parts of the transmission coefficient. In other words, the KK relations provide a spectral correlation between the real and imaginary components of the transfer function which in turn may translate to a spectral correlation between the phase and amplitude of the transmitted signal. However, the variations in phase do not necessarily imply the presence of a varying index of refraction, nor does an amplitude variation suggest the existence of material absorption (dissipation). Ultimately, this implies that any mechanism causing a variation in amplitude (including reflection, scattering, or absorption) must be accompanied by a phase variation. (One should note that the reverse of the previous statement is not necessarily true; i.e., a variation in phase does not have to be accompanied by an amplitude modulation.)

In nonlinear optics with the 'black box' approach of Figure 1, the optical perturbation ξ (with frequency Ω) can render an amplitude variation in the probe (at ω) using various frequency mixing schemes in a noncentrosymmetric material (i.e., with nonzero $\chi^{(2)}$). For instance, the probe at ω can be depleted by nonlinear conversion to $\omega_{\text{sum}} = \omega + \Omega$ via sum-frequency generation involving $\chi^{(2)}(\omega, \Omega)$ and/or to $\omega_{\text{diff}} = \omega - \Omega$ via difference-frequency generation involving $\chi^{(2)}(\omega, -\Omega)$. Such a conversion (or depletion) should be accompanied by a phase variation according to the KK dispersion relations. This type of nonlinear phase modulation is known as a $\chi^{(2)}{:}\chi^{(2)}$ cascaded nonlinearity. Such cascaded processes are routinely (and more simply) analyzed with Maxwell's equations governing the propagation of beams in a second-order nonlinear material. The KK relations, however, provide an interesting physical perspective of the process. We find that cascaded second-order nonlinearities are yet another manifestation of causality in nonlinear optics.

List of Units and Nomenclature

α	linear absorption coefficient
α_2	nonlinear absorption coefficient
β	two-photon absorption coefficient
$\chi^{(n)}$	nth-order nonlinear optical susceptibility
n	linear refractive index
n_2	nonlinear refractive index coefficient, coefficient of optical Kerr effect
$\Theta(t)$	step function
$\wp$	principal value
2PA	two-photon absorption
KK relations	Kramers–Krönig relations

Nomenclature Associated with the Excitation Light

Particular care must be used when characterizing the excitation beam in nonlinear optical experiments compared to linear measurements. By definition, nonlinear optical phenomena depend on the electric field to high order. The higher the order, the more sensitive the observed behavior depends on the input. Extracting a representative nonlinear coefficient from an experiment, for example, becomes progressively more difficult as the order of the optical nonlinearity increases. In other words: the errors associated with optical beam characterization get magnified by the order of the nonlinearity under study.

There is an extensive nomenclature for characterizing the light (almost always laser light) interacting with the nonlinear optical medium. Different descriptions may be used depending on whether the excitation light is pulsed, continuous, or a continuous train of pulses. When a laser beam is constant or continuous, it is often described by its 'cw power'. 'Cw' stands for 'continuous wave', an acronym taken from the nomenclature of electronics. The cw power of a laser is determined by placing a power meter in the path of a beam. Repetitively pulsed lasers can be characterized in the same way, provided the response time of the power meter is slower than the pulse separation period. This will almost certainly be the case with a continuously pumped mode-locked laser such as a dye laser, fiber laser, or Ti:sapphire laser, which produce pulses at repetition frequencies of tens of megahertz. Cw power may also be suitable for describing pulsed flashlamp lasers, gas discharge lasers, or any laser that is excited in a periodic fashion.

When the optical output can be distinguished as individual pulses, additional metrics are used. A pulse, by definition, exists during a window of time, i.e., there is a time when light is present and a time when light is absent. How one characterizes the time light is present – the pulse duration – is critically important and not always obvious. There are a myriad of ways the pulse temporal envelope can manifest itself; common examples include square pulses, triangular pulses, Gaussian pulses, and hyperbolic secant pulses. These names refer to the mathematical waveforms that map the pulse envelope as a function of time.

A pulse waveform that exhibits symmetry about the peak in its temporal envelope is commonly characterized by its 'full-width, half-maximum', abbreviated FWHM. One obtains the full-width, half-maximum by locating the two points on the pulse profile that are at half the peak value. The temporal separation of these two points is the FWHM. One uses this measure because in a strict mathematical sense, waveforms such as the Gaussian or hyperbolic-secant exist even at times $t = \pm\infty$. A less common term is the 'half-width, half-maximum' or HWHM. As the name implies, the HWHM is exactly half the FWHM value. Not all light-pulses are temporally symmetric, however, so greater detail may be needed when giving a mathematical description of asymmetric pulses.

Light pulses are also characterized by their energy and peak power. The temporal envelope recorded by a so-called square-law detector (all laboratory detectors are square-law detectors) shows the power of the pulse as a function of time, provided the detector response time is sufficiently fast. Integrating this waveform gives the pulse energy. It makes no sense to talk about the energy of a cw beam of light, unless that beam is composed of repetitive, distinguishable pulses. Each pulse in the train carries a distinct amount of optical energy.

'Ultrafast' or 'ultrashort' laser pulses generally refer to light pulses that are of such small duration they cannot be measured directly with detectors and oscilloscopes because of bandwidth limitations. To infer the pulse duration, so-called intensity autocorrelation measurements are often made. The temporal power profile is then deduced from the autocorrelation signal with the appropriate mathematical conversion factor. Equally important is the spectrum of a short pulse. The optical bandwidth determines the lower limit of temporal compression; such ideally compressed pulses are said to be 'transform limited'. If different components of the spectrum can be distinguished at specific positions on the pulse temporal profile, then the pulse is 'chirped'. Information on the methods of ultrafast laser science can be found in **Ultrafast Laser Techniques:** Generation of Femtosecond Pulses.

Nonlinear optical effects take place when light is concentrated on a target – there is a cross-section or 'footprint' of the beam on the medium.

The interaction of the light and material takes place in a region called the beam area, beam cross-section, focal area, or focal volume. One must then define the appropriate interaction area or volume.

Specification of the beam area allows one to define two important quantities used frequently in nonlinear optics. The power/area is known as irradiance or power density. This quantity is commonly called the intensity, although the strict radiometric definition of intensity is power/(solid angle). The second important quantity is energy/area, which is called the energy density or fluence.

The convention in nonlinear optics is to define the optical electric field as:

$$\mathbf{E}(\mathbf{z}, t) = \frac{1}{2} E_0 \exp[\mathrm{i}(\mathbf{k}\cdot\mathbf{z} - \omega t)] + \text{c.c.} \qquad [1]$$

where E_0 is the peak field, $\mathbf{k}$ is the propagation vector, ω is the angular frequency of the light, and c.c. stands for complex conjugate. This represents a forward- and backward-propagating (in the z-direction) infinite, transverse plane wave. Other definitions are also used. In SI/mks units and using the convention of eqn [1], the irradiance (I in units of W/m^2) inside a material of refractive index n is related to the electric field vector of the light ($\mathbf{E}$ in units of V/m) as follows:

$$I = \frac{1}{2} cn\varepsilon_0 |\mathbf{E}|^2 \qquad [2]$$

Here c is the speed of light (2.998×10^8 m/s) and ε_0 is the permittivity of free space (8.854×10^{-12} F/m). Nonlinear optics has an unfortunate tradition of mixing mks and cgs units, resulting in a lot of confusion. Irradiance is usually expressed in units of W/cm^2. One can calculate the peak electric field (in units of V/cm) of a laser beam given its irradiance (in units of W/cm^2) by using this simple formula:

$$E_0 = 38.82\sqrt{\frac{I}{n}} \left(\frac{\mathrm{V}}{\mathrm{cm}}\right) \qquad [3]$$

The root-mean-square value of the electric field is obtained by replacing the factor 38.82 by 27.45. In Gaussian/cgs units, irradiance is expressed in units of ergs/(cm^2 sec) and is related to the field as:

$$I = \frac{cn}{8\pi} |\mathbf{E}|^2 \qquad [4]$$

where the field is in units of statvolt/cm and $c = 2.998 \times 10^{10}$ cm/sec. Conversion between mks and cgs for the electric field is 3×10^4 V/m = 1 statvolt/cm; irradiance is converted using 1 erg/(cm^{2}sec) = 1×10^{-3}W/m^2. The following point must be emphasized: depending on how the electric field is defined, there can be factors of 2 or even 4 discrepancies in the irradiance values quoted by different authors. The common definitions are used here, although they are certainly not universal.

A very common realization of the spatial irradiance profile of a laser beam is the radially symmetric Gaussian function:

$$I(r) = I_0 \exp\left(-\frac{2r^2}{w^2}\right) \qquad [5]$$

where I_0 is the peak irradiance at the center of the beam ($r = 0$) and w is the 'spot size'. The spot size changes continuously as the beam propagates and the minimum spot size is known as the waist. One often hears the spot size referred to as the radius, but the radius of a Gaussian beam traditionally denotes the curvature of the phase front. By definition, the phase front radius is infinite at the waist. The factor of 2 appearing in the argument of the exponential in eqn [5] stems from the fact that the spot size w is conventionally defined for the electric field of the Gaussian beam. When the field is squared to obtain the irradiance, the factor of 2 appears. Using this function for the irradiance spatial profile leads to the common parameter '1/e^2 diameter'. The irradiance falls to 1/e^2 (0.1353) of its peak value when $r = w$.

The Gaussian spatial profile or 'Gaussian beam' results when the laser has been designed to operate in the lowest-order transverse mode, usually denoted TEM$_{00}$. The TEM$_{00}$ Gaussian beam is particularly convenient because the same relative power profile is maintained in the near- and far-field, whether or not the beam is collimated or focused.

The cross-sectional area of a TEM$_{00}$ Gaussian beam normally incident on a surface is found as follows. The power in the beam is obtained by integrating the irradiance profile (I) over the surface:

$$P = \iint_{\pm\infty} I \mathrm{d}A \qquad [6]$$

Referring to eqn [5], the integral becomes:

$$P = \int_0^{2\pi} \mathrm{d}\theta \int_0^{\infty} r\,\mathrm{d}r\, I_0 \exp\left(-\frac{2r^2}{w^2}\right) = I_0 \frac{\pi w^2}{2} \qquad [7]$$

Hence the effective area of a TEM$_{00}$ Gaussian beam normally incident on a surface is:

$$A = \frac{\pi w^2}{2} \qquad [8]$$

There are many situations where the Gaussian formulation of eqn [5] is not suitable. Beams produced by unstable laser resonators, for example, are not Gaussian. A multitransverse mode beam profile obtained from a stable resonator does not usually lend itself to a simple mathematical characterization.

Nomenclature Associated with the Nonlinear Optical Medium

In nonlinear optics texts, the subject is often introduced by writing the macroscopic polarization in Maxwell's equations as a power series expansion in the electric field. This approach, proposed by Bloembergen and coworkers in the early 1960s, has been spectacularly successful for interpreting experiments, though it has also led to confusion in the definition of nonlinear optical coefficients. The confusion, which stems from arbitrary definitions and nomenclature used by different authors, cannot be resolved here. The reader should, however, be alert for these discrepancies. Comparison of results published by different laboratories requires that the fundamental equations for extracting the nonlinear coefficients from their data are known. As the discipline has matured, the nonlinear optics community largely recognized the ambiguities and confusion; precise definitions of terms and coefficients are now commonly provided in the research literature.

It should also be noted that the power-series framework may not always be the best formulation for modeling and characterizing nonlinear optical effects. A carefully designed optical limiter, for example, may exhibit an abrupt decrease of transmission at a specific 'threshold irradiance' or 'threshold fluence', perhaps at a given laser pulse duration. The physical phenomenon or phenomena driving this behavior may not readily succumb to characterization by an nth-order coefficient in a power series expansion. In this situation it may be appropriate to specify a threshold optical input parameter. Another example is a homogeneously broadened saturable absorber, in which the absorption of an optical medium decreases with increasing input irradiance. The irradiance-dependent absorption coefficient α (refer to eqn [26]) is characterized by a 'saturation irradiance' I_{sat}:

$$\alpha(I) = \frac{\alpha_0}{1 + \dfrac{I}{I_{\text{sat}}}} \qquad [9]$$

where α_0 is the linear absorption coefficient.

Nonlinear Susceptibility

The power-series expansion of the macroscopic polarization is the standard approach for modeling nonlinear optical behavior and categorizing the various phenomena. A common way to write the polarization, nonlinear in the electric field, is (mks units):

$$\mathbf{P} = \varepsilon_0\left(\chi^{(1)}\cdot\mathbf{E} + \chi^{(2)} : \mathbf{EE} + \chi^{(3)}\vdots\mathbf{EEE} + \ldots\right) \qquad [10]$$

where the polarization $\mathbf{P}$ is a time- and space-dependent vector and the terms $\chi^{(n)}$ are the various orders of the nonlinear susceptibility (the cgs equation is obtained by dropping the free-space permitivitty coefficient ε_0). A second-order effect is associated with $\chi^{(2)}$, a third-order with $\chi^{(3)}$, and so on. In general, there are distinguishable electric field vectors (in eqn [10], the fields have not been individually designated for clarity). The susceptibility terms are generally tensors, which means the medium is sensitive to the orientation of the input fields. The dots in eqn [10] indicate tensor products. The input field vectors can have different frequencies and the presence of complex conjugates in eqn [1] indicates that the frequency components will have both + and − signs, i.e. the jth electric field term will have associated frequency factors $\exp(\pm \mathrm{i}\omega_j t)$.

The nomenclature used here can be illustrated by example. In the case of the second-order nonlinear polarization (mks units):

$$\mathbf{P}_j = \varepsilon_0 \chi^{(2)}_{jkl} : \mathbf{E}_k\mathbf{E}_l \qquad [11]$$

Note that subscripts have been introduced. The indices correspond to Cartesian space vectors. This equation says that the polarization in the j-direction results from the tensor product of the appropriate $\chi^{(2)}$ with the input fields at $\mathbf{E}_k$ and $\mathbf{E}_l$. The jth component of polarization has an oscillation frequency that is determined by mixing of the input fields. In this example, the indices j, k and l can each take the value of x, y, and z. Let each input field be at one of two possible frequencies, call them ω_1 and ω_2. There are an enormous number of permutations (81 to be exact) of eqn [11]. One term is:

$$P_x(\omega_1 + \omega_2) = \varepsilon_0 \chi^{(2)}_{xzy}(\omega_1 + \omega_2)E_z(\omega_1)E_y(\omega_2) \times \exp[-\mathrm{i}(\omega_1 + \omega_2)t] \qquad [12]$$

Another possibility is:

$$P_z(\omega_2 - \omega_1) = \varepsilon_0 \chi^{(2)}_{zyx}(\omega_2 - \omega_1)E_y(\omega_2)E_x(-\omega_1) \times \exp[-\mathrm{i}(\omega_2 - \omega_1)t] \qquad [13]$$

Equation [12] corresponds to sum frequency generation ($\omega_1 + \omega_2$) and eqn [13] shows difference frequency generation ($\omega_2 - \omega_1$).

Not explicitly written on the right-hand side of the above equations is the exponential containing the mixing of the propagation vectors. To maximize the nonlinear polarization, which is the source of nonlinear behavior in Maxwell's equations, the vector sum $\sum \mathbf{k}_j$ for *all* the interacting fields should be close to zero. Arranging the propagation vectors to accomplish this is known as 'phase matching'.

It is important to point out that there are eight more terms describing the nonlinear polarization at $P_x(\omega_1 + \omega_2)$ in addition to eqn [12]; likewise for $P_z(\omega_2 - \omega_1)$. Also note that the indices k and l may be identical, hence a nonlinear polarization driven by $\chi^{(2)}_{xyy}$ for example, is allowed. Higher-order nonlinear polarizations get progressively more complicated. The general third-order nonlinear polarization is

$$\mathbf{P}_j = \varepsilon_0 \chi^{(3)}_{jklm} \vdots \mathbf{E}_k \mathbf{E}_l \mathbf{E}_m \qquad [14]$$

Sometimes the second-order nonlinear susceptibility is written with the coefficient d instead of $\chi^{(2)}$. The relation between the d-coefficient and $\chi^{(2)}$ depends arbitrarily on how it is defined; a common definition is

$$d_{jkl} = \frac{1}{2}\chi^{(2)}_{jkl} \qquad [15]$$

but the reader is cautioned that the factor $\frac{1}{2}$ is sometimes missing. In the preceding discussion it was pointed out how there can, in principle, be a large number of tensor components involved in the expansion of the nonlinear polarization. Simplification occurs when it is realized that there is no discernible physical difference between the frequency terms ω_j and $-\omega_j$ and that ordering of the fields in eqn [14] – which suggests a time order in the arrival of the fields – is irrelevant. These symmetry arguments show that $d_{jkl} = d_{jlk}$, which reduces the number of independent d-coefficients from 81 to 18. A simpler subscript notation is then introduced that uses the integers 1–6 to represent pairs of Cartesian components k and l. This reduces the number of subscripts from three to two. An example of this notation is $d_{xzz} = d_{14}$.

In certain situations, one can take advantage of crystal symmetry to further reduce the complicated summations to a single scalar coefficient for the nonlinear susceptibility, which is referred to as 'd-effective'. For these specialized cases, the nonlinear polarization is

$$P = \varepsilon_0 d_{\text{eff}} E_1 E_2 \qquad [16]$$

In SI/mks units, the polarization is in units of coul/m^2. The second-order susceptibility (i.e. $\chi^{(2)}$, d_{jkl}) must therefore have units of m/volt. The units of $\chi^{(3)}$ are m^2/volt^2, $\chi^{(4)}$ is m^3/volt^3, and so on. In Gaussian/cgs units, $\chi^{(2)}$ has dimensions cm/statvolt, $\chi^{(3)}$ will be cm^2/statvolt^2, etc. although sometimes in the Gaussian system *all* the coefficients $\chi^{(n)}$ are discussed with shorthand 'electrostatic units' or 'esu'.

Complex Quantities

In linear optics, the susceptiblity has real and imaginary parts

$$\chi^{(1)} = \chi^{(1)}_{\text{real}} + \mathrm{i}\chi^{(1)}_{\text{imaginary}} \qquad [17]$$

The complex linear index is, in turn, written as the sum of real and imaginary components, derived from the linear susceptibility as follows (mks units):

$$\sqrt{1 + \chi^{(1)}} = n_0 + \mathrm{i}\kappa \qquad [18]$$

where n_0 is the linear refractive index and κ is the imaginary term leading to absorption of light. In general, the nonlinear susceptibilty $\chi^{(n)}$ is also a complex number:

$$\chi^{(n)} = \chi^{(n)}_{\text{real}} + \mathrm{i}\chi^{(n)}_{\text{imaginary}} \qquad [19]$$

As in linear optics, the complex notation is a bookkeeping method that conveniently accounts for what is known as 'resonant enhancement'. Nonlinear optics research has revealed that the nonlinear susceptibility $\chi^{(n)}$ can be a strong function of frequency. Specifically, this quantity will be strongly enhanced when sums and/or differences of the photon energies in the interacting light beams coincide with quantum mechanical energy resonances in the material. When a resonance condition is achieved, $\chi^{(n)}$ will be dominated by its imaginary component. Far from the resonances, $\chi^{(n)}$ behaves more like a real quantity. These complex terms directly enter the wave equations describing how light propagates in a nonlinear medium and are particularly important for $\chi^{(3)}$; the complex quantity $\chi^{(3)}$ determines whether light will be refracted or absorbed and by how much. The real part of $\chi^{(3)}$ drives nonlinear refraction while the imaginary portion characterizes nonlinear absorption (e.g., two-photon absorption) and the inverse effect – gain. This rich subject – in particular the critical importance of the wavelength dependence of the nonlinear phenomena – is considered in **Nonlinear Optics, Basics:** Kramers–Krönig Relations in Nonlinear Optics.

Nonlinear Refraction

The most common manifestation of nonlinear refraction arises from the third-order nonlinear susceptibility, the so-called optical Kerr effect. In this case, the refractive index is linearly proportional to the irradiance (I) of a monochromatic light beam. The irradiance-dependent refractive index is

$$n(I) = n_0 + n_2 I \qquad [20]$$

where n_0 is the linear, irradiance-independent refractive index and n_2 is the nonlinear refractive index coefficient. Because n is a dimensionless quantity, n_2 must be in units of area/power.

The optical Kerr effect is usually written in mks units with the expression shown in eqn [20]. In cgs units, the common (but by no means universal) convention is to write:

$$n(E) = n_0 + \frac{1}{2}\tilde{n}_2|\mathbf{E}|^2 \qquad [21]$$

where the field is in units of statvolts/cm. The nonlinear coefficient $\tilde{n}_2$ (cgs) must therefore be in units of cm^2/statvolt^2, which is sometimes abbreviated to 'esu'. The conversion for n_2 between these two equations is:

$$\tilde{n}_2(\text{cgs}) = \frac{n_0 c}{40\pi} n_2(\text{mks}) \qquad [22]$$

where n_2(mks) is in units of m^2/W and c is in m/sec. Also useful is the relation between n_2 and $\chi^{(3)}$, written in mks units as:

$$\Delta n = n_2 I = \frac{\text{Re}\left(\chi^{(3)}\right)}{4\varepsilon_0 n^2 c} I \qquad [23]$$

where 'Re' denotes the real part of $\chi^{(3)}$. In cgs units we have:

$$\Delta n = \frac{1}{2}\tilde{n}_2|\mathbf{E}|^2 = \frac{4\pi^2 \text{Re}\left(\tilde{\chi}^{(3)}\right)}{n^2 c} I \qquad [24]$$

where I is in units of ergs/(cm^2 sec) defined by eqn [4]. The reader is again advised that different authors will show discrepancies of 2, 4, or even 8 when writing these equations. The susceptibilities $\chi^{(3)}$ are related as follows:

$$\tilde{\chi}^{(3)}(\text{cgs}) = \frac{9 \times 10^8}{4\pi} \chi^{(3)}(\text{mks}) \qquad [25]$$

If the coefficients n_0 and n_2 exist, does the nomenclature imply there are terms n_1, n_3, and others? These coefficients are certainly allowed, but not often seen in discussions of nonlinear refraction. When one refers to nonlinear refraction, the common understanding is that the index depends linearly on irradiance, which is conveniently modeled by eqn [20]. But there are other physically relevant situations to consider. The coefficient n_1, for example, describes the linear electro-optic effect in which the change in index is linearly proportional to the electric field (although it is called the linear electro-optic effect, it is actually derived from the second-order nonlinear susceptibility). The electric field can be the oscillating field of a laser beam, for example, or a dc field applied to an electro-optic crystal (e.g., Pockel's cell). When other terms are added to eqns [20] or [21], the units of the coefficients must be chosen to keep the equation dimensionless.

In the preceding discussion, there is an implication that the nonlinear index is an instantaneous function of the irradiance or field. Although the material system can never respond instantaneously, this is a good approximation in many situations. Sometimes it is not. Consider a pulsed laser beam that heats the material. When the local temperature increases, the linear refractive index can change. A short, Q-switched laser can have a pulse duration far less than a microsecond, while the temperature change it induces can last many orders of magnitude longer. This means optical modification of the refractive index may persist long after the exciting pulse has vanished, i.e., when the irradiance is at zero.

Another example is when a laser beam promotes electrons from their ground state to higher energy states of the material system. These excited electrons may modify the refractive index of the material. In general, the excited electrons remain in high-energy states for some period of time before relaxing to the ground level – if this time is longer than the excitation, the change of the refractive index persists beyond the time the laser beam is present. In these situations, the model of nonlinear refraction suggested by the above equations is inaccurate. One cannot obtain the nonlinear refraction from a simple algebraic analysis. A system of time-dependent equations – describing the dynamics of excitation and relaxation – must be solved using numerical procedures. Such phenomena are sometimes loosely categorized as 'dynamic linear optical effects' or 'effective third-order nonlinearities'.

Nonlinear Absorption

Consider a single-frequency light beam passing through an optically absorbing region of length L.

For simplicity, neglect reflections caused by surfaces that may define the region of interest, i.e., ignore reflections at surfaces that may be located on the optical axis z at points $z = 0$, $z = L$, or any other point in the path. Linear absorption means that the optical power extracted from the light beam as it traverses the absorbing medium is a direct function of the power at a given point. This is described mathematically by an elementary, linear differential equation known as Beer's law:

$$\frac{\mathrm{d}}{\mathrm{d}z} I(z) = -\alpha I(z) \qquad [26]$$

The constant of proportionality is α, which is the linear absorption coefficient. Equation [23] is solved by direct integration:

$$\int_{I(0)}^{I(L)} \frac{\mathrm{d}I}{I} = -\alpha \int_0^L \mathrm{d}z \qquad [27]$$

This has the solution:

$$\frac{I(L)}{I(0)} = \exp(-\alpha L) \qquad [28]$$

which means the irradiance decreases exponentially as a function of propagation distance in a linearly absorbing medium.

In the nonlinear regime, we don't expect a classical Beer's law model to hold. By definition, the absorption will be a nonlinear function of irradiance at a given point. One makes the following power-series expansion to describe nonlinear absorption of monochromatic light:

$$\frac{\mathrm{d}}{\mathrm{d}z} I = -\alpha I - \beta I^2 - \gamma I^3 - \cdots \qquad [29]$$

The coefficient β corresponds to a two-photon absorption process and γ is the coefficient of three-photon absorption. What about four-photon and even higher-order processes? These are rarely encountered, but certainly possible. To make these distinctions, eqn [29] is sometimes written with coefficients K_i or α_i instead of the sequential Greek alphabet:

$$\frac{\mathrm{d}}{\mathrm{d}z} I = -K_1 I - K_2 I^2 - K_3 I^3 - K_4 I^4 - \cdots \qquad [30]$$

The units of the various absorption coefficients must maintain the dimensional consistency of eqns [29] and [30], which is irradiance/length or power/(length)^3. These are shown in Table 1.

If there is linear absorption, the nonlinear processes at that wavelength are often (but not always) negligibly weak. This means we have the following inequalities:

$$K_1 I \gg K_i I^i, \qquad \text{where } i \geq 2 \qquad [31]$$

Nonlinear absorption is generally observed in the wavelength region where the medium is transparent to low-irradiance light, i.e., where linear absorption is negligible. It should be emphasized that there are situations where linear absorption is large and in fact a crucial component of the aggregate nonlinear effect. We will return to this point later in the discussion. For the moment, we neglect linear absorption. If the energy of the incident photons and energy levels of the system permit it, the lowest-order nonlinear process is two-photon absorption, described by the equation

$$\frac{\mathrm{d}}{\mathrm{d}z} I = -K_2 I^2 \qquad [32]$$

which can be solved by elementary integration:

$$\frac{I(L)}{I(0)} = \frac{1}{1 + I(0) K_2 L} \qquad [33]$$

Unfortunately, the situation is rarely this convenient. The above integration has ignored the fact that nonlinear absorption may enable significant linear absorption. This is possible because nonlinear absorption promotes electrons from low- to high-energy states in the medium. The change in excited electron density associated with absorption of light (both linearly and nonlinearly) is called 'photocarrier generation'. These photocarriers (e.g., photo-electrons) may modify the linear absorption as well as the refractive properties of the material. If two-photon absorption causes the linear absorption to increase, for example, the assumption that allowed us to ignore K_1 when writing eqn [32] ceases to be valid. While eqn [32] was appropriate at the very start of the light–matter interaction, the generation of photocarriers after the passage of time may change that condition. The behavior of the system is therefore time-dependent, i.e., it is dynamic. Simple analytic solutions are almost

Table 1 Dimensions of optical absorption coefficients

Process	*Coefficient*	*Units*
Linear absorption	α, K_1	(length)$^{-1}$
Two-photon absorption	β, K_2	length/power
Three-photon absorption	γ, K_3	length^3/power^2
Four-photon absorption	K_4	length^5/power^3

always not possible when dealing with nonlinear absorption.

The time rate of change of the photocarrier population (N) is modeled by the following equation:

$$\frac{\partial}{\partial t}N = \frac{K_1 I}{\hbar\omega} + \frac{K_2 I^2}{2\hbar\omega} + \frac{K_3 I^3}{3\hbar\omega} + \frac{K_4 I^4}{4\hbar\omega} + \cdots - \text{recombination} - \text{diffusion} \quad [34]$$

where ω is the angular frequency ($\omega = 2\pi f$) of the incident light. Also included are place-holders for loss processes such as recombination and diffusion, which may themselves have complicated mathematical descriptions. The coefficients K_i have exactly the same units, dimensions, and interpretation as in eqn [30] and Table 1; in the spirit of the preceding discussion, these coefficients may be time dependent. Note that the dimensions of eqn [30] describe absorption of light (irradiance/length), while eqn [34] models the photocarrier population density (length^{-3} time^{-1}). The units of these two equations are very different.

List of Units and Nomenclature

CARS	Coherent anti-Stokes Raman scattering
c.c.	Complex conjugate
CSRS	Coherent Stokes Raman scattering
DFG	Difference frequency generation
DFM	Difference frequency mixing
DFWM, FWM	(Degenerate) Four wave mixing
DRO	Doubly resonant OPO
EIT	Electromagnetically induced transparency
ESA	Excited state absorption
GVD	Group velocity dispersion
GVM	Group velocity mismatch
NLA	Nonlinear absorption
NLR	Nonlinear refraction
OFID	Optical free-induction decay
OPA	Optical parametric amplification/amplifier
OPG	Optical parametric generation/generator
OPL	Optical power limiter
OPO	Optical parametric oscillation/oscillator
2PA, TPA	Two-photon absorption
PCM	Phase conjugate mirror
QPM	Quasi phase matching
RIKES	Raman-induced Kerr effect spectroscopy
RSA	Reverse saturable absorption
SBS	Stimulated Brillouin scattering
SFG	Sum frequency generation
SHG	Second harmonic generation
SIT	Self-induced transparency
SRO	Singly resonant OPO
SRS	Stimulated Raman scattering
SRWS	Stimulated Rayleigh wing scattering
SVEA, SVAA	Slowly varying envelope (amplitude) approximation
THG	Third harmonic generation
TPF	Two-photon fluorescence

Nonlinear Optical Phase Conjugation

B Y Zeldovich, University of Central Florida, Orlando, FL, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Phase conjugation (PC) beams and their applications are best illustrated by Figure 1, which shows the passage of a coherent planewave incident upon a transparent optical element with inhomogeneities of refractive index (Figure 1a). Reversibility of light propagation implies the existence of such an 'anti-distorted' beam, which reverts back to a planewave after reversing through the same inhomogeneities (Figure 1b). A real-valued monochromatic optical wave, $E_{\text{real}}(\mathbf{R},t)$, may be represented by the complex amplitude $E(\mathbf{R})$ via $E_{\text{real}}(\mathbf{R},t) = 0.5[E(\mathbf{R})\exp(-i\omega t) + E^*(\mathbf{R})\exp(i\omega t)]$, where $E^*(\mathbf{R})$ represents the complex conjugate of $E(\mathbf{R})$:

$$E(\mathbf{R}) = |E(\mathbf{R})|\exp[i\varphi(\mathbf{R})]$$
$$E^*(\mathbf{R}) = |E(\mathbf{R})|\exp[-i\varphi(\mathbf{R})] \qquad [1]$$

Mathematical expression of time-reversal, $E_{\text{real}}(\mathbf{R},t) \rightarrow E_{\text{real}}(\mathbf{R},-t)$, becomes the exchange $E(\mathbf{R}) \leftrightarrow E^*(\mathbf{R})$ for monochromatic waves. The reversibility of propagation means that the complex propagating field $E(\mathbf{R})$ (for example, planewave $\exp(i\mathbf{k}\cdot\mathbf{R})$), is a wave equation solution equivalent to $E^*(\mathbf{R})$ (in this example, $\exp(-i\mathbf{k}\cdot\mathbf{R})$). Conjugation of complex amplitude means reversal of the sign of the phase, and a mixed label PC has been coined and nowadays is firmly established. Terms such as 'wave front reversal' and 'generation of time-reversed replica of the beam' are also used to describe PC.

Figure 1 also illustrates one of the most important applications of PC. If the element in question is a laser-type amplifier, then double-passage allows the extraction of energy from the optically inhomogeneous laser medium in the form of a perfectly collimated beam of diffraction-limited divergence. A PC device may also serve as a mirror of a laser resonator, resulting in the same beam-correction purpose.

One of the most practical and robust methods of PC is based on stimulated Brillouin back-scattering (SBS). The incident beam illuminates the SBS-active transparent medium, for example, liquids (CS_2, CCl_4, acetone, etc.), compressed gases (CH_4, SF_6, etc.), or solids (fused or crystalline quartz, glass, etc.). This 'pump' beam, $E(\mathbf{R}) \equiv E(\mathbf{r},z)$, must possess well-developed transverse inhomogeneities of intensity $|E(\mathbf{r},z)|^2$. Here, $\mathbf{r} = \{x,y\}$ is the part of coordinate vector transverse with respect to the central direction z of the beam in question, and $\mathbf{R} = \{\mathbf{r},z\}$. These inhomogeneities may constitute a narrow focal waist in the case of weakly distorted focused beams, speckle-inhomogeneities in cases of strong distortions, or a combination thereof; see Figure 2, where solid lines symbolize the 'rays' of the incident pump.

Spontaneous scattering of the pump results in a multitude of possible transverse profiles $S(\mathbf{r}, z=0)$ of the signal, whose 'rays' are depicted via the dotted lines on Figure 2. The signal is amplified exponentially due to SBS processes. This exponent in a simplified form may be represented as $|S(\mathbf{r},z)|^2 \propto \exp(\int g dz)$, with the gain $g(z)$ being the result of transverse overlapping of the intensity profiles of signal and pump:

$$g(z) \approx \text{const} \cdot \langle |E(\mathbf{r},z)|^2 \cdot |S(\mathbf{r},z)|^2 \rangle / \langle |S(\mathbf{r},z)|^2 \rangle \qquad [2]$$

Thus, the similarity of the intensity profile of the signal to that of the pump is rewarded by the exponential preference in the output signal level. However, this is not enough to guarantee that the output backward-scattered signal $S(\mathbf{r},z)$ is phase

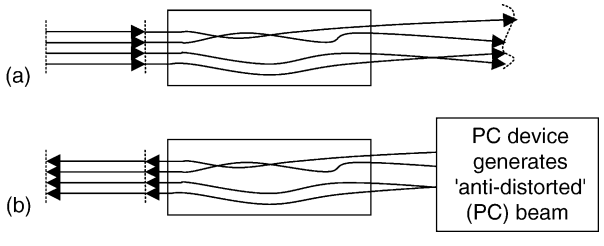

Figure 1 (a) Collimated beam is distorted by propagation through inhomogeneous medium. (b) Conjugate, a.k.a. antidistorted beam becomes collimated after backward passage through the same medium.

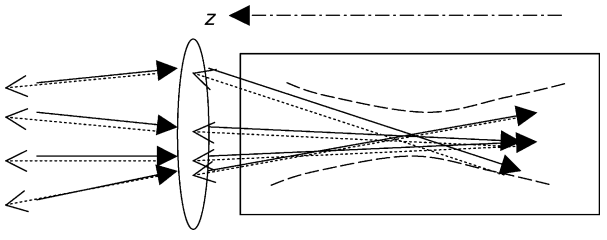

Figure 2 Stimulated Brillouin Scattering (SBS) method of PC. Solid lines symbolize the rays of incident 'beam', while dotted lines depict the rays of the signal amplified by the SBS process.

conjugate with respect to the pump. It is here that the mutual reversibility of propagation of strongly inhomogeneous signal and pump becomes crucial. Namely, good transverse overlapping is sustained along the entire interaction length z, only if $S(\mathbf{r}, z) \propto E^*(\mathbf{r}, z)$. This constitutes the 'discrimination mechanism' of SBS-PC: the 'conjugate mode' of the signal has a z-sustained advantage in exponential gain and, under appropriate conditions, suppresses all nonconjugate signal configurations in competition for pump power. Nonlinear-optical wave theory of this discrimination process has been developed further.

The holographic mechanism of PC has a different nature. It may take the form of static holography or dynamic holography; the latter essentially may be considered as a part of nonlinear optics. Here is a simplified description of one of the variants. Suppose one wants to obtain a conjugate replica of the incident monochromatic signal, whose complex profile is $S(\mathbf{R})$. A plane reference wave $A(\mathbf{R}) = \exp(i\mathbf{k}_A \cdot \mathbf{R})$ is also directed to the registering medium. If $S(\mathbf{R})$ and $A(\mathbf{R})$ are mutually coherent, then an interference pattern of intensity is produced $\{S^*(\mathbf{R})A(\mathbf{R}) + \text{compl. conj.}\}$. The medium records this pattern in the form of the modulation of refractive index and/or of the absorption coefficient, $\delta\varepsilon(\mathbf{R}) \propto (c_1 + ic_2)\{S^*(\mathbf{R})A\ (\mathbf{R}) + \text{c.c.}\}$ (Figure 3a). At the 'reconstruction' stage, the hologram is illuminated by another plane reference wave, $B(\mathbf{R}) = B_0 \exp(i\mathbf{k}_B \cdot \mathbf{R})$. In the specific case, when $\mathbf{k}_B = -\mathbf{k}_A$, the source δD_{conj} of the reconstructed wave becomes, as shown by Figure 3b:

$$\delta D_{\text{conj}} = (c_1 + ic_2)[S^*(\mathbf{R})A(\mathbf{R})] \cdot B(\mathbf{R}) \propto S^*(\mathbf{R}) \times (c_1 + ic_2)A_0B_0 \qquad [3]$$

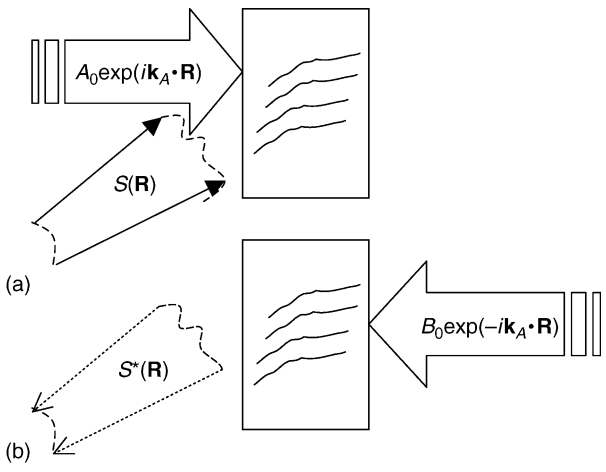

Figure 3 (a) Recording of a hologram in a photosensitive medium by a reference wave A and signal wave S. (b) Read-out of that hologram by the wave B counter-propagating to A results in generation of the conjugated signal S^*.

Reversibility of propagation laws guarantees that this source will indeed excite a conjugate wave with high efficiency. Both processes, recording of the interference pattern and reconstruction of the conjugate wave, may occur simultaneously, if one deals with the dynamic holography. The same process may also be described as nonlinear-optical four-wave mixing (FWM) via cubic nonlinearity $\chi^{(3)}$:

$$\delta D_{\text{conj}}(\mathbf{R}) = \chi^{(3)}S^*(\mathbf{R})A(\mathbf{R})B(\mathbf{R}) = \chi^{(3)}S^*(\mathbf{R})A_0B_0 \qquad [4]$$

with the four waves; A, B, S, S^*.

Important characteristics of a PC device are: fidelity of conjugation, efficiency of returning back-reflected power/energy, and reaction time or build-up time. The fidelity parameter must show how close the output of the device $E_{\text{out}}(\mathbf{r})$ is to the perfectly conjugate profile $S^*(\mathbf{R})$ of the incident signal (up to an arbitrary constant complex factor). Among other definitions, the square modulus of the normalized transverse overlapping integral of the fields is often discussed:

$$f = \frac{|\iint E_{\text{out}}(x, y)S(x, y)\mathrm{d}x\mathrm{d}y|^2}{\left(\iint |E_{\text{out}}(x, y)|^2\mathrm{d}x\mathrm{d}y \cdot \iint |S(x, y)|^2\mathrm{d}x\mathrm{d}y\right)} \qquad [5]$$

To achieve good (close to 1) fidelity of PC in the holographic or FWM scheme, one has to guarantee that the reference waves, $A_0 \exp(i\mathbf{k}_A \cdot \mathbf{R})$ and $B_0 \exp(i\mathbf{k}_B \cdot \mathbf{R})$, are exactly conjugate to each other, $\mathbf{k}_A = -\mathbf{k}_B$. That, in turn, requires the absence of any distortions in the holographic or nonlinear medium. To the contrary, there are very modest requirements on the phase inhomogeneities of the medium in the SBS scheme of PC, and for that reason it is usually labeled as a scheme of self-phase conjugation.

A hybrid scheme, Brillouin-assisted FWM, has been suggested and implemented, where mutually conjugate reference waves are produced via SBS-PC, while FWM, in a separate medium, exploits SBS nonlinearity. This scheme has produced extremely high, up to about 10^{10}, reflectivity, accompanied by an extremely low-noise detection of incoming signals.

A number of other PC schemes were first realized with the use of an important class of materials for nonlinear optics: photo-refractive crystals (PRC). These are crystals where ionization of the dopants by the incident light creates interference pattern of charge separation. The linear electro-optic (Pockels) effect transforms the resulting patterns of the electrostatic field into patterns of refractive index, thus creating dynamic holograms. A remarkable property of these crystals is that most of them act as very good electrical insulators. Therefore, the only source of conductivity, which tends to erase the

hologram, is photoconductivity, the value of the latter being proportional to the intensity of incident light itself. For this reason, the steady-state strength of the hologram turns out to be independent of the intensity. It is the build-up time that must be increased, if intensity is low. One can achieve various processes in PRC, including those similar to the $\chi^{(3)}$-type optical Kerr effect, stimulated scattering, etc.

The simplest use of PRC for generation of PC waves is to devise a FWM scheme (see Figure 3). However, a multitude of other, nontrivial schemes have been devised and implemented. The most impressive use of PRC for PC is based on interactions of the beams in the vicinity of a corner of a rectangular crystal, typically $BaTiO_3$, these interactions being of the stimulated scattering type. To honor J. Feinberg's cat, whose image was reconstructed in the first demonstration, this scheme is universally called 'cat conjugator'. It turned out to be a very reliable and robust scheme of self-phase-conjugation (SPC).

Another important group of the SPC scheme is called 'tail-biting'. One of the variants of the latter is shown in Figure 4. Incident 'pump' wave $A(\mathbf{R})$, whose transverse profile one wants to conjugate, enters the medium, and then is redirected by mirrors back into the same medium, to 'bite itself'. For the purpose of discussion, this redirected pump is labeled as wave $B(\mathbf{R})$ on its second arrival into the medium. Spontaneous scattering results in a seed for the amplification of the wave $C(\mathbf{R})$ via the process of stimulated scattering (SS) $A(\mathbf{R}) \rightarrow C(\mathbf{R})$.

Wave $C(\mathbf{R})$ is also redirected into the medium by the same mirrors, and is labeled as wave $D(\mathbf{R})$ on its second arrival into the medium. Both $C(\mathbf{R})$ and $D(\mathbf{R})$ are depicted in Figure 4 by white arrows. Wave $D(\mathbf{R})$ is also amplified due to the SS process $B(\mathbf{R}) \rightarrow D(\mathbf{R})$.

As it follows from the macroscopic description of SS process, volume gratings of refractive index are recorded in the medium, $\delta n(\mathbf{R}) \propto -i[A^*(\mathbf{R})C(\mathbf{R}) + B^*(\mathbf{R})D(\mathbf{R})]$. Among all the transverse profiles for the seed $C(\mathbf{R})$, the one that happens to be proportional to $B^*(\mathbf{R})$ will be reflected by the mirrors into the medium in the form $D(\mathbf{R}) \propto A^*(\mathbf{R})$. The latter case is again a consequence of the reversibility of propagation laws, where both gratings have the same profile and add coherently in the form $A^*(\mathbf{R})B^*(\mathbf{R})$. What is even more important, the grating $B^*(\mathbf{R})D(\mathbf{R}) \propto B^*(\mathbf{R})A^*(\mathbf{R})$ serves to close the feedback loop for seeding the appropriate $C(\mathbf{R})$. This, and other variants of tail-biting schemes, have also proved to be reliable and robust. Quite often a laser amplifier is inserted in the path $A \rightarrow B$ and $C \rightarrow D$, thus enhancing the feedback.

Another important scheme is traditionally called 'double PC'; albeit it may be better described as 'mutual PC'. Figure 5 should help in understanding that scheme. Consider the beam $A(\mathbf{R})$ incident to a medium active with respect to the stimulated-scattering-type process $A(\mathbf{R}) \rightarrow C(\mathbf{R})$. This process originates from a random seed and results in a fan of different waves $C(\mathbf{R})$. Such a process is characteristic of PRCs and is a consequence of recording dynamic gratings of refractive index $\delta n(\mathbf{R}) \propto -i[A^*(\mathbf{R})C(\mathbf{R})]$. Suppose another beam $B(\mathbf{R})$, typically incoherent with respect to $A(\mathbf{R})$, illuminates the medium from the other side, and also is engaged in the fanning process, this time $B(\mathbf{R}) \rightarrow D(\mathbf{R})$, with the grating of refractive index $\delta n(\mathbf{R}) \propto -i[B^*(\mathbf{R})D(\mathbf{R})]$ involved. Among all the transverse profiles for the seed grating $C(\mathbf{R})A^*(\mathbf{R})$, the one that happens to be proportional to $B^*(\mathbf{R})A^*(\mathbf{R})$ will be supported by similar profiles in the $B(\mathbf{R}) \rightarrow D(\mathbf{R})$ scattering. In this way, two fanning

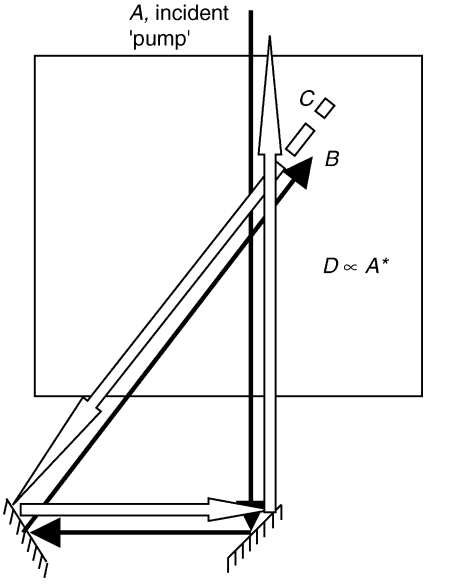

Figure 4 Tail-biting scheme of phase conjugation.

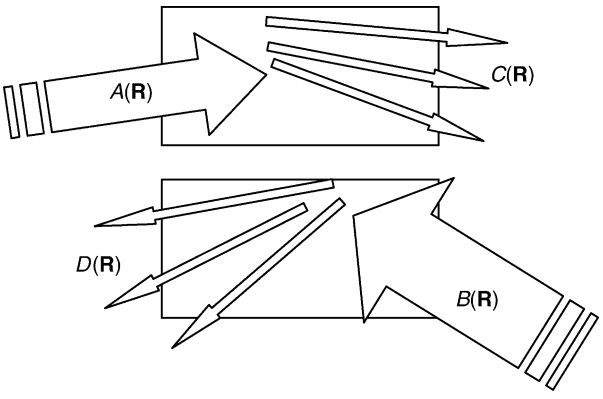

Figure 5 Towards the mechanism of double PC (mutual PC).

processes enhance each other and close the feedback loop. An important consequence is that one obtains the following output waves:

$$C(\mathbf{R}) = \text{const}_1 \times B^*(\mathbf{R})$$
$$D(\mathbf{R}) = \text{const}_2 \times A^*(\mathbf{R}) \qquad [6]$$

One can say that the output wave $C(\mathbf{R})$ presents a conjugate replica of $B(\mathbf{R})$-beam, while the output wave $D(\mathbf{R})$ presents a conjugate replica of $A(\mathbf{R})$-beam; hence the label 'mutual PC'. In some experiments the incident beams, $A(\mathbf{R})$ and $B(\mathbf{R})$, were of somewhat different colors (i.e., from different lasers), or their pulses did not overlap in time in the medium. It is the grating memory that 'informs' one beam about the presence of the other. The mechanism of cat conjugator is considered to be a combination of tail-biting and double PC schemes.

Pumped laser material with saturable gain often serves as an important nonlinear-optical medium for implementing PC. One of the evident advantages is that possible low efficiency of properly nonlinear process may be compensated by the gain in the same piece of material.

Considerable attention is paid nowadays to the chirp reversal of optical pulses that are used in fiber optical communications. Such chirped pulses, $S(t) = \exp(-i\omega_0 t + i\beta t^2/2 - t^2/\tau_1^2)$, with the value of the 'chirp' $\mathrm{d}\omega/\mathrm{d}t = -\beta$ and an increased pulse duration τ_1, arise as a result of propagation in a fiber which possesses group velocity dispersion (GVD). Pulse stretching and chirp are the consequences of different propagation times for the different frequency constituents of the pulse. If some device changes the sign of that chirp, then subsequent propagation of the pulse, through a piece of fiber with the same GVD, restores the duration of the pulse to original shorter value τ_0. A scheme has been suggested to use nonlinear optical FWM in a $\chi^{(3)}$-medium or three-wave mixing (ThWM) in a $\chi^{(2)}$-medium:

$$\delta D_{\text{conj}}(t) = \chi^{(3)} S^*(t) A(t) B(t)$$
$$\delta D_{\text{conj}}(t) = \chi^{(3)} S^*(t) C(t) \qquad [7]$$

Indeed, complex conjugation of the time dependence of the signal's field is equivalent to the change of the chirp sign. The second (ThWM) expression is written assuming that the reference wave $C(t) \propto \exp(-2i\omega_0 t)$, so that is has the frequency double that of the signal. The same process of ThWM has been shown to yield the conjugation of transverse phase profile of the beams, but for a number of reasons it was not applied.

As for the applications of PC, one of them was discussed above (**Figure 1**: double-pass scheme of a laser amplifier). Lasers with one or two PC mirrors, or with more complicated PC scheme, promise generation of high-transverse-quality beams with the use of realistic laser media, the latter inevitably possessing thermal and other distorting inhomogeneities. Another important potential application is free-space optical communications: Earth–Earth or Earth–satellite through atmosphere, or satellite–satellite communications. An 'interrogating' beam may be sent in one direction through an imperfect optical system and/or through turbulent atmosphere. Conjugation of transverse profile of the 'interrogating' beam at the other end of the communication link leads to an almost perfect redirection of the reflected beam towards the 'beacon' source, while time modulation may carry the information.

Readout of information data from a holographic storage is almost always performed in the regime of reading the conjugate wave, since it corrects for the most part of aberrations of optical systems in question.

To conclude, one may use a citation from the two consecutive *Scientific American* popular papers on PC: 'at present the number of applications would seem to be limited only by imagination.'

Reviews of various aspects of phase conjugation may be found in monographs and *Scientific American* papers listed below. The author of the present article was introduced to PC by his colleague V. V. Ragulskii, and has greatly benefited from collaboration with V. V. Ragulskii and V. V. Shkunov.

Introduction and Basics of the Photorefractive Effect

In 1966 Ashkin and coworkers were pursuing research on optical devices using the electro-optic material lithium niobate. They noticed that the refractive index of lithium niobate would change when it was exposed to laser light, and upset the expected operation of their devices. They called the effect optical damage. Shortly thereafter, Chen, LaMacchia, and Fraser reported on the use of the optical damage effect for holographic data storage. Thus began the field of photorefractive nonlinear optics, which has been used in various applications such as real-time holography, optical data storage, optical image amplification, nondestructive testing, distortion compensation by phase conjugation, pattern recognition, and radar signal processing. Many inorganic and organic materials have been investigated for their photorefractive effects, including ferroelectrics, semiconductors, and sensitized polymers. The most well-known inorganic materials are lithium niobate, bismuth silicon oxide, barium titanate, and strontium barium niobate. Most organic photorefractive materials are based on polymeric photoconductors such as those used in xerography that are doped with electro-active molecules, some plasticizers, and sensitizers.

While in its broadest interpretation, the photorefractive effect occurs whenever light incident on a material causes a refractive index change, one usually applies the term to electro-optic index changes resulting from optically generated space charge fields. Materials that are photorefractive in this sense share the following properties

- high transmission at the operating wavelengths;
- linear electro-optic coefficients or orientational Kerr effects;
- charge carriers that become mobile when optically excited;
- trapping centers for these charge carriers to enable spatially non-uniform redistribution of charge.

Consider two beams from the same laser crossing inside a photorefractive material such as barium titanate. The interference pattern will have bright and dark fringes. Charge carriers are excited where the light is bright, then drift and diffuse to regions of relative darkness where they preferentially recombine into trapping centers. In this way, a net excess charge develops in the dark regions, and a net deficit of charge develops in the bright regions. The spatially varying charge distribution has an electric field associated with it and this electric field causes a spatially varying refractive index profile. Because the space charge, its field, and resulting refractive index have the same spatial periodicity as the original interference pattern we have a holographic phase grating. The diffraction efficiency of the hologram can easily approach 100% for materials such as barium titanate and strontium barium niobate which have high electro-optic coefficients. Likewise, such high diffraction efficiencies are easily obtained in 100 micrometer-thick photorefractive polymer films.

The Standard Rate Equation Model

The development of photorefractive gratings can be modeled using standard semiconductor rate equations. Figure 1 shows two beams incident

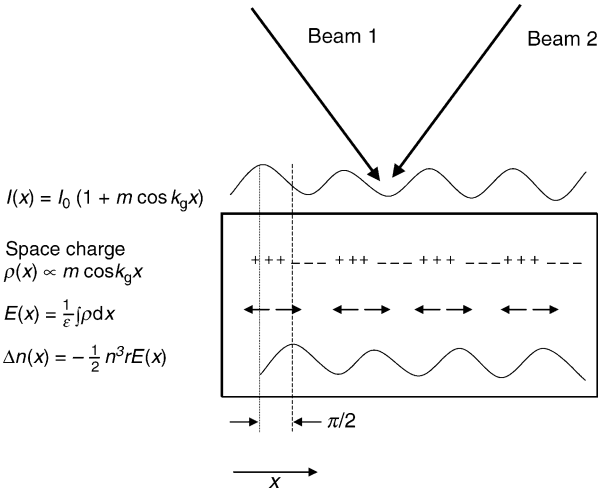

Figure 1 Diagram of two-beam coupling process showing optical interference pattern, space charge, resultant electric field, and $\pi/2$ phase shifted electro-optically induced refractive index grating.

symmetrically on a photorefractive crystal or polymer. They form an interference pattern whose intensity may be written:

$$I(x) = I_0(1 + m\cos(k_g x)) \qquad [1]$$

where x is the direction perpendicular to the interference fringes, I_0 is the average intensity, m is the modulation index, and k_g is the wavenumber of the interference pattern.

The crystal may be considered a wide bandgap semiconductor containing electron donors in the bandgap with density N_D and electron acceptors with density N_A. It is assumed that some electrons ionized from the donors permanently occupy these acceptors so that when charge in the crystal is distributed uniformly in the dark, the number density of ionized donors N_D^i is equal to N_A. Likewise, polymers contain donor and acceptor-like molecules that can be neutral or ionized. The spatially varying light distribution ionizes the donors at the following rate, assuming that $N_D^i \ll N_D$:

$$\frac{\partial N_D^i}{\partial t} = sIN_D - \gamma_R n_e N_D^i \qquad [2]$$

where s is a photoionization coefficient, γ_R is a recombination parameter, and n_e is the density of excited charge carriers, which we assume here to be electrons. The model can easily be generalized to include holes. We also use the equation of charge conservation:

$$\frac{\partial N_D^i}{\partial t} = \frac{\partial n_e}{\partial t} - \frac{1}{e}\nabla\cdot\mathbf{j} \qquad [3]$$

where e is the charge of an electron, and $\mathbf{j}$ is the current in the conduction band.

$$\mathbf{j} = \mu e n_e \mathbf{E} + k_B T \mu \nabla n_e \qquad [4]$$

where μ is the electron mobility, k_B is Boltzmann's constant, and T is the temperature. The electric field obeys Gauss's law:

$$\nabla\cdot\mathbf{E} = -e(n_e + N_A - N_D^i)/\varepsilon \qquad [5]$$

where N_A is the density of acceptors. These equations may be linearized by approximating the electron density, ionized donor density, and electric field with their first Fourier components:

$$\begin{aligned} E &= E_0 + \tfrac{1}{2}(E_1\exp(\mathrm{i}k_g x) + E_1^*\exp(-\mathrm{i}k_g x)) \\ N_D^i &= N_{D0}^i + \tfrac{1}{2}(N_{D1}^i\exp(\mathrm{i}k_g x) + N_{D1}^{i*}\exp(-\mathrm{i}k_g x)) \\ n_e &= n_{e0} + \tfrac{1}{2}(n_{e1}\exp(\mathrm{i}k_g x) + n_{e1}^*\exp(-\mathrm{i}k_g x)) \end{aligned} \qquad [6]$$

This assumption is strictly valid only when the modulation index m is much less than unity. Otherwise, a generalization to higher orders in the Fourier series is required. However, the linearized theory is sufficient to illustrate the most important features of the photorefractive effect. The solution for the space charge field E_1 for the case when the interference pattern is applied at time $t = 0$ is

$$E_1 = m\frac{-\mathrm{i}E_Q(E_0 + \mathrm{i}E_D)}{E_0 + \mathrm{i}(E_D + E_Q)}(1 - \exp(-t/\tau)) \qquad [7]$$

where E_0 is an externally applied or photovoltaic field (if any), E_D is the diffusion field

$$E_D = \frac{k_B T k_g}{e} \qquad [8]$$

and E_Q is the limiting space charge field

$$E_Q = \frac{eN_A}{\varepsilon k_g} \qquad [9]$$

Some photorefractive crystals, most notably $LiNbO_3$, exhibit the photovoltaic effect in which optical illumination induces a dc field across the crystal.

The sinusoidally varying space charge field E_1 operates through the linear electro-optic effect with effective coefficient r to produce a sinusoidal variation in the refractive index n of the crystal:

$$n(x) = n_0 + \tfrac{1}{2}(n_1\exp(\mathrm{i}k_g x) + n_1^*\exp(-\mathrm{i}k_g x)) \qquad [10]$$

where

$$n_1 = -\frac{1}{2} r n_0^3 E_1 \qquad [11]$$

The effective electro-optic coefficient r may be found from tensor analysis of the electro-optic tensor and

the vector space charge and optical fields. Notice that there is a 90-degree phase shift between the interference pattern and the refractive index grating when E_0 is zero. The time constant τ is given by

$$\tau = \frac{N_A}{sN_D I_0}\frac{E_0 + i(E_D + E_\mu)}{E_0 + i(E_D + E_Q)} \quad [12]$$

where E_μ is a mobility field

$$E_\mu = \frac{\gamma_R N_A}{\mu k_g} \quad [13]$$

When E_0 is nonzero, there is an oscillatory component to the time constant.

In contrast to the case of ordinary optical nonlinearities such as the optical Kerr effect, in which the nonlinear coupling strength is proportional to the optical intensity, the steady state strength of the photorefractive effect is independent of optical intensity while the time constant is inversely proportional to intensity in the basic model described above. The time constant varies with the photoconducting performance of a given material. In the fastest polymeric and inorganic materials it is, at the time of writing, of the order of a few milliseconds at 1 W cm^{-2} of incident optical intensity.

At low intensities (below the equivalent dark intensity, 1 W cm^{-2} in barium titanate), the above equations need to be modified to include the effect of dark conductivity. Even in the dark, there will be a few mobile charge carriers in the conduction band that tend to erase the grating. This will result in the effect appearing more Kerr-like, except still with the 90-degree phase shift between the index grating and the interference pattern.

Coupled Wave Equations

The change in refractive index n_1 can be large enough to produce substantial interactions between the writing beams. The writing beams generate a phase grating that diffracts the beams into each other. The grating influences the writing beams, which in turn influence the grating. In the cases where the diffusion field dominates, for example when the externally applied or photovoltaic field E_0 is absent, one beam is amplified by in-phase diffraction of the other beam from the grating. As shown in Figure 2, this amplification results from a 90-degree phase shift due to diffraction from a phase grating coupled with a -90-degree phase shift from the spatial phase shift between the interference pattern and the index grating. The second beam is attenuated by destructive interference with the first beam diffracted by the

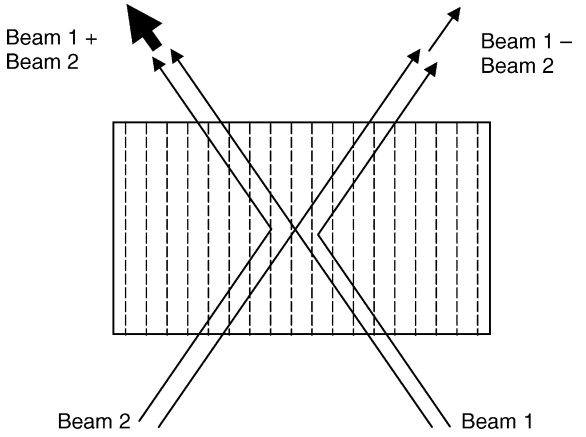

Figure 2 Two-beam coupling amplification. Beam 1 is amplified by constructive interference. Beam 2 is de-amplified by destructive interference.

grating. These interactions can be modeled by standard coupled wave theory. Let the electric field amplitude associated with the jth beam be

$$\mathbf{E}_j(\mathbf{r}, t) = \mathbf{e}\Big[A_j(\mathbf{r})\exp(i(\mathbf{k}_j \cdot \mathbf{r} - \omega t) + A_j^* \exp(-i(\mathbf{k}_j \cdot \mathbf{r} - \omega t))\Big] \quad [14]$$

where $\mathbf{e}$ is the polarization unit vector. Using the scalar wave equation

$$\nabla^2 \mathbf{E} + k^2 \mathbf{E} = 0 \quad [15]$$

and the slowly varying envelope approximation

$$\left|\frac{d^2 A_j}{dz^2}\right| \ll k\left|\frac{dA_j}{dz}\right| \quad [16]$$

we find

$$\frac{dA_1}{dz} = +\gamma\frac{A_1|A_2|^2}{I_0}$$
$$\frac{dA_2^*}{dz} = -\gamma\frac{A_2^*|A_1|^2}{I_0} \quad [17]$$

with the coupling constant γ given by

$$\gamma = -\frac{i\omega\Delta n_m}{c\cos\vartheta} \quad [18]$$

where ϑ is the half-angle between the writing beams and Δn_m is given by

$$\Delta n_m = -\frac{1}{2}n_0^3 r\frac{E_1}{m} \quad [19]$$

Equation [17] shows that beam 1 is amplified and beam 2 is attenuated. That beam 1 is amplified

instead of beam 2 is a result of the choice of crystal orientation and hence the sign of γ. These nonlinear equations can be solved for normalized intensity $I_j = |A_j|^2$:

$$I_1(z) = \frac{I_0}{1 + (I_2(0)/I_1(0))\exp(+\Gamma z)}$$
$$I_2(z) = \frac{I_0}{1 + (I_1(0)/I_2(0))\exp(-\Gamma z)} \quad [20]$$

where $\Gamma = \gamma + \gamma^*$ is the intensity coupling constant. In the limit where $I_1 \ll I_2$, the weak beam, beam 1, experiences exponential amplification. This amplification can be used to build optical oscillators with many of the same properties as conventional laser oscillators. The solution can be generalized to the case where γ has an imaginary component due to an applied or photovoltaic field E_0. Linear absorption can also be included.

Materials

Photorefractive materials may be separated into two broad classes: inorganic and organic. The first materials investigated were inorganic oxides and semiconductors. Their success led to efforts to endow more easily produced organic materials with the required photoconductivity, charge trapping centers, and electro-optic coefficients.

Inorganic Materials

The first requirement in a classic photorefractive material is a linear electro-optic coefficient, such as appears in sillenites such as bismuth silicon oxide $Bi_{12}SiO_{20}$ and bismuth germanium oxide $Bi_{12}GeO_{20}$. These were some of the first photorefractive materials used for image processing and phase conjugation applications. However, their electro-optic coefficients (a few pm/V) are not large enough to easily give rise to large diffraction efficiencies, or to photorefractive oscillators. Materials at a temperature near a phase transition generally have higher electro-optic coefficients because their crystal structures are on the verge of changing. They are extremely susceptible to the effect of any external influence such as the application of electric fields including photorefractive space charge fields. That is why ferroelectric materials are good candidates for photorefractive materials. These include barium titanate $BaTiO_3$, potassium niobate $KNbO_3$, and strontium barium niobate $Sr_xBa_{1-x}Nb_2O_6$. The mean free path of charge transport is less than that in sillenites, so they require more photons to reach a steady state. Therefore, ferroelectric materials are typically less sensitive than sillenites.

The second requirement is for photoconductivity. This requires the existence of photoexcitable charge carriers, either from valence band to conduction band or from intraband trapping centers. The latter source of photocarriers is used most often because the absorption length of light whose energy is greater than the bandgap is usually only a few micrometers. This places a severe restriction on the beams' interaction length ℓ. Thus there has been considerable research on suitable dopants, most commonly Fe^{2+} and Fe^{3+}. These dopants also act as trapping centers.

Lithium niobate is an example of a material with a large photovoltaic effect. When illuminated, this crystal develops a large dc field, which acts to enhance the grating strength. In those cases where the photorefractive effect is not wanted, such as in the design of lithium niobate waveguide devices, the photovoltaic effect can be greatly diminished by the addition of MgO to the crystal melt during growth.

For photorefractivity in the near infrared, semiconductors such as gallium arsenide and indium phosphide have been used with success. These materials also have the advantage that they can be grown in layered structures to produce, for example, multiple quantum wells that can be used to tailor the characteristics of optical excitation and charge transport.

Organic Materials

First-generation photorefractive polymers were designed to mimic the properties of their inorganic counterparts. Owing to their rich structural flexibility, organic synthetic materials with suitable charge transport, trapping, linear electro-optic effects and low optical absorption, were developed. This approach did build on the know-how developed previously in making photoconducting polymers for xerography and electro-optic polymers for optical modulation. Current polymers are based on an orientational photorefractive effect that leads to higher refractive index changes compared with traditional photorefractive materials. In materials with orientational photorefractivity, the refractive index change is produced by the field induced reorientation of anisotropic conjugated molecules that possess a permanent dipole moment and that have a high polarizability anisotropy. The photorefractive space charge field together with the applied field will periodically reorient these molecules and produce a periodic refractive index modulation through an orientational Kerr effect. The build-up and dynamics of this space-charge field are similar to

those of traditional photorefractive crystals and can be described by eqns [2]–[7]. The time constant of the hologram is a convolution of the build-up time of the space-charge and the orientational diffusion time of the dipolar molecules in the total electric field. In contrast to crystals, polymers are nearly amorphous and the transport properties are described by charge hopping processes instead of band-type transport in crystals. Consequently, the photoconducting properties of polymers are strongly field dependent and photorefractivity is mainly observed under strong applied voltages. Numerous polymer composites have been developed using the hole transport polymer poly(N-vinylcarbazole). Several materials with a refractive index modulation amplitude of the order of a percent and two-beam coupling constants $\gamma > 100\ \mathrm{cm}^{-1}$ have been reported. New polymer composites are continuously being tested. Photorefractivity is also studied in other organic materials including organic crystals, liquid crystals, nanocomposites such as polymer-dispersed liquid crystals, or hybrid materials such as sol-gels.

Applications

Holographic Data Storage

Holographic data storage takes advantage of the Bragg selectivity of thick gratings. This allows many holograms to be superimposed in the same small volume, typically of the order of one cubic centimeter. A page of data is displayed on a spatial light modulator and a laser beam passing through the modulator is holographically recorded in the crystal with a reference beam at a specific angle. Many pages of data can be superimposed by recording many holograms with angularly multiplexed reference beams. Other multiplexing schemes are implemented by changing the shape of the wavefront of the reference beam. In principle, the upper limit of recording density is determined by the wavelength of light: one bit per cubic wavelength. If the recording wavelength is 0.5 μm, then one cubic centimeter can contain 1000 gigabytes of data. In practical circumstances, when noise is taken into consideration, the capacity is more realistically of the order of one gigabyte if a 1000×1000 spatial light modulator is used.

Distortion Compensation by Phase Conjugation

Photorefractive materials can be used to make high-reflectivity phase conjugate mirrors. The phase conjugate of a laser beam is produced when a hologram of the beam is read by another beam traveling in the opposite direction to the original reference beam. The phase conjugate reconstruction is a time-reversed copy of the original beam. If the original beam has passed through distorting optics, then the phase conjugate beam will retrace the path of the original beam through the distortion and emerge in its undistorted original state. In the standard nomenclature of phase conjugation, the input beam is called the signal, or probe, and the two reference beams are called the pumps. The output beam at $z = 0$ is called the phase conjugate beam and has zero amplitude at its input at $z = \ell$, where ℓ is the interaction length. Applications for phase conjugation exist, for example, in signal transmission through distortions and laser cavity design. If a phase conjugate mirror is used as a cavity mirror, then the effects of intracavity distortions are removed.

Since the photorefractive gratings can be very strong, the diffraction efficiency of the counterpropagating reference beam can be so high that the phase conjugate reflectivity can exceed unity. The simplest generalization of eqn [17] to the four-wave mixing phase conjugation case is when only transmission gratings are important, as occurs in many circumstances depending on the mutual coherence properties of the beams, and the material's properties. The coupled wave equations are

$$\begin{aligned}
\frac{\mathrm{d}A_1}{\mathrm{d}z} &= \gamma\frac{(A_1A_4^* + A_2^*A_3)A_4}{I_0} \\
\frac{\mathrm{d}A_2^*}{\mathrm{d}z} &= \gamma\frac{(A_1A_4^* + A_2^*A_3)A_3^*}{I_0} \\
\frac{\mathrm{d}A_3}{\mathrm{d}z} &= -\gamma\frac{(A_1A_4^* + A_2^*A_3)A_2}{I_0} \\
\frac{\mathrm{d}A_4^*}{\mathrm{d}z} &= -\gamma\frac{(A_1A_4^* + A_2^*A_3)A_1^*}{I_0}
\end{aligned} \qquad [21]$$

In the undepleted pumps approximation, $(I_1, I_2 \gg I_3, I_4)$, the equations become linear and the solution for phase conjugate reflectivity $R = I_3(0)/I_4(0)$ is

$$R = \left|\frac{\sinh[\gamma\ell/2]}{\cosh[(\gamma\ell + \ln r)/2]}\right|^2 \qquad [22]$$

where $r = I_2/I_1$ is the ratio between the intensities of the pumping beams.

The fact that the reflectivity of the phase conjugate mirror can be greater than unity means that we can build an optical oscillator bounded by a regular mirror and a phase conjugate mirror only. Not only does it not require any additional optical gain, but it also compensates for intracavity distortions. The regular mirror can have any shape, provided that it is sufficiently reflective.

Self-pumped Phase Conjugate Mirrors

If a laser beam passes through a crystal placed inside an optical cavity formed by two facing mirrors, light scattered by imperfections in the crystal can be amplified through the photorefractive effect. The cavity provides feedback and optical oscillation can build up. The oscillation beams pump the crystal as a phase conjugate mirror for the incident beam, thus forming a self-pumped phase conjugate mirror. The feedback can even be provided by total internal reflection in the crystal in which case the crystal by itself can become a phase conjugate mirror.

Pattern Recognition and Image Filtering

Photorefractive wave mixing can be used to perform pattern recognition by matched filtering. One example would be to identify a tank in a battlefield scene, another would be to identify all of the occurrences of a particular word on a page of text. Suppose the input beams contain the corresponding pictorial information, such as might be obtained by passing the beams through an image-bearing transparency or spatial light modulator. Equation [21] shows that the source for beam 3 contains a term proportional to the product of the amplitudes of the three input beams. If lenses are placed in the input beams so that the crystal receives the Fourier transforms of those beams, then the output beam at the crystal, beam 3, will be proportional to the product of the Fourier transforms of the input beams 1, 2, and 4. A lens may then be used to perform the inverse Fourier transform of the product of the Fourier transforms of the input beams, producing an output proportional to beam 1 convolved with beam 2 correlated with beam 4. If beam 1 is a point source before its Fourier transforming lens, then it will be a plane wave at the crystal. Beam 3 after inverse Fourier transformation by its lens will be the correlation of beams 4 and 2. For example, suppose we want to find all the occurrences of a particular word, say 'optics' in a given page of text. Then we would make a transparency of the word 'optics' and place that in input beam 4. We would then place an image of the page of text in beam 2. Beam 3 would then contain a field with bright spots at the places containing the word 'optics' in the original text.

The real-time holographic recording properties of photorefractive materials can also be exploited in medical imaging applications by performing time-gated holography. In this method, a hologram is formed by the temporal overlap in the photorefractive sample of a reference pulse and the first-arriving (ballistic photons) light from a stretched image-bearing pulse that has propagated through a scattering medium. The filtering of the useful photons from the scattered ones is achieved by reconstructing the hologram formed with the ballistic photons in a four-wave mixing geometry.

Optical Limiting, the Novelty Filter, and Laser Ultrasonic Inspection

The attenuation of beam 2 in eqn [17] can be used in several applications including optical limiting and novelty filtering. If one wants to protect a sensor from high-intensity laser radiation, then one could split a small portion of the input beam directed at the sensor and use it as beam 1 in a photorefractive recording setup with the input beam acting as beam 2. If the laser intensity is above the equivalent dark intensity such that the optically excited charge density is greater than the thermally excited charge density, the photorefractive effect will be activated and the input beam will be de-amplified by destructive interference with beam 1, thus protecting the sensor. In materials with high gain–length products ($\gamma\ell > 1$), separate provision of beam 1 is unnecessary because light scattered from the input beam by imperfections in the material and other scattering centers will be greatly amplified, often to such an extent that the input beam is almost completely attenuated. This photorefractive amplification of scattered radiation is known as the fanning effect, because the amplified scattered light often appears as a fan, or brush of light, as can be seen in Figure 3. The effect can also be used to make a novelty filter, which transmits only the moving portion of a scene. The crystal is only fast enough to

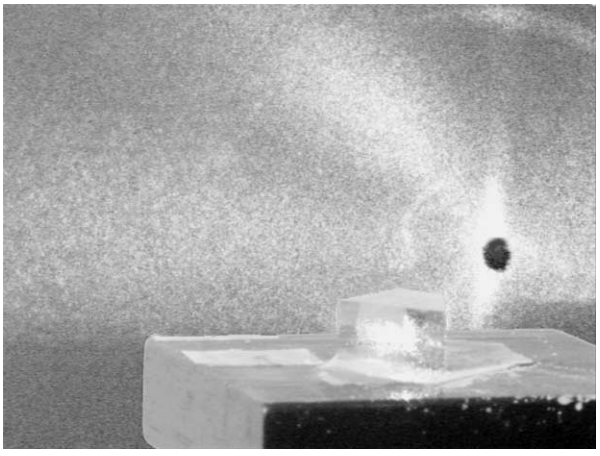

Figure 3 Photorefractive barium titanate exhibiting amplified scattering. A helium neon laser beam is incident from the lower left, passes through the crystal to a screen where it is blacked out to prevent saturation of the camera. The screen shows brushes of amplified scattering, or fanning.

respond to the slowly changing or static components of an image-bearing beam. Since the grating formed is Bragg-matched only to the slow component, the grating will only attenuate that slow component. Any rapidly changing parts of a scene pass through the crystal unattenuated. Such a filter is useful for picking out moving objects in a static cluttered background, for example a tank on a battlefield, or a micro-organism swimming against a stationary background.

A related application is in laser ultrasonic inspection. Defects in industrial material processing such as welding have characteristic ultrasonic signatures. The part under test is pinged by a pulsed laser and a probe laser is reflected from the part. As the part is shaken by the ultrasound, speckle in the reflected beam vibrates. A photorefractive recording is made of the speckle beam. Electrodes are placed on the photorefractive material, so that any optically induced currents can be detected. If the speckle pattern is not moving, or is moving more slowly than the speed of response of the photorefractive material, the photorefractive grating will be essentially at steady state: the drift currents balance the diffusion currents so there is no net current. There is no signal as the part moves through the process line. However, if the speckle beam is moving faster than the response time of the material, it will move photoexcited charge back and forth past the quasistatic grating and generate a net current for detection via the electrodes.

Adaptive Signal Processing

The relatively slow speed of photorefractive devices can be used to advantage in radio-frequency (RF) signal processing, such as signal extraction and coherent combination of signals from antenna arrays. The signal extraction application depends on grating competition in two-beam coupling. Suppose we wish to separate signals on two different RF carrier frequencies ω_1 and ω_2, respectively. The combined signal is applied to an optical carrier beam using a high-speed modulator. The resulting optical field may be represented as

$$S_1(t)\exp(\mathrm{i}\omega_1 t) + S_2(t)\exp(\mathrm{i}\omega_2 t) \qquad [23]$$

It is used to pump a unidirectional ring resonator so that grating competition allows oscillation only on the strongest component of the combined signal, say S_1. The output of the oscillator is proportional to the extracted component S_1. The effectiveness of the intersignal competition is enhanced by placing another photorefractive material in the cavity. A portion of the intracavity beam is picked off by a beamsplitter and used as a two-beam coupling pump in the second material. The crystal is oriented so that the photorefractive grating diffracts the picked-off beam back into the cavity. The return of the picked-off component is most effective for the stronger component S_1 thus decreasing its loss compared to that of the weaker component S_2. This beamsplitter/crystal combination is known as a reflexive coupler.

Photorefractive Solitons

Under favorable conditions, a single beam incident on a photorefractive crystal will induce a positive refractive index change at the center of the beam. This provides a self-focussing tendency that counteracts the beam's divergence due to diffraction. When these two effects balance each other, the beam can propagate with a constant diameter. Such a beam is known as a spatial soliton in analogy with temporal solitons in optical fibers and can occur when there is a component of the photorefractive response due to drift. The drift component of the photorefractive effect appears when a dc field E_0 is applied to the material. Potential applications are optically written waveguides and couplers.

List of Units and Nomenclature

Amplitude gain	$[\mathrm{cm}^{-1}]$	γ
Applied dc field	$[\mathrm{Vm}^{-1}]$	E_0
Current	$[\mathrm{Am}^{-2}]$	$\mathbf{j}$
Dielectric permittivity	[Farads m^{-1}]	ε
Diffusion field	$[\mathrm{Vm}^{-1}]$	E_D
Electron acceptor density	$[\mathrm{m}^{-3}]$	N_A
Electron charge	[C]	e
Electron donor density	$[\mathrm{m}^{-3}]$	N_D
Grating wavenumber	$[\mathrm{m}^{-1}]$	k_g
Intensity gain	$[\mathrm{cm}^{-1}]$	Γ
Interaction length	[cm]	ℓ
Ionized donor density	$[\mathrm{m}^{-3}]$	N_D^i
Limiting space charge field	$[\mathrm{Vm}^{-1}]$	E_Q
Mobility	$[\mathrm{m}^2\,\mathrm{V}^{-1}\,\mathrm{sec}^{-1}]$	μ
Mobility field	$[\mathrm{Vm}^{-1}]$	E_μ
Normalized intensity	$[\mathrm{V}^2\,\mathrm{m}^{-2}]$	I
Photo-ionization coefficient	$[\mathrm{kg}\,\mathrm{sec}^{-2}]$	s
Photorefractive time constant	[sec]	τ
Pump ratio	[1]	r
Radian frequency	$[\mathrm{sec}^{-1}]$	ω
Recombination coefficient	$[\mathrm{m}^3\,\mathrm{sec}^{-1}]$	γ_R
Slowly varying optical electric field	$[\mathrm{Vm}^{-1}]$	A

Introduction

The tremendous development of high-powered femtosecond laser systems since the 1980s, has opened up new areas of research in nonlinear optics, plasma physics, atomic and molecular dynamics, and intense-field physics. For many of these applications, it is important to understand how ultrashort light pulses propagate through a medium under conditions in one or more of the processes in which nonlinear optics play an important role.

The starting point for the modeling of light propagation under these conditions is Maxwell's wave equation for the electric field $E(\mathbf{r}, t)$ which is given in Gaussian units as

$$\nabla^2 E - \frac{\partial^2 E}{\partial t^2} = 4\pi \frac{\partial^2 P}{\partial t^2} \qquad [1]$$

where the $P(\mathbf{r}, t)$ is the polarization inside the medium. Typically, the polarization is separated into a term P_l that depends linearly on the field E and into a term P_{nl} that depends nonlinearly on the applied field. The Fourier transform of the linear polarization can be expressed as $\tilde{P}_l(\mathbf{r}, \omega) = \chi^{(1)}(\omega)\tilde{E}(\mathbf{r}, \omega)$, where $\tilde{E}(\mathbf{r}, \omega)$ is the Fourier transform of electric field $E(\mathbf{r}, t)$. For the laser–matter interactions that we consider here, we assume that the linear susceptibility $\chi^{(1)}(\omega)$ is real, in which case the wave equation can be expressed as

$$\nabla^2 \tilde{E} + \left[\frac{n_l(\omega)\omega}{c} \right]^2 \tilde{E} = -\frac{4\pi\omega^2}{c^2} \tilde{P}_{\mathrm{nl}} \qquad [2]$$

where $n_l(\omega) = \sqrt{1 + 4\pi\chi^{(1)}(\omega)}$ is the frequency-dependent linear refractive index of the medium.

For light pulses that are longer than an optical period, the envelope description is valid and the electric field can be described by an amplitude envelope $A(\mathbf{r}, t)$ and a carrier frequency ω_0 such that

$$E(\mathbf{r}, t) = A(\mathbf{r}, t)\mathrm{e}^{\mathrm{i}(k_0 z - \omega_0 t)} + c.c \qquad [3]$$

where $k_0 = k(\omega_0) = n_0\omega_0/c$ is the wavevector amplitude and $n_0 = n_l(\omega_0)$. This envelope description is advantageous for performing analytical and numerical studies of pulse propagation. However, for sufficiently short laser pulses, where the shape of the envelope function does not depend on the carrier phase of the carrier wave, such a description is no longer applicable. Nevertheless the envelope description can be made valid for pulses that are nearly as short as a single cycle or, alternatively, that have spectral bandwidths that are comparable to the central frequency ω_0. To derive an equation for the spatio-temporal evolution of the pulse envelope, the relation for the electric field is substituted into the

wave equation (eqn [2]) and the following two approximations are made: i) $k_0 \partial A/\partial z \ll \partial^2 A/\partial z^2$, which signifies that the envelope varies slowly in space over a distance compared to the central wavelength; ii) $v_{\mathrm{ph}} \sim v_{\mathrm{gr}}$ where $v_{\mathrm{ph}} = c/n_0$ is the phase velocity and $v_{\mathrm{gr}} = (\mathrm{d}k/\mathrm{d}\omega)^{-1}$ is the group velocity. This latter approximation is invariably well satisfied when the frequencies contained in the laser field are highly nonresonant with any transition frequencies of the medium.

For an input pulse at $z = 0$ with a peak amplitude A_0, and characteristic widths in space and time given by w_0 and τ_p, respectively, the equation for the normalized amplitude $u(r_\perp, z, t) = A(r_\perp, z, t)/A_0$ can be expressed as

$$\frac{\partial u}{\partial \xi} = \frac{i}{4}\left(1 + \frac{i}{\omega_0 \tau_p}\frac{\partial}{\partial \tau}\right)^{-1} \nabla_\perp^2 u - i \sum_{n=2} \frac{L_{\mathrm{ds}}}{n! L_{\mathrm{ds}}^{(n)}} \frac{\partial^n u}{\partial \tau^n} + i\left(1 + \frac{i}{\omega_0 \tau_p}\frac{\partial}{\partial \tau}\right) p^{\mathrm{nl}} \qquad [4]$$

where $\tau = (t - z/v_g)/\tau_p$ is the normalized retarded time for the pulse traveling at the group velocity v_g, $L_{\mathrm{ds}}^{(n)} = \tau_p^n/\beta_n$ is the nth-order dispersion length, $\beta_n (n \geq 2)$ is the nth-order dispersion constant, $L_{\mathrm{ds}} = |L_{\mathrm{ds}}^{(2)}|$ is the dispersion length, $\zeta = z/L_{\mathrm{df}}$ is the normalized distance, $L_{\mathrm{df}} = k w_0^2/2$ is the diffraction length, p_{nl} is the normalized nonlinear polarization, and $\nabla_\perp^2$ is the transverse Laplacian. The presence of the operator $(1 + i\partial/\omega_0 \partial\tau)$ in the diffraction term $(\nabla_\perp^2 u)$ of eqn [4] leads to space–time focusing, while its presence in the nonlinear term results in self-steepening and both these terms arise from not making the slowly varying envelope approximation in time (i.e., $k_0 \partial A/\partial t \ll \partial^2 A/\partial t^2$) in deriving eqn [4]. For a self-consistent analysis of pulse propagation in the nonlinear regime, both the effects of space–time focusing and self-steepening must be included.

Nonlinear Refractive Index

For an isotropic medium in the highly nonresonant limit, the third-order term is the lowest-order contribution to the nonlinear susceptibility. This term gives rise to the nonlinear refractive index, that is, the index of refraction depends on the local intensity of the laser field. For many materials there are two contributions to the nonlinear refractive index: i) an instantaneous part that arises from the electronic response of the medium; and ii) a noninstantaneous contribution due to the nuclear motion of the molecules (i.e, the Raman contribution). For such a medium, the nonlinear polarization may be expressed as

$$p_{\mathrm{nl}}(\zeta, \tau) = \frac{L_{\mathrm{ds}}}{L_{\mathrm{nl}}}\left[(1 - f)|u(\zeta, \tau)|^2 + f\gamma_R \int_{-\infty}^{\tau} \mathrm{d}\tau' R(\tau - \tau')|u(\zeta, \tau')|^2\right] u(\zeta, \tau) \qquad [5]$$

where $L_{\mathrm{nl}} = (c/\omega_0 n_2 I_0)$ is the nonlinear length, $I_0 = n_0 c|A_0|^2/2\pi$ is the peak input intensity, f is the fraction of the Raman contribution to the nonlinear refractive index, and $R(\tau) = \left\{\left[1 + (\Omega_R \tau_R)^2\right]/\Omega_R \tau_R\right\} \exp(-\tau/\tau_R) \sin(\Omega_R \tau)$ is the Raman response function, τ_R is the characteristic Raman response time, Ω_R is the characterstic Raman frequency, and $\gamma_R = \tau_p/\tau_R$. For example, for fused silica $f = 0.15$, $\tau_R = 50$ fs, and $\Omega_R \tau_R = 4.2$. For a noble gas such as Xe, there is no Raman contribution and $f = 0$.

Self Focusing, Supercontinuum Generation, and Filamentation

The presence of the nonlinear refractive index with $n_2 > 0$ can lead to self-focusing of a laser beam. For sufficiently long pulses such that dispersion, self-steepening, and space–time focusing effects can be neglected, it is found that laser beams with input powers greater than the critical power $P_{\mathrm{cr}} = \alpha\lambda^2/4\pi n_0 n_2$ will undergo catastrophic self-focusing collapse. The dimensionless parameter $\alpha \geq 1.86$ depends on the spatial profile of the input beam and for a Gaussian input beam is given by $\alpha = 1.9$, in which case the ratio of the input power P to the critical power satisfies the relation $P/P_{\mathrm{cr}} = 1.055 L_{\mathrm{df}}/L_{\mathrm{nl}}$. Extensive studies have been made on the dynamics of laser beams undergoing self-focusing. For example, it has been shown that the shape of the collapsing beam evolves to a radially symmetric profile as it approaches the collapse point and that the total power contained in the collapsing portion always corresponds to the minimum value (i.e., $\alpha \sim 1.86$) regardless of the initial power in the beam.

For light pulses shorter than a picosecond, the role of material dispersion plays an important role and completely alters the dynamics of the self-focusing process. These dispersive effects lead to a temporal splitting of the pulse into two pulses and the arrest of its collapse. At even higher powers, other phenomena can occur, such as 'optical shock' formation at the rear edge of the pulse, due to self-steepening and space–time focusing. Shock formation leads to the emission of a broad spectrum of radiation extending from the ultraviolet to the mid-infrared, known as supercontinuum generation (SCG). This phenomenon was first observed in 1970, and since then it has been

observed in many different solids, liquids, and gases, under a wide variety of experimental conditions.

If the peak intensity of the pulse approaches intensities of $> 10^{13}$ W/cm^2, either through self-focusing or external focusing, multiphoton ionization occurs and a plasma is formed in the medium. (See section below on Plasma Nonlinearities and Relativistic Effects.) The generation of the plasma lowers the refractive index and effectively counteracts the self-focusing process, resulting in the spatial confinement of the pulse for distances far beyond what would be allowed by ordinary linear diffraction and has been observed in gases, liquids, and solids. A striking example of this apparent self-waveguiding is the observation of 'light strings' in air which can extend more than 10 km into the atmosphere. This phenomenon was first observed with 100 fs laser pulses in the near infrared ($\lambda = 800$ nm). Researchers found that pulses with energies greater than 10 mJ undergo self-focusing collapse in air and produce a highly intense ($> 10^{13}$ W/cm^2) 100-micron-diameter light filament tens of meters long.

Multiphoton Absorption

Multiphoton absorption is a process in which an atom or molecule makes a transition from a ground state to an excited state by means of the simultaneous absorption of N photons. In the lowest order of perturbation theory, such a process can be described by means of a susceptibility of order $(2N-1)$, that is, by $\chi^{(2N-1)}$. Alternatively, this process can be described in terms of an N-photon cross-section $\sigma^{(N)}$ defined such that the transition rate per atom is given by

$$R^{(N)} = \sigma^{(N)} I^N \qquad [6]$$

where I is the intensity of the laser field. Quantum mechanical expressions for the N-photon cross-sections are readily obtained. One finds, for instance, that

$$R_{\mathrm{ng}}^{(2)} = \left| \sum_m \frac{\mu_{\mathrm{nm}}\mu_{\mathrm{mg}}E^2}{\hbar^2(\omega_{\mathrm{mg}} - \omega)} \right|^2 2\pi\rho_{\mathrm{f}}(\omega_{\mathrm{ng}} - 2\omega)$$

$$R_{\mathrm{og}}^{(3)} = \left| \sum_{mn} \frac{\mu_{\mathrm{on}}\mu_{\mathrm{nm}}\mu_{\mathrm{mg}}E^3}{\hbar^3(\omega_{\mathrm{ng}} - 2\omega)(\omega_{\mathrm{mg}} - \omega)} \right|^2 2\pi\rho_{\mathrm{f}}(\omega_{\mathrm{og}} - 3\omega) \qquad [7]$$

In each of these expressions, the quantity ρ_{f} represents the density of final states, or equivalently the atomic lineshape function, evaluated at the N-photon transition frequency.

Optical Damage

High-intensity laser fields can produce unwanted damage to optical materials. As a point of reference, the threshold for laser damage to fused silica at a wavelength of 1.05 micrometers for a pulse of 30 ps duration corresponds to an intensity of 230 GW/cm^2 or a fluence of 7 J/cm^2. Over a wide range of pulselengths (approximately 1 ps to 1 μs), the threshold intensity for laser damage decreases with pulse length T as $T^{-1/2}$ and correspondingly the threshold fluence for laser damage increases with pulse length $T^{1/2}$. In this range of pulse durations, the dominant mechanism of laser damage is avalanche breakdown. In this process, free electrons are accelerated by the laser field until they acquire sufficient energy to impact-ionize other atoms in the sample. These additional electrons are similarly accelerated and create still more free electrons. The combined action of the breaking of chemical bonds and the deposition of heat energy leads to the fracturing of the optical material. For pulses shorter than 1 ps, processes such as multiphoton absorption and multiphoton dissociation contribute to the mechanism of optical damage. For laser pulses longer than approximately 1 μs (including continuous wave laser beams), the dominant damage mechanism is direct heating of the optical material by linear absorption.

High-Harmonic Generation

Let us consider how nonlinear optical effects are modified when excited by a super-intense pulse. Nonlinear optical effects are traditionally modeled using a power-series expansion, such as

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \cdots \qquad [8]$$

but this series is not expected to converge if the laser field strength E exceeds the atomic unit of field strength $E_{\mathrm{at}} = e/a_0^2 = 2 \times 10^7$ statvolt/cm $= 6 \times 10^9$ V/cm. This field strength corresponds to a laser intensity of $I_{\mathrm{at}} = 4 \times 10^{16}$ W/cm^2, which constitutes the threshold intensity for exciting nonperturbative nonlinear optical response.

One of the consequences of excitation with intensities comparable to the atomic unit of intensity I_{at}, is the occurrence of high-harmonic generation. In a typical experimental arrangement, a gas jet is irradiated by high-intensity laser radiation, and all odd harmonics of the fundamental laser frequency, up to some maximum value N_{max}, are observed. The various harmonics below N_{max} are typically emitted with approximately equal intensity; such an

observation is incompatible with a perturbative explanation of this phenomenon. Recent work has demonstrated harmonic generation with N_{max} as large as 341.

The phenomenon of high-harmonic generation can be understood in terms of a simple physical model. One imagines an atomic electron that has received kinetic energy from the laser field and is excited to a highly elliptical orbit. The positively charged atomic nucleus is at one focus of this ellipse, and each time the electron passes near the nucleus it undergoes strong acceleration and emits a short pulse of radiation. This radiation will occur in the form of a train of short pulses; the spectrum of the radiation will be the square of the Fourier transform of this pulse train, which will contain the odd harmonics of the oscillation frequency up to some maximum frequency, that is approximately the inverse of the time the electron spends near the atomic core. This argument can be made quantitative to show that the maximum harmonic number is given by

$$N_{max}\hbar\omega = 3.17K + U_p \qquad [9]$$

where $K = e^2E^2/m\omega^2$ is the 'ponderomotive energy' (the kinetic energy of an electron in a laser field) and U_p is the ionization energy of the atom.

Plasma Nonlinearities and Relativistic Effects

The process of multiphoton ionization can liberate a sufficient number of free electrons to transform the optical medium into a plasma, that is, a fully or partially ionized gas. The process of plasma formation is described by the equation

$$\frac{dN_e}{dt} = \frac{dN_i}{dt} = (N_T - N_i)\sigma^{(N)}I^N - rN_eN_i \qquad [10]$$

where N_e is the number density of electons, N_i is the number density of ions, N_T is the total number of atoms (both ionized and un-ionized) in the material, and r is the electron–ion recombination coefficient. The optical properties of plasmas are very different from those of typical dielectric materials; the plasma contribution to the dielectric constant is given by

$$\epsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2} \qquad [11]$$

where $\omega_p = \sqrt{4\pi Ne^2/m}$ is known as the plasma frequency.

Nonlinear effects can occur in the propagation of light through a plasma. One example is the nonlinear response resulting from the relativistic change in mass of the electron due to the large velocity that it can attain in the field of an intense laser beam. Detailed consideration of this effect shows that the nonlinear change in refractive index can be described as $\Delta n = n_2 I$ where

$$n_2 = \frac{2\pi\omega_p^2e^2}{n_0^2m^2c^3\omega^4} = \frac{1}{2\pi n_0^2}\left(\frac{\omega_p}{\omega}\right)^2 1.1\times10^{-26}\,\frac{\text{cm}^2}{\text{W}} \qquad [12]$$

Nonlinear Quantum Electrodynamics

One can imagine an electric field so intense that it could lead to the spontaneous creation of electron–positron pairs. Such a field would have a strength of the order of $E_{QED} = mc^2/e\lambda\!\!\!^{-}_c$ where $\lambda\!\!\!^{-}_c = \hbar/mc$ is the reduced Compton wavelength of the electron. The intensity of a light beam with a peak field amplitude of E_{QED} is $I_{QED} = 4\times10^{29}$ W/cm^2. Detailed consideration shows that even for fields weaker than I_{QED} there will be a field-induced change in the dielectric tensor given by

$$\epsilon_{ik} = \delta_{ik} + \frac{e^4\hbar}{45\pi m^4c^7}\left[2(E^2 - B^2)\delta_{ik} + 7B_iB_k\right] \qquad [13]$$

Because of the unusual tensor properties of this relation, it displays a different polarization dependence than typical optical nonlinearities. Nonetheless, to an order of magnitude one can describe the strength of this response as

$$n_2 = \frac{7}{15c}\frac{e^2}{\hbar c}\frac{1}{E_{QED}^2} = 5.6\times10^{-34}\,\text{cm}^2/\text{W} \qquad [14]$$

Harmonic Generation in Gases

Introduction

The generation of laser harmonics in gases provides high-brightness ultraviolet and soft X-ray radiation induced by an intense laser pulse. This phenomenon was discovered experimentally in the late 1980s, in a simple setup as that sketched in Figure 1. The laser pulse is focused in the interaction medium, which may be a gas jet formed by a pulsed electromagnetic valve, a capillary, or a small chamber filled with the gas. The beam leaving the interaction region includes a part of the laser pulse and a number of odd harmonics.

The harmonic orders generated in this way may reach and exceed an order of 300, so that this mechanism, often referred as high-order harmonics (HHs) generation (HHG), directly up-converts low frequency radiation, usually in the near-infrared spectrum, to extreme-ultraviolet (XUV) or soft X-rays. An example of a HH spectrum is shown in Figure 2, where several tens of discrete harmonic peaks are present. The striking difference with ordinary nonlinear processes is the flatness of the photon yield versus nonlinear order, up to a sharp cut-off point.

The HHG is based on the sequence of three processes: the electric field of an intense laser pulse ionizes atoms placed near the laser focus; the liberated electrons are driven by the laser electric field in a trajectory which returns on the parent ion; and the electron recombines releasing a photon whose energy is the ionization potential plus the electron's kinetic energy. The process is periodic in time, with the period of the laser pulse, and the emitted spectrum is then expressed by discrete components, multiples of the laser frequency. The emission is in the form of a traveling wave in the direction of the laser beam and so only odd harmonics are present.

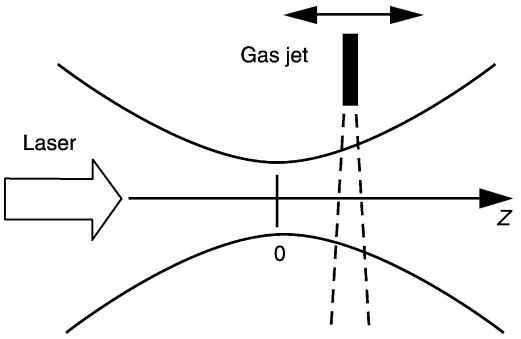

Figure 1 Scheme of the interaction between a focused laser pulse and a gas jet. *z* axis originates at laser focus.

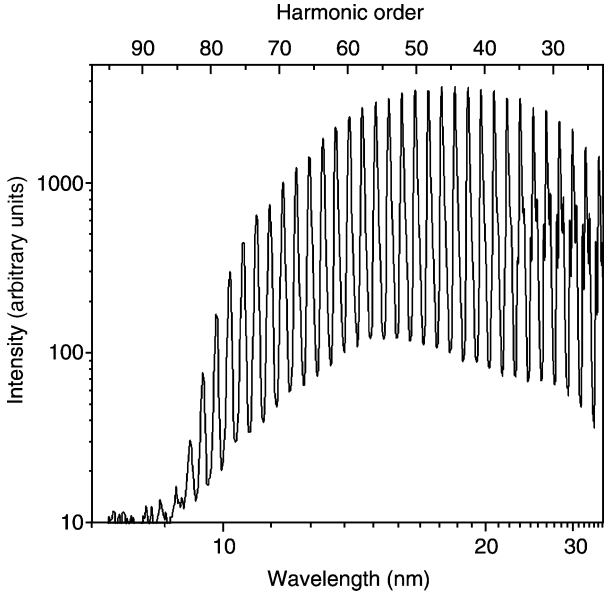

Figure 2 HHs experimental spectrum, obtained from helium gas, and a Ti:sapphire laser pulse at 790 nm, with 25 fs duration and 6×10^{14} W/cm^2 intensity.

The individual processes in HHG have highlighted the coherent response of electrons in the laser field, that show up interferences between quantum trajectories, as well as a nonlinear phase-matching issue – which have provided a simple method to investigate the interaction of single particles with the electromagnetic field, where plasma effects and bonds may be of minor influence.

Background

The interest to produce laser harmonics using gases instead of crystals was expressed by many. For the gas medium; the mass-density is three order of magnitude lower than for solids and the nonlinear susceptibility can be strongly enhanced for suitable resonance frequencies. Moreover, the phase-matching of the phase velocities may be achieved by tuning the gas pressure or by mixing diverse gases, so realizing a highly homogenous conversion region, free from walk-off and with an extension much longer than for crystals. In addition, gases have a high threshold for the intensity-induced damage, which is also non-permanent.

This research was made possible with the introduction of chirped-pulse laser amplifiers in the early 1980s, when picosecond lasers pulses reached intensities capable of directly ionizing solids and matter with their own electric field. This effect, known as optical ionization, was further enhanced when the laser pulses were reduced to subpicosecond duration, up to a few femtoseconds (10^{-15} s), close to their natural limit, which is the optical cycle. The experimental observation of HHs and of the ejection of electrons with unexpected high energy, the above threshold ionization (ATI), dramatically changed the scenario of laser matter interaction and has indicated a new regime in the coupling of laser radiation with the matter. The ordinary nonlinear optics, using the perturbative approach, was not capable of interpreting the findings and so the request was made for new models for the description of the interaction, which has been now named nonperturbative.

Typical Experimental Parameters

In the experimental investigation of the HHG, many laser wavelengths and pulse durations were used, including radiation from excimer, visible, Ti:sapphire, Nd:YAG (first and second harmonics) and CO_2 lasers, and pulses of duration from hundreds of picoseconds to a few femtoseconds. Among these, the more effective strategy in the generation of high harmonic order with high conversion efficiency, has been that of near infrared pulses with shortest duration. In order to induce optical single-ionization, the required laser intensity needs to span in the 10^{14} W/cm^2 range. Different elements are a possible choice for the gas in the interaction medium, though noble gases are used for the generation of the highest orders, since these have the higher ionization potential. Due to the very short duration of the laser pulse, the gas temperature is not relevant, while a pressure range of 10–500 mbar is usually chosen to balance, on one side, the needs of a large number of atoms that take part in the HHG and on the other side, the limit posed by the attenuation of the XUV and soft X-ray radiation after the generation, caused by the gas absorption. For the same reason, a powerful pumping system is needed, in order to reduce the ambient pressure in the apparatus below 10^{-5} mbar level.

The Models for the High Harmonics Generation

The physical processes involved in HHG are many: in the emission of the HH photons, the laser field interacts with a single atom of gas and induces the ionization, the electron's motion and its recollision with its parent ion; besides, the beam of HHs is the result of the superposition of the radiation from all the ionized atoms, as in an ordinary nonlinear medium, where the phase velocity of the laser field and of HHs is a function of the position and of the laser intensity and phase; therefore, the phase-matching issue has to be addressed in order to understand the global yield of HHG. The more relevant causes for the mismatch are the geometrical phase shift at the beam focus, which for Gaussian-profile beams is the Gouy phase, the nonlinear phase from the atomic polarization, and the effects of the plasma induced by the laser pulse itself. In addition, other effects have to be considered, such as the nonuniform density distribution of the target gas or the fact that the propagation of XUV radiation through a gas is usually influenced by a strong absorption, which is frequency dependent.

The study of HHG is first approached by introducing what is known as the simple man model, in which simplifications are introduced in order to treat the problem in a simple classical scheme, but from which the essential characteristics are derived. We then introduce the more complex quantum model based on the path integrals.

First Step: Ionization

The first step in the HHG model is the process with which the laser electric field applies to an electron, belonging to an atom or a molecule, a force that causes its detachment. This takes place only if such a field is strong enough to liberate the electron from its atomic bond. This may happen when the laser, which is taken here as linearly polarized and periodic in time, has modified the potential well so that the electrons may tunnel through it or pass over it. In fact, the sum of the atomic potential with that associated to the laser, which can be thought of as a plane that swings between a positive and negative slope at the laser frequency, gives rise to a finite sized well, through which the electron escapes by tunneling, or eventually to an aperture from which the electron is drawn away from the nucleus. In Figure 3, is shown such a well and the tunnel path for the electron.

Once freed, the electron responds to the periodic force from the laser which makes it oscillate. The

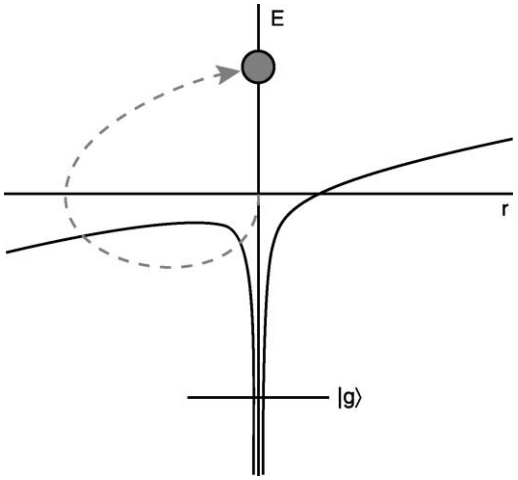

Figure 3 Electron potential when the laser pulse shines on the atom; |g⟩ indicated the level of the ground state; in red, a possible trajectory of the liberated electron after tunneling.

average kinetic energy on such oscillations is known as the ponderomotive potential U_p, and is related to the laser intensity and wavelength, according to the following: $U_p = e^2E_0^2/4m\omega_0^2$, which reads numerically as $U_p(\text{eV}) = 9.3I_0(10^{14}\ \text{W/cm}^2)\lambda^2(\mu\text{m})$, where λ is the laser wavelength, E_0 and I_0 the laser peak electric field and intensity.

Second Step: Free-electron Trajectory

On the freed electron are applied both the time-varying force due to the laser field and the ionic potential. Its motion can be approximated according to the simple man model as a nonrelativistic classical-mechanics trajectory; its initial velocity is set to zero, and its initial position is by the ion; finally, the laser exerts a force much stronger than that from the ion as well as from the laser magnetic field, thus these two latter forces are cancelled out.

As mentioned above, the electron trajectories that induce HHs are those where the electron returns by the ion with strong kinetic energy. If the laser is linearly polarized, the induced trajectory takes place along a line, at which also belongs to the parent ion. Moreover, the electron final velocity is related to the actual instant of ionization, or phase of the field, with respect to the laser peak. Therefore, electron final energies span from zero to a maximum value $K_{\text{max.}}$ By considering the first semi-cycle, K_{max} occurs at about 17° of field phase angle, while for the second semi-cycle it is at 197°.

In Figure 4 the electron trajectories for different ionization in the first semi-cycle are shown: the electron displacement in the laser-field direction with

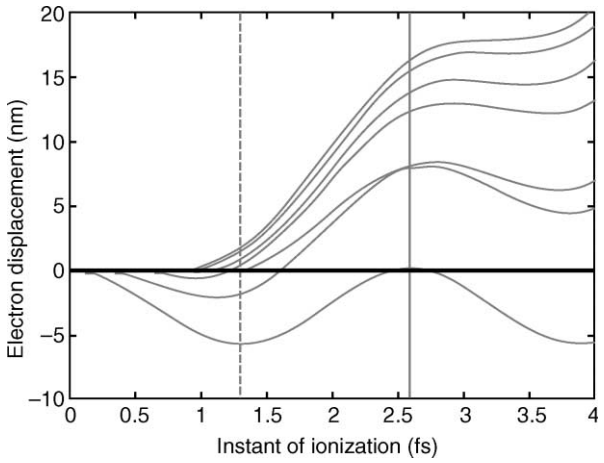

Figure 4 Electron trajectories relative to different ionization instant within the first semi-cycle; in dotted red, half-cycle, in continuous red, the whole optical cycle. Trajectories for later times do not return to the ion, do not contribute to HHG and correspond to ejected photoelectrons.

respect to the ion position, which is the initial as well as the final position, is represented versus time, where the time origin is at the laser peak, where field phase is equal to zero. The laser intensity directly influences the value of $K_{\max}$, according to the following expression: $K_{\max} = 3.17\,U_p$. In the case shown in the figure, the peak laser intensity is $I_0 = 8 \times 10^{14}$ W/cm^2 and the ponderomotive potential is $U_p = 45$ eV and $K_{\max} = 143$ eV.

Moreover, for a given final energy below $K_{\max}$, there are more than one value of the phase of the laser field where the trajectory results with the same final kinetic energy. This indicates that multiple trajectories may produce a given HH, and this is relevant in terms of the interference between them.

Third Step: Recombination

The final process which occurs in the HHG, is the recombination of the ionized electron with the parent ion. The energy conservation means that the kinetic energy and the ionization potential have to be delivered to the emitted photon. In the simple man model, the spectrum of HH then spans from I_p to the maximum values of $E_{\max} = I_p + 3.17\,K_{\max}$. In the case of Figure 2, obtained using helium gas at 6×10^{14} W/cm^2, the spectral position of cutoff can be estimated at about 9 nm, or 140 eV, which is in good agreement with the prediction of the relationship described above.

The electron recombination is not a unique process occurring at this point: the electron may be scattered by the ion and be emitted with a kinetic energy of up to 10 U_p, which is known as the rescattering plateau in ATI, or it may ionize the ion by collision, leaving a double ionized atom via sequential ionization, with a strong increase in the observed cross-section of this process.

Feynman Path-Integral Approach

The ideas in the simple man model have been expanded in order to include the quantum mechanical description of the laser-electron-ion interaction. By using the Feynman path-integral approach, the evolution of the electron driven by the laser force is associated to a probability which depends on the sum of an infinite number of amplitudes $\mathbf{f}_n$. These are complex numbers and correspond to different trajectories, or quantum orbits, $\mathbf{r}_n(t)$, followed by the electron. Their phase is proportional to the classical action of the electron motion, $S[\mathbf{r}_n(t)]$, calculated along $\mathbf{r}_n(t)$, which begins at time t_i and ends at a later time $t_f = t_i + \tau$. Here τ defines the duration of the liberated electron trajectory. In our case, the action is the sum of three terms:

$$S[\mathbf{r}_n(t)] = S_{\text{bound},n} + S_{\text{free},n} + S_{\text{final},n} \qquad [1]$$

that correspond respectively to the electron ionization:

$$S_{\text{bound},n} = -E_0 t_{i,n} \qquad [2]$$

where E_0 is the binding energy of electron in the atom ground state, $E_0 < 0$, to the free electron trajectory:

$$S_{\text{free},n} = \int_{t_i}^{t_f} [\mathbf{k} - e\mathbf{A}(t)^2]\mathrm{d}t \qquad [3]$$

where $\mathbf{k}$ is the electron momentum after ionization, directed parallel the laser electric field, and $\mathbf{A}(t)$ is the vector potential of the laser field, and to the final recombination with the parent ion:

$$S_{\text{final},n} = (\hbar\omega_q + E_0)t_{f,n} \qquad [4]$$

The condition that normally points out the trajectory made by the electron may be obtained from the principle of least action. Within the path integral approach, this principle can be used to deduce some equations which have to be obeyed by the quantum orbits, and that express the energy conservation in both the ionization and recombination process and the fulfilment of boundary conditions for electron trajectory. These are known as saddle-point equations, and reads as:

$$[\mathbf{k} - e\mathbf{A}(t_i)]^2 = 2mE_0 \qquad [5]$$

for the ionization process:

$$\mathbf{k}\tau = e\int_{t_i}^{t_f} \mathbf{A}(t)\mathrm{d}t \qquad [6]$$

which compares the initial momentum with that exchanged with the laser field during the trajectory, and

$$[\mathbf{k} - e\mathbf{A}(t_f)]^2 = 2m(\hbar\omega_q + E_0) \qquad [7]$$

for the recombination process which emits an harmonic of order q.

From eqn [5] we note that the solution for the ionization time t_i is a complex number, since the right hand side is negative. This suggests that the quantum orbits are complex as well. The reason for this is that the tunnel through the potential well is a nonclassical process.

The orbits solutions to eqns [5]–[7] have different durations, and for some of them τ is shorter than an optical cycle, while for the others the electron returns in a later cycle than the one where it was ionized. This latter solution is of minor influence, since the electron wavefunction spreads out along the trajectory, decreasing the recombination probability. Those within the initial optical cycle sum the amplitudes to give the probability of the generation of q-th harmonic, and their interference is evident from the irregular single-atom spectrum.

The time evolution of the laser pulse as well as the interaction geometry are experimental tools that influence the relevance of the different trajectories. In particular conditions it is possible to set the condition for HHG from a single trajectory, with a very simple phase structure and clear spectrum; some cases are described below.

HHs Generated by Few-Optical-Cycle Pulses

The laser electric field considered so far has been taken as stationary, relying on the hypothesis that the pulse envelope has a duration much longer than the laser optical cycle. For the analysis of the electron trajectories, that last a fraction of the laser optical cycle, this hypothesis is valid for pulses down to about 20 fs. For shorter pulses, as those generated with the hollow fiber technique, there is a noticeable variation of the electric field between a cycle and the next. The generation process is now aperiodic, and the characteristics of HH spectrum and conversion is strongly influenced by the pulse actual duration.

In order to show the striking changes in this regime, Figure 5 shows the laser electric field, the envelope and the ionization probability of helium gas in the case of a pulse of 5 fs of full width at half-maximum (FWHM) duration and a laser intensity of 9×10^{14} W/cm^2. The atom can be ionized during only three intervals, of sub-fs duration but where only one is dominant.

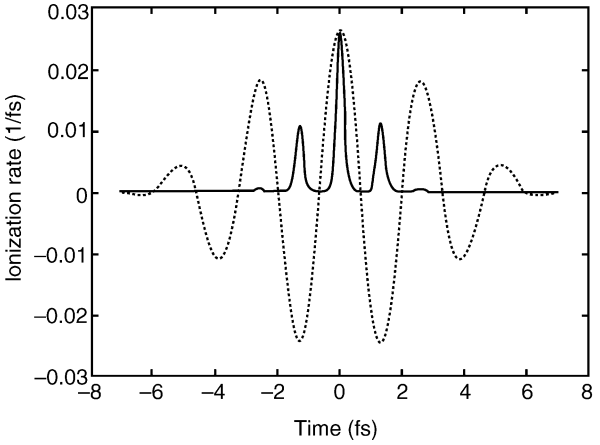

Figure 5 Ionization rate for helium gas shined by a 5 fs FWHM pulse of intensity 9×10^{14} W/cm^2. The dotted line shows the normalized evolution of electric field of the pulse. Only the three central half-cycles induce ionization.

The HHG experiment in this temporal regime have revealed that the influence of the plasma in the interaction region is progressively reduced and eventually vanishes for pulses of duration of about 5 fs. This is because the atoms are exposed directly to the maximum electric field, and so there is no pre-ionization of the gas caused by the initial part of the pulse. This effect, which is present in the case of many-cycle pulses, causes a reduction in the HHG efficiency, due to a depletion of the neutral density available at the time of maximum electric field, where the higher HHs are produced with a large dispersion, which deteriorates the phase-matching.

Moreover, the effect of the carrier-envelope-phase in the HHs spectrum has been demonstrated as an evident spectral shift of the cut-off harmonics generated with few-cycle pulses. The reason can be found in the variation of the phase of the emission from each electron after its trajectory. For the few-cycle pulses, this phase changes for every laser semi-cycle, due to the change in the actual electric field which drives the electron motion.

This portion of the spectrum is also relevant to its phase structure, since here the HHs are generated by a single electron trajectory. This condition sets a constant phase difference between the subsequent harmonic orders. In this way, similarly to the mode locking laser, this effect allows the synthesis of a pulse, from the combination of several harmonic orders, which has a duration much lower than the

individual harmonics. This process has been exploited to produce a soft X-ray pulse of duration of 650 as (1 as, attosecond $= 1 \times 10^{-18}$ s).

HHs Beam Characteristics

The HHG is a coherent process, in that the emitted radiation has a direct relationship with the laser pump. The emitted HH beam also reflects this fact in its good directional characteristics and in its spatial and temporal coherence, as different experiments have demonstrated.

Using a 110 fs laser pulse, the interference fringes produced in the far field of two spatially separated HH beams were measured as a function of the mutual delay. The HH coherence time t_c resulted in agreement with the expected duration of the HHs, which is a fraction of that of the laser pulse. Moreover, it has been observed at a different t_c in the central and external regions of the far field of harmonic 23rd, 50 fs and 20 fs respectively. This is because different phase-matching in the HHG contribute to the on-axis and off-axis part of the HHs beam, where the more prominent quantum orbit is also different.

The measurement of the beam divergence for different harmonic orders is relevant for both the estimate of the beam brightness and the irradiance available in the case of the HH applications. Moreover, it is useful for the understanding of the phase-matching which is realized in actual interaction geometry. The experimental measurements requires an astigmatic spectrometer, as is described later. In this kind of experiment, the focalplane images of the HH spectrum are taken for different generation conditions, usually moving the gas-jet position with respect to the laser focus, the z coordinate in Figure 1. The harmonic peaks appear as elongated spots, as shown in Figure 6 for helium gas and an intensity of 4×10^{14} W/cm^2 and duration of 20 fs, whose length in a transverse direction to the dispersion plane can be related, by a optical calculation, to the beam divergence.

A comparison between divergences for HHG driven by few- or many-optical-cycle pulses has revealed another aspect of the phase-matching condition. In this case, the laser pulse was compressed in time by means of the hollow fiber technique, and so the resulting phase front is of the Bessel-beam type, truncated at the first zero. The experiment indicates a divergence for plateau harmonics of about 3 mrad FWHM of the beam, in the case of the 7 fs pulse and larger values by more than 50% using the 20 fs pulse. In both cases, the beam divergence increase moving downstream the gas jet and with increasing harmonic order. The reduced divergence can be ascribed to a more regular wavefront of the harmonic beam, which can be related to the simpler phase structure of the few-cycle case.

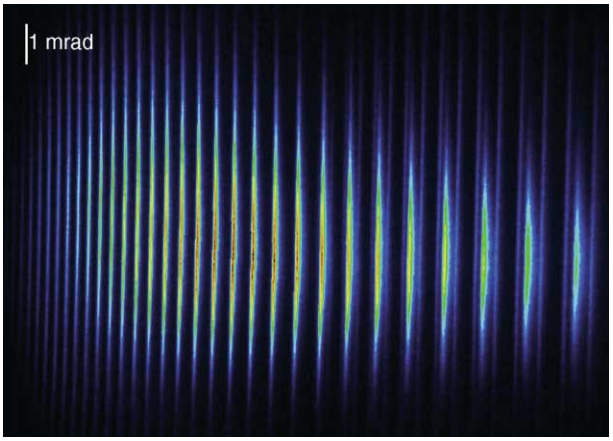

Figure 6 Focal plane image obtained from the spectrograph shown in Figure 9, relative to the HHs spectrum of helium with 20 fs and 4×10^{14} W/cm^2. The bar in upper-left corner indicates the scale-length of vertical axis corresponding to a divergence of the HH beam of 1 mrad.

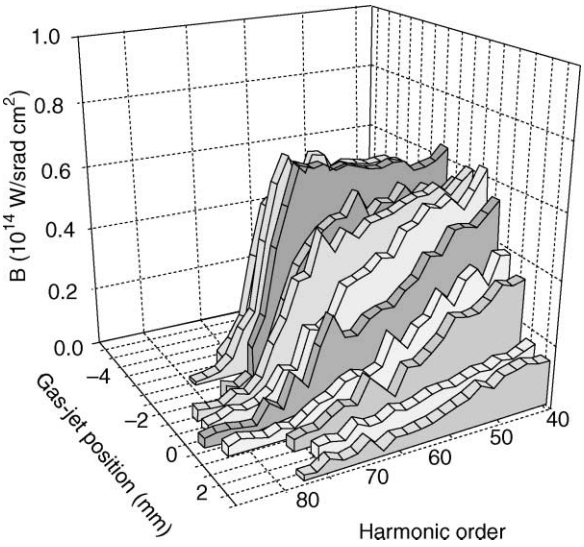

Figure 7 Peak brightness of the HHs beam determined from absolute-intensity and divergence measurements, using neon gas and a 790 nm laser pulse with 7 fs duration and 9×10^{14} W/cm^2 intensity.

By using an intensity-calibrated detector, the number of photons per harmonic order per laser shot can be measured. Combining this measure with that of the divergence, the HH beam brightness can be calculated. The source size and the HH pulse duration can be easily modeled from the experimental parameters. The result for the case of neon with 7 fs pump-pulse with intensity of 9×10^{14} W/cm^2 is shown in Figure 7, as a function of the gas-jet

position, with positive values when the jet is downstream with respect to laser focus.

The large divergence reduces the brightness of downstream positions. Maximum values of about 8×10^{13} W/srad cm^2 are found close to the focus, relatively flat with respect to harmonic order.

The conversion efficiency η_{HH} from the fundamental intensity to that of the HHs can also be derived from this kind of measurement. The more convenient parameters for HHG in the range 41–71 were found using neon gas jet from a pulsed valve and a pulse duration of 7 fs, which leads to η_{HH} in the scale of 10^{-7}, while for lower orders, from 17 to 31, a value about two orders of magnitude larger has been obtained using a short hollow fiber filled with argon gas. A remarkable intracycle optimization mechanism was introduced in this case, in order to maximize the given harmonic order of chosen. This was done by tailoring the shape of the pump pulse in spectrum and time, using an adaptive component in the laser compressor. In this case, the optimal pulse shape to maximize the efficiency in the driving of the electron on a trajectory producing the required harmonic order, is sought by means of a genetic algorithm.

A strong efficiency enhancement has also been demonstrated by manipulating the laser wavefront by means of a deformable mirror (DM). In this case, the DM was controlled by a genetic algorithm, aiming to increase the HHs intensity in a given spectral interval. The purpose of this technique is the correction of the optical aberrations on the beam, introduced by both the optical components in the beam focusing line and the phase distortion caused by nonlinear effects leading to an optimum laser front. The effect is shown in Figure 8, where the spectrum obtained with the original beam is compared with that optimized by the genetic algorithm. It can be noticed there is both a remarkable extension of the HHs spectrum, of about 20 orders, as well as a strong enhancement of the plateau intensity.

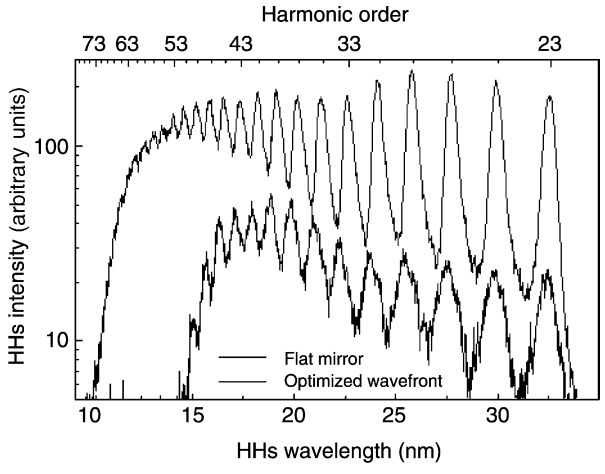

Figure 8 Comparison of the HHs spectrum obtained with and without the wavefront correction using a deformable mirror. Neon gas was used and a 790 nm laser pulse with 6 fs duration and 0.3 mJ energy.

Spectrometers and Monochromators for HHs

The extended spectrum of HHs reaches the optical domains of the extreme-ultraviolet (XUV, 10–100 nm) and soft X-ray (1–10 nm). In these regions, the optical materials have very poor or zero transmission, and so the optical design of instruments for HHs analysis uses reflective optics only. Exceptions sometimes used are the frequency-selective XUV transmission filters, whose thickness does not exceed a few tenths of a micrometer, and the diffracting zone-plates. Moreover, for the radiation of wavelength shorter than 30 nm, even the reflectivity of optics becomes poor, and this forces the use of grazing-incidence mountings or the narrow band XUV and soft X-ray multilayer mirrors.

On the other hand, HHs as optical sources have favorable characteristics, in that they are emitted in a region smaller than the laser waist focus, so usually of a few tens of micrometers, and their divergence is small, as seen above. In addition, the very short duration of the pump pulses broadens the HHs spectrum, due to time-bandwidth inequality, usually smearing details below 0.1 nm of width.

The spectrograph is then realized with the least number of components, usually combining in one or two optics of the spectral dispersion, the gathering of the HH beam and its focusing on the detector. Moreover, it is not feasible to collect with a single detector all the broad HH spectrum in once, so usually a spectral interval of interest is selected and acquired with a linear or bidimensional detector, or scanned sequentially by rotating the grating.

An example of spectrograph with 2D-detector, is shown in Figure 9, the layout of the instrument developed for the simultaneous measure of the divergence and the intensity of HHs generated from few-optical-cycle pulses.

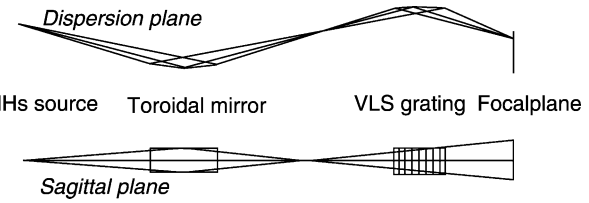

Figure 9 Optical layout of the astigmatic spectrometer for the divergence measurement.

The upper part of Figure 9 shows the optics in the dispersion plane, where the toroidal mirror gathers the HH radiation and relays it to the source point for the spherical grating. The latter has a varied line spacing (VLS) of the grooves, in order to image an erected spectrum in the focalplane. This feature is convenient in order to use a bidimensional detector. In the sagittal plane, the grating has negligible effect, and the toroidal mirror is designed to realize an astigmatic image of the source in the focalplane, from which the divergences can be extracted. The detector needs to be blind at the radiation of the laser and at the lower harmonics, and to have an extended linear response in the XUV and soft X-ray. A good solution can be obtained with an open micro-channel plate (MCP), with a suitable photocathode such as MgF_2, placed in the focalplane, coupled with a high-resolution and a high dynamic CCD camera.

For the selection of a single harmonic order or of a narrow spectral region, an XUV monochromator is used. This device is based on the spectral dispersion of the HHs beam by using a diffraction grating. The desired harmonic order is selected by scanning the wavelength which falls on the slit, usually by rotating the grating. This technique uses a single optical component, a concave grating, to reduce the reflection losses. On the other hand, the single-grating monochromator introduces a remarkable time broadening in the selected radiation. In fact, the grating diffraction is based on the optical path length difference for the rays diffracted by subsequent grating grooves. Therefore the selected beam, of wavelength λ, is composed of rays whose difference in length is $\Delta L = N_g m\lambda$, where m is the diffraction order and N_g is the number of illuminated grooves, given by the beam diameter on grating multiplied by the groove density. The time broadening of the selected pulse is then $\Delta\tau = \Delta L/c$. For a HH XUV pulse, the diffracted pulse results is 7 ps of duration, if beam size is of 3 mm and it is diffracted at 87° by a 1200 gr/mm grating.

The solution to this problem may be found in adopting a twin grating design. In this case, the dispersion induced by the first grating is used to select the desired spectral portion of the HH spectrum, and will be cancelled by the second grating. This latter grating has to be mounted in order to compensate for the different optical path length of different rays within the aperture of the HH beam. The layout of this optical scheme is reported in Figure 10. The ray tracing of this compensated monochromator indicates that for both the grazing incidence and the normal incidence regions, the residual broadening results is of the order of one femtosecond.

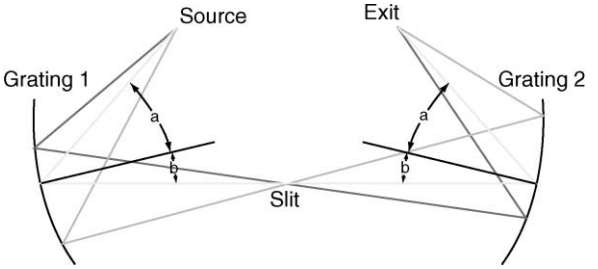

Figure 10 Scheme of the compensated XUV monochromator, for the selection of a spectral portion of the HHs spectrum without introducing temporal broadening. HHs at Work: Applications and Perspectives

The advantages of HHs with respect to other XUV and soft X-ray sources, as laser-plasma, synchrotron radiation or X-ray lasers, are mainly the very short duration of their emission, their high brightness, and the source compactness and their intrinsic synchronization with a laser pulse. These aspects have been already exploited in a few experiments, based either on the detection of a photoelectron emitted in the time-dependent interaction of the matter with the HHs plus fundamental laser beams, or the observation of changes in the HHs XUV spectrum.

As examples of direct application, the interferometry of a laser-plasma has been obtained with HHs, to determine spatial distribution of the electron density. In this case, two beams of harmonic radiation were generated by splitting in equal parts the laser pulse, with one of them passing through a laser-generated plasma from a solid aluminum target. By means of a grating monochromator, a single harmonic order is selected, of both beams, and their interference pattern in the far field is acquired. From the shift in the fringes pattern, the map of the plasma electron density was estimated. Here, the broad spectrum of the HHs was exploited to operate the interference at the most convenient wavelength, far from atomic resonances and with fair fringe contrast.

The direct monitoring of a chemical reaction at the surface was achieved by pumping, with a part of the laser pulse, a platinum surface with some adsorbed molecular oxygen. By observing changes in the spectrum of the photoelectrons generated by the delayed HHs beam, the oxygen-platinum bond switch from a superoxo (O_2^-) to a peroxo (O_2^{2-}) state was observed in the time domain.

The electron bond in an atom may be dressed by a laser field, and the changes induced in its orbital are diagnosed by a HHs beam, which photo-ionizes the atom. This phenomenon have been exploited as a diagnostic of the temporal structure of a HHs beam: the sidebands in the photoelectron spectrum have been related to the phase of different harmonics. The findings indicate that HHs are locked in phase and their superposition produces a train of 250 as pulses.

By using the mixing scheme of some suitable orders of a HHs beam generated with few-optical-cycle pulses, mentioned already in section 'HHs beam characteristics,' a pulse with sub-femtosecond duration may be generated. This was used in the detailed analysis of the photoelectron spectrum in a pump-probe experiment, with time resolution of 150 as. Again using the IR and HHs radiation together, this technique has accessed the direct probe of the laser field oscillation, as demonstration by the use of HHs in the new domain of attosecond spectroscopy and metrology.

Finally, the HH radiation can also be considered as the seed for an amplifier of radiation in the soft X-ray region, as in the case of a free electron laser.

Introduction

The transmission distance of a fiber-optic communication system is limited by fiber loss and dispersion. For long-haul lightwave systems, the loss limitations have traditionally been overcome by periodic regeneration of the optical signals at repeaters applying conversion to an intermediate electric signal. Because of the complexity and high cost of such regenerators, the need for optical amplifiers became obvious in the mid-1980s. The optical amplifier is ideally a transparent box that provides gain and is also insensitive to the bit rate, modulation format, power and wavelength of the signal passing through it.

Several means of obtaining optical amplification has been suggested since the 1970s, including direct use of the transmission fiber as gain medium through nonlinear effects, semiconductor amplifiers, or doping optical waveguides with an active material (rare-earth ions), that could provide gain. Due to the spectacular results on erbium-doped fiber amplifiers, which are particularly suitable in the third transmission window (around 1.5 μm), an intense worldwide research activity on optical amplifiers has developed. As a consequence, the development of erbium-doped fiber amplifiers has reached an industrial level, and commercial devices are now available.

Semiconductor amplifiers, on the other hand, have the same technical basis as semiconductor lasers. Although the strong nonlinearity of semiconductor amplifiers degrades the performances of transmission systems, the state-of-art semiconductor devices seem to be the most interesting amplifiers for transmission in the second transmission window (around 1.3 μm).

Amplifier Gain and Bandwidth

In a perfect amplifier, the amplification process would be insensitive to the bit rate, modulation format, power, state of polarization, wavelength, and optical bandwidth of the signal passing through it. On the other hand, no interaction would take place if more than one signal were amplified simultaneously. In practice, however, the optical gain depends not only on the wavelength (or frequency) of the incident signal, but also on the electromagnetic field intensity at any point inside the amplifier. Details of wavelength and intensity dependence of the optical signal depend on the amplifying medium.

We consider a case in which the gain medium is modeled as a homogeneously broadened two-level system. In such medium, the gain coefficient (i.e., the gain per unit length) can be written as:

$$g(\nu, P) = \frac{g_0}{1 + \dfrac{(\nu - \nu_0)^2}{\Delta\nu_0^2} + \dfrac{P}{P_{\text{sat}}}} \qquad [1]$$

where g_0 is the peak value of the gain coefficient determined by the pumping level of the amplifier, ν the optical frequency, ν_0 the atomic transition frequency, $\Delta\nu_0$ the 3 dB local gain bandwidth, P the optical power of the signal, and P_{sat} the saturation power, which depends on the gain medium parameters. It must be emphasized that $\Delta\nu_0$ and P_{sat} refer to the local gain. However, from the communication system point of view, it is more desirable to use the related concepts of amplifier bandwidth and amplifier saturation power that will be evaluated below.

The amplifier gain G is defined as

$$G = \frac{P_{\text{out}}}{P_{\text{in}}} \qquad [2]$$

where P_{in} is the input power and P_{out} the output power of a continuous wave (CW) signal being amplified. The amplifier gain G may be found by using the relation:

$$\frac{\mathrm{d}P}{\mathrm{d}z} = g(\nu, P)P \qquad [3]$$

where $P(z)$ is the optical power at a distance z from the amplifier input end.

If the signal power obeys the condition $P \ll P_{\text{sat}}$ throughout the amplifier, the gain coefficient given by eqn [1] can be considered independent of the signal power. In such a case, the amplifier is said to be operated in the unsaturated regime and works as a linear device. The gain coefficient presents in this situation a Lorentzian profile that is characteristic of homogeneously broadened two-level systems. However, the gain spectrum of actual amplifiers can deviate significantly from the Lorentzian profile.

The solution of eqn [3] in the unsaturated regime is an exponentially growing signal power, given by

$$P(z) = P_{\text{in}} \exp(gz) \qquad [4]$$

For an amplifier length L, we then find that the linear amplifier gain is

$$G(\nu) = \exp(gL) = \exp\left[\frac{g_0 L}{1 + (\nu - \nu_0)^2/\Delta\nu_0^2}\right] \qquad [5]$$

Both the amplifier gain $G(\nu)$ and the gain coefficient $g(\nu)$ are maximum when $\nu = \nu_0$. However, $G(\nu)$ decreases much faster than $g(\nu)$ with the signal detuning $\nu - \nu_0$, because of the exponential dependence of G on g. As a consequence, the amplifier bandwidth $\Delta\nu_{\text{A}}$, which is defined as the FWHM of $G(\nu)$, is much smaller than the gain bandwidth $\Delta\nu_0$ (Figure 1). This can result in signal distortion in the case where a broadband optical signal is transmitted through the amplifier. From eqn [5] we can obtain the following relation between the amplifier bandwidth and the gain bandwidth:

$$\Delta\nu_{\text{A}} = \Delta\nu_0 \sqrt{\frac{\ln 2}{g_0 L - \ln 2}} \qquad [6]$$

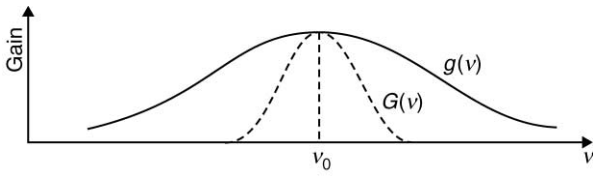

Figure 1 Gain coefficient profile $g(\nu)$ and the corresponding amplifier gain spectrum $G(\nu)$.

Gain Saturation

An important limitation of the nonideal amplifier is related with the power dependence of the gain coefficient given by eqn [1]. This property is known as gain saturation and it appears when the signal power ratio P/P_{sat} is non-negligible. Since the gain coefficient is reduced when the signal power P becomes comparable to the saturation power P_{sat}, the amplifier gain G will also decrease.

Assuming that $\nu = \nu_0$ and substituting g from eqn [1] in eqn [3] gives

$$\frac{\mathrm{d}P}{\mathrm{d}z} = \frac{g_0 P}{1 + P/P_{\text{sat}}} \qquad [7]$$

Considering the initial condition $P(0) = P_{\text{in}}$, we obtain from eqns [2] and [7] the following implicit relation for the amplifier gain:

$$(1 - G)\frac{P_{\text{in}}}{P_{\text{sat}}} = \ln\left(\frac{G}{G_0}\right) \qquad [8]$$

where $G_0 = \exp(g_0 L)$. The input saturation power P_{in}^{s} is defined as the input power for which the amplifier gain G is reduced by a factor of 2 from its unsaturated value G_0 (Figure 2). Indeed, it is obtained by using $G = G_0/2$ in eqn [8]:

$$P_{\text{in}}^{\text{s}} = \frac{2\ln(2) P_{\text{sat}}}{(G_0 - 2)} \qquad [9]$$

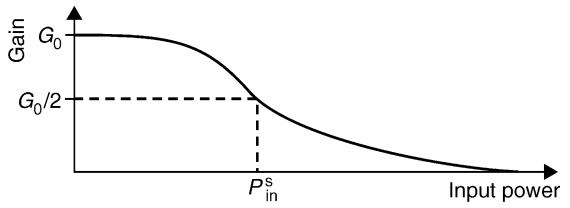

Figure 2 Saturated amplifier gain as a function of the input power.

As observed from eqn [9], the input saturation power P^s_{in} does not coincide with P_{sat}. The output saturation power is given by $P^s_{out} = G_0 P^s_{in}/2$. In practice, $G_0 \gg 2$ and P^s_{out} is found to be smaller than P_{sat}, by about 30%.

Gain saturation can be seen as a serious limitation, particularly for multichannel communication systems. However, the self-regulating effect of gain saturated amplifiers can be useful in long-haul lightwave communication systems, including many concatenated amplifiers. In fact, if the signal level in a chain of amplifiers is unexpectedly increased along the chain, the saturation effect causes a lower gain provided by the following amplifiers and vice versa for a sudden signal power decrease.

Amplifier Noise

Besides the bandwidth and gain saturation limitations, another property must be considered concerning practical optical amplifiers. In fact, optical amplifiers always add spontaneously emitted photons to the signal during the amplification process. Those photons are amplified besides the signal photons so that, at the amplifier output, an amplified spontaneous emission (ASE) noise is presented. Since spontaneous emission always takes place, ASE noise is unavoidable and does not depend on the amplifier temperature. This is one of the most important differences between optical and electrical amplifiers, where amplifier noise is of thermal origin and can be reduced by lowering the amplifier temperature.

The ASE determines a degradation of the signal-to-noise ratio (SNR). The SNR degradation is usually characterized by the amplifier noise figure, which is defined as the SNR ratio between input and output:

$$\mathrm{NF} = \frac{\mathrm{SNR}_{in}}{\mathrm{SNR}_{out}} \qquad [10]$$

The SNR is usually referred to the electrical power generated when the optical signal is converted to electrical current by using a photodetector. Therefore, the noise figure as defined in eqn [10] would usually depend on several detector parameters, which determine the shot noise and thermal noise associated with the practical detector. We will consider the case of an ideal detector, whose performance is limited by shot noise only.

The SNR of the input signal is simply determined by the detection shot noise and can be written as:

$$\mathrm{SNR}_{in} = \frac{P_{in}}{2h\nu\Delta f} \qquad [11]$$

where Δf is the detector bandwidth.

To evaluate the term SNR_{out}, one should add the contribution of spontaneous emission to the receiver noise. The ASE noise spectral density is assumed to be constant and can be written as

$$S_{sp}(\nu) = (G-1)n_{sp}h\nu \qquad [12]$$

where G the amplifier gain and

$$n_{sp} = \frac{N_1}{N_1 - N_0} \qquad [13]$$

is known as the spontaneous emission factor or the population inversion factor. In eqn [13] N_0 and N_1 are the atomic populations for the ground and excited states, respectively.

Considering a low noise amplifier, the signal power impinging the photodetector is larger than the optical noise power and the shot noise power. As a consequence, the electrical noise, due to the signal-ASE beating, is the dominant contribution and the SNR of the amplified signal is given by:

$$\mathrm{SNR}_{out} \approx \frac{GP_{in}}{4S_{sp}\Delta f} \qquad [14]$$

Using eqns [11]–[14], the amplifier noise figure defined by eqn [10] becomes:

$$\mathrm{NF} = 2n_{sp}\frac{G-1}{G} \approx 2n_{sp} \qquad [15]$$

where the approximation holds when the gain is much higher than one. In the case of an ideal amplifier, $n_{sp} = 1$ and eqn [15] show that the SNR is degraded by 3 dB. For most practical amplifiers, NF can be as large as 6–8 dB.

Basic Amplifier Configurations

The relative importance of the different limiting factors discussed above depends on the actual

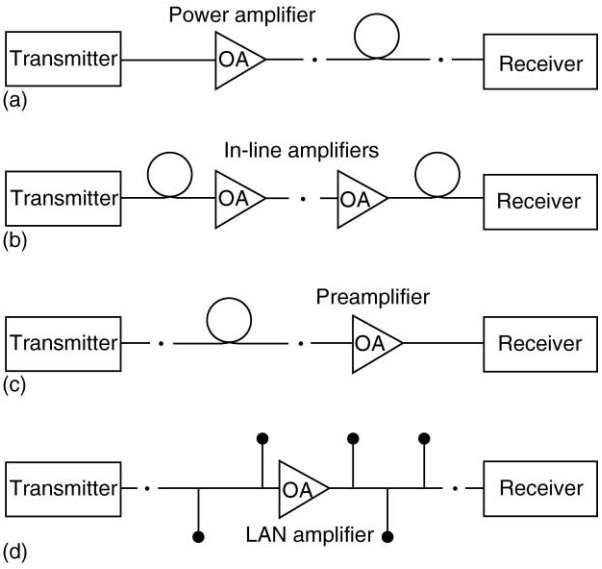

Figure 3 Four generic configurations for incorporating optical amplifiers into transmission systems: (a) as a power amplifier; (b) as in-line amplifiers; (c) as a preamplifier; (d) for compensation of distribution losses in local-area networks.

amplifier application. Figure 3 shows the four basic system configurations envisioned for the incorporation of optical amplifiers. The first configuration is to place the amplifier immediately following the laser transmitter to act as a power amplifier or booster (Figure 3a). The main purpose of such amplifiers is to boost the signal power, which can provide an increase of the transmission distance by 100 km or more. Since the signal input power is typically large (0.1–1.0 mW), the key parameter for the power amplifier will be to maximize the saturation output power and not necessarily the absolute gain.

The second configuration is to place the amplifier in-line and perhaps incorporated at one or more places along the transmission path (Figure 3b), replacing the electronic regenerators. The in-line amplifier corrects for periodic signal attenuation and may exist in a cascade form. The use of in-line optical amplifiers is particularly attractive for multichannel communication systems, since they can amplify all channels simultaneously.

The third configuration consists of using the amplifier immediately before the receiver, so it functions as a preamplifier (Figure 3c). The purpose of such an amplifier is to improve the receiver sensitivity. The main figures of merit are high gain and low amplifier noise, because the entire amplifier output is immediately detected.

In local-area networks (LANs), distribution losses often limit the number of possible nodes. The fourth application of optical amplifiers consists of using them for compensating such distribution losses (Figure 3d).

List of Units and Nomenclature

g_0	peak value of the gain coefficient at peak	m^{-1}
$g(\nu)$	gain coefficient	m^{-1}
G_0	unsaturated amplifier gain	
$G(\nu)$	amplifier gain	
L	amplifier length	m
n_{sp}	spontaneous emission factor	
P	signal power	W
P_{in}	input signal power	W
P_{in}^{s}	input saturation power	W
P_{out}	output signal power	W
P_{out}^{s}	output saturation power	W
P_{sat}	saturation power	W
$S_{sp}(\nu)$	ASE noise spectral density	J
Δf	detector bandwidth	Hz
$\Delta\nu_0$	bandwidth of the gain coefficient	Hz
ν	optical frequency	Hz
ν_0	atomic transition frequency	Hz

Introduction

The telecommunications industry has undergone a revolution since the 1980s, by using glass optical fibers for the transmission of information encoded as pulses of light. A single telecommunications-grade optical fiber has been shown to support the propagation of more than 1 Tbit per second (1×10^{12} pulses per second) over distances comparable to typical city separations (>100 km). From this technology, optical fiber links have evolved to become a network on a planet-wide scale, and form the physical backbone of the information age.

Erbium-doped fiber amplifiers (EDFAs) are an enabling technology for optical fiber communication networks. They have several important properties that make them the amplification component of choice in long-distance commercial data transport networks. Erbium ions deposited in silica-based glass allow amplification in the lowest loss region of commercial-grade optical fiber (<0.25 dB/km from approximately 1530–1620 nm). Erbium-doped fiber (EDF) is manufactured in a form that allows for low-loss fusion splicing to standard communications fiber. Compact semiconductor laser diodes are available to excite the erbium ions into an amplification state. The long lifetime of the excited state of erbium provides the ability to simultaneously amplify multiple wavelength channels without significant cross-channel interference. Multiple channel systems have been deployed with more than 100 optical channels (or wavelengths) through each EDFA, and this has allowed network capacities to be dramatically increased. The low noise properties of the EDFA also allow networks to be constructed with many amplified spans before the optical signal has to be electronically regenerated. Practically unlimited transmission distance has been demonstrated using a small number of optical soliton channels through periodically amplified EDFA lightwave systems.

The development history of the EDFA can be traced back to the first optical amplifier. In 1962, a neodymium-based fiber amplifier was invented that operated at 1064 nm. During the 1980s, the need for an optical amplifier at telecommunications wavelengths initiated research at many locations throughout the world. In 1987, the University of Southampton (UK) was first to demonstrate an EDFA that had optical gain at 1550 nm, and during the following years the design of erbium-doped fiber was optimized for this application. In 1989, a practical semiconductor laser diode became available to pump EDF, and the first compact optical fiber amplifier modules soon appeared for commercial deployment. The traditional method of signal regeneration, prior to 1990, was to use electronics to detect the optical signal after each transmission span, recover the digital signal, and then retransmit using another laser diode. The EDFA allows practical wavelength division multiplexing (WDM) of multiple optical signals with all optical signal amplification, and provides significant performance and cost advantages over electronic regeneration.

EDFAs have emerged from the laboratory to be widely deployed in communication networks. EDFAs are used to boost transmitted power of the signal lasers (booster amplifier), amplify signals in transit to compensate losses sustained in the fiber (line amplifier), or amplify signals before a receiver (pre-amplifier). Typically, the amplifier module is specifically manufactured for particular systems that are mounted on electronic circuit boards. These circuit packs are then housed in central offices (local telephone exchanges), remote 'repeater huts', or even in undersea 'bottles' as part of a transoceanic cable. The high cost of network failure requires that the manufactured EDFA modules comply with stringent reliability criteria, to provide a useful operating lifetime greater than 25 years when subject to extreme environmental conditions.

Amplifiers are constructed for incorporation into either existing fiber links as part of an upgrade, or for newly planned systems. Because of the high cost of installing new fiber into the ground and securing property rights, it has become economically desirable to upgrade many existing fiber links rather than to build new systems. Transmission cables usually have many pairs of individual optical fibers, some of which will not initially be transporting data, and these 'unlit' or 'dark fibers' can be activated as consumer demand increases over time. Typically, each fiber of a pair is used to carry either 'east'- or 'west'-bound traffic. Around city areas metropolitan area networks can be expanded in this way, but for long-distance links (long haul networks with distances >1000 km) operation is designed for a larger number of channels (40 to 120 wavelengths) at higher data rates (10 or 40 GHz per channel) over specialized transmission

cables containing low numbers of fiber pairs. Typically communication systems are designed to meet certain cost targets, expressed as dollars per Gbit/s per km, for total transmission distances. The total transmission distance is limited by the optical signal to noise ratio (OSNR) degradation after each fiber-amplifier link, with a smaller permissible degradation at higher bit rates. The required gain and OSNR performance for the system is then translated to an EDFA module specification.

This article discusses EDFA design and applications, and shows the elements involved in producing reliable modules for commercial lightwave systems.

Components for EDFAs

EDFAs are comprised of passive optical components, erbium-doped fiber, and pump lasers. Passive components are chosen to meet optical and environmental specifications, while the erbium-doped fiber is selected based on the optical power, gain, and noise figure requirements. Pump lasers are a key influence on the price and performance of optical amplifiers.

The amplifier module is typically connected to the transmission fiber using fiber connectors. These polished fiber connectors have a higher insertion loss and reflectivity than fusion splicing, but allow for easy deployment in the network. Internal optical components are fusion spliced together to provide low loss, low back reflection, high strength, and high reliability joins. Fusion splicing is tailored to particular fiber types, so that optical components with dissimilar fiber types are joined with the lowest loss.

The signal and pump radiation is combined with low loss using optical components called wavelength division multiplexers (see **Figure 1**). These components are based on fused fiber or interference filter based technology. Fused fiber WDMs offer the lowest insertion loss (<0.1 dB is commercially available) but is restricted to widely spaced wavelengths (e.g., 980 nm pump and 1550 nm signal). Interference filter based WDMs are available for closely spaced wavelengths (e.g., 1480 nm pump and 1530 nm signal) and have a very low wavelength dependent insertion loss (flatness). Interference filters can be designed to produce sharp low-pass, high-pass, or bandpass type filters suitable for combining closely spaced wavelengths, as well as broader peaks suitable for lowering the gain in particular signal wavelength regions to produce gain flattened amplifiers.

Signal reflections can cause an amplifier to act as a laser, and this detrimental effect is eliminated in EDFAs by using optical isolators. In an isolator the signal light is coupled out of the single-mode fiber through a graded index (GRIN) lens and passes through a nonlinear crystal before being coupled back into the optical fiber. The isolator consists of a birefringent rutile (TiO_2) or Yttrium OrthoVanadate (YVO_4) wedge, followed by a Yttrium Iron Garnet (YIG) Faraday rotator, followed by another birefringent wedge. The YIG crystal is surrounded by a permanent magnet that rotates the light's polarization by 45 degrees. The 45-degree polarization rotation, coupled with the two birefringent wedges, ensures that light is efficiently coupled to the output fiber but not in the reverse direction. Commercial isolators are available with low insertion losses across the signal band, with some samples below 0.35 dB. Note that the YIG crystal works well for the 1480 nm pump and 1530–1620 nm signal bands, but currently there is no suitable isolator material that covers 980 to 1550 nm and this puts some limitations on certain EDFA designs.

The isolator design has been extended to make multiport circulators. A three-port circulator has the input into port 1 and output of port 2, light entering port 2 is directed to port 3, and light entering port 3 is blocked with an isolator. The circulator allows for adding and dropping of individual channels when a

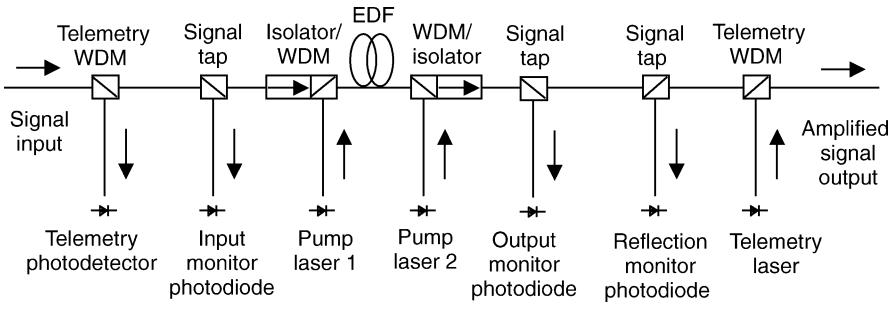

Figure 1 Single-stage EDFA with features.

narrow bandwidth reflective filter is placed on port 2. Circulators also can be used to separate co-propagating and counter-propagating traffic on a single transmission fiber before amplification is done.

Erbium-doped fiber has two strong absorption bands around 980 nm and 1480 nm that are suitable for achieving a population inversion in the erbium ion. The 980 nm wavelength allows low noise amplification, while 1480 nm lasers provide higher EDFA output. 980 nm pump lasers usually incorporate fiber Bragg gratings to stabilize the laser wavelength to match the narrow EDF absorption peak, and also have lower drive current requirements. A 1480 nm pump can provide more amplification, since there are more photons in each mW of laser power at 1480 nm than 980 nm. High-output power pump lasers incorporate thermo-electric coolers (TECs) within the pump laser package and can provide fiber coupled power greater than 500 mW. Both high-power lasers have been qualified to meet the most stringent reliability standards, with typical mean time before failure beyond 25 years. Low-cost 980 nm pump lasers, that do not have TECs, are also available in smaller packages and can supply up to $\sim$200 mW. By using wavelength division or polarization combining techniques, it is possible to further increase the available pump power in the erbium fiber.

The EDFA module is assembled into a package that may contain passive optical components, several meters of coiled EDF, pump lasers, photo-detectors, and electronic circuit boards. In some cases, it is advantageous to thermally stabilize the components so that the amplifier performance can be maintained when exposed to extreme environmental conditions. This may occur when the central office's environmental control is compromised (e.g., air conditioning failure). In particular, EDF can exhibit undesirable spectral gain changes if the ambient temperature changes by more than 5 °C.

Pump lasers with internal TECs can dissipate more than 5 Watts of heat per laser and since cooling fans usually do not have the required reliability, passive cooling is commonly used in the module in the form of a metal heat sink. The amplifier module's size can be compact, limited by the height of optical components or pump laser diodes, or by the size of a built-in heat sink. The module is designed to survive conditions of electrostatic discharge, humidity, temperature, thermal shock, extreme vibration, and other stresses that may be inadvertently present during operation in the field. In addition, all material in the EDFA module is also qualified against problems with out-gassing (e.g., hydrogen release), combustion and chemical or biological exposure.

The Single-Stage Amplifier

A simple single-stage EDFA consists of an erbium-doped fiber spool with signal and pump combining multiplexer. The fiber is optically pumped by 980 nm and/or 1480 nm laser(s), whose light is coupled into the signal fiber by a passive component called an optical multiplexer. The pump wavelengths are readily absorbed by erbium ions embedded in silica raising them to an excited state. Amplification occurs when, stimulated by a nearby signal photon, an excited erbium ion relaxes back to the ground state producing a second, identical signal photon. The erbium ion can be approximated as a three-level atomic system that can be completely inverted by a 980 nm photon, to provide the lowest noise amplification. In contrast, the 1480 nm pump will excite the erbium ion directly into the upper laser level as a two-level system, and because of rapid spontaneous emission from this level, the maximum inversion in this case cannot exceed approximately 75%. Note that as the pump photons are absorbed, the inversion will be nonuniform along the EDF length.

There are two signal wavelength regions commonly amplified by EDFAs, the C-band (conventional band) from approximately 1528 to 1565 nm, and the L-band (long band) from approximately 1570 to 1620 nm. Amplification in the C-band readily occurs when moderate pump power is available, and relies on the erbium ion's spectral absorption and emission wavelength window that is suited to high levels of atomic inversion. L-band amplification is also achieved with moderate pump powers, but because of the lower absorption and emission cross-sections, similar gain is reached using approximately five times more EDF with a lower average inversion. The C-band amplifier is typically less costly because less EDF is used, while high-concentration erbium fibers are available specifically for L-band EDFAs.

An EDFA's most critical performance parameters are its amplified signal output power (typically stated in dBm) and its noise figure (stated in dB). Output power is mainly determined by total pump power and the amplifier internal loss. The noise figure (NF) is defined as the ratio of the signal-to-noise ratio at the input to the signal-to-noise ratio at the output.

A single-stage amplifier typically has 1 or 2 pump lasers but can have more if polarization- or wavelength-pump-combining is implemented for higher power. When the pump radiation propagates in the same direction as the signal, the amplifier is co-pumped, while counter-pumping denotes the case when the pump laser propagates against the signal. For a single pump, a co-pumping 980 nm

laser minimizes the NF (suitable for a pre-amplifier) while counter-pumped 1480 nm architecture optimizes output power at some expense to the NF (suitable for a booster amplifier). Recent semiconductor pump laser improvements have enabled 980 nm pump lasers with output powers >500 mW to be commercially available, allowing most single- or dual-stage EDFAs to be energized by one laser.

Single-stage designs can be enhanced, as shown in Figure 1. To control the network an optical signal may be used as a telemetry or network supervisory channel, and this is removed with a filter. Telemetry wavelengths are usually outside of the useful EDF amplification window, and commonly range from 1500–1520 nm and from 1620–1640 nm. An isolator may be used at the input and/or output to prevent pump laser or amplified spontaneous emission from the erbium-doped fiber 'leaking' into the transmission path. Optical taps may be included to provide information about signal spectra at the input and output sides. Their feedback can be used to control pump laser biases for tuning output power, monitoring amplifier performance, or simply to trigger alarms. In addition, a reflection monitor is sometimes placed at the output to observe backwards propagating optical signals arising from reflections. Electronics in the module will continuously monitor the pump lasers and photodetectors and, for example, can place the module in an 'eye-safe' low-output power (<10 mW) mode within milliseconds if a transmission fiber break is detected through increased back-reflected optical power.

The amplifier has a signal input power of −30 to −10 dBm (1–100 μW) for each optical channel, and has a gain of 25 dB to compensate for a typical span loss of 100 km optical fiber link. This signal level allows high powers at the receiver photodetector for high-quality signal detection, yet is low enough to avoid nonlinear propagation effects in the transmission fiber. The typical total output signal power of an 80 channel (wavelength) C-band EDFA is less than 200 mW (+23 dBm) to avoid stimulated Raman scattering (SRS) in standard transmission fiber. The use of improved low nonlinearity transmission fibers and longer transmission distances can lead to specified total EDFA output powers to be greater than 400 mW (+26 dBm). To provide the best performance, the amplifier usually will allow only a single direction of propagation, with bi-directional communications systems using one transmission fiber and circulators to separate 'east' and 'west' traffic into individual EDFAs.

Figure 2 shows the results of a numerical simulation for a single-stage amplifier as a function of the input power and EDF length. The amplifier was assumed to have EDF with peak absorption of 5.5 dB/m near 1530 nm, and was pumped with 100 mW at 980 nm. The amplifiers signal loss before and after the EDF was taken to be 0.8 and 1.2 dB, respectively. As amplifier input power increases there is a decrease in gain provided by the medium since there is a fixed amount of pump power available. The maximum gain is usually achieved near 1530 nm where the difference between the EDF's emission and absorption cross-sections is greatest. Selecting the length of EDF is critical to achieving the desired performance, and this can be examined using numerical simulation for a wide range of design options.

Undersea systems, with their long distances and large costs of network failure, place stringent design requirements on EDFAs. These systems mostly use single-stage designs with emphasis on low noise operation. This can be achieved by eliminating most of the optical components prior to the EDF, and also by co-propagating a strong 980 nm pump using a low loss fused fiber WDM. Undersea repeaters are spaced by 30 to 80 km, shorter than terrestrial networks, with each channel operated at higher power to achieve multi-thousand kilometer distances. For example, the trans-Pacific TPC-5J cable spans 8600 km from Coos Bay, Oregon (USA) to Ninomiya (Japan), using EDFAs spaced every 33 km. The tight electrical power budgets available to each repeater (powered from land) necessitate using pump lasers without TECs. During installation, the EDFA will experience large mechanical shock, as the cable and metal repeater bottles are unwound aboard ship and dropped into the ocean. Other design considerations are done for operation at the constant ambient temperature of the ocean bottom (~+2 to 4 °C) or for seasonal temperature changes on the continental shelves, where the optics and EDF will operate at 15 to 30 degrees above ambient due to heating from the electronics.

Single-stage optical amplifiers are suited for a wide range of applications such as single-channel amplifiers, simple WDM amplifiers, and low-cost amplifiers. Using high-power pump lasers or combined pump laser schemes allows such amplifiers to deliver output powers >20 dBm. However, single-stage amplifiers cannot meet the requirements of all telecommunications architectures, leading to increasing demand for multiple-stage EDFAs that are discussed below.

Multiple-Stage EDFAs

The most common implementation of a multiple-stage EDFA is to improve the noise and output power

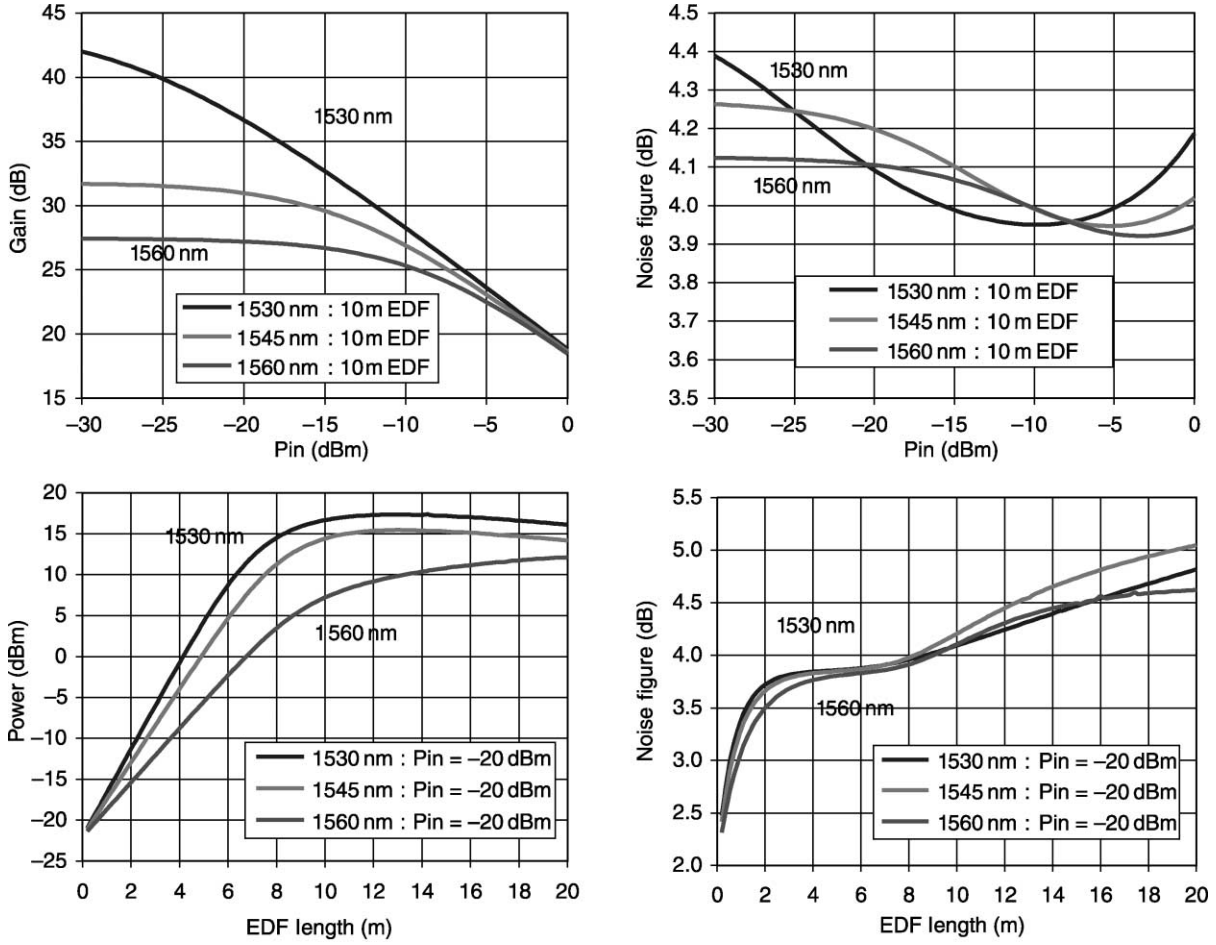

Figure 2 Typical single-channel performance of a single-stage EDFA.

characteristics by imbedding an optical isolator between two sections of EDF. The isolator blocks backward-traveling amplified spontaneous emission to improve the efficiency of the amplifier. This is shown in Figure 3 for two common single-pump designs. The first is the 'pump by-pass', design where the residual pump radiation from the first stage is redirected around the mid-stage isolator. This is often used when pumping with 980 nm since signal band optical isolators will not transmit 980 nm radiation. This design can introduce problems when using low-quality components as small signal levels can propagate around the pump by-pass fiber to create multiple path interference (MPI) effects. Although MPI effects can be eliminated by using a pump splitting coupler to directly pump each EDF section, the pump by-pass design makes the most efficient use of available pump power. The second design is called the 'pump through' design, and is used when pumping at 1480 nm since both the pump and signal band (e.g., 1550 nm) photons will transmit through commercial isolators with only small loss. Note that for cost and space constraints within the module, it is sometimes advantageous to use hybrid optical components, e.g., an isolator and WDM can be combined into one compact package.

An EDFA with multiple input signals will have a very nonuniform output gain profile. This is a consequence of the erbium ion's wavelength-dependent emission and absorption cross-sections in the host glass material. Figure 4 shows gain spectra for both C-band and L-band EDFAs with and without gain-flattening filters (GFFs). The gain spectrum is dependent on the EDF's chemical composition and EDFA design features. For an amplifier with 25 dB gain, a GFF with peak loss less than 10 dB is usually needed to correct for these gain deviations. Although many technologies are available for GFFs (e.g., thin-filter interference filters, Bragg gratings, tapered fiber filters, etc.) the basis function of these technologies is usually not identical to the EDF's gain profile, and this mismatch results in gain

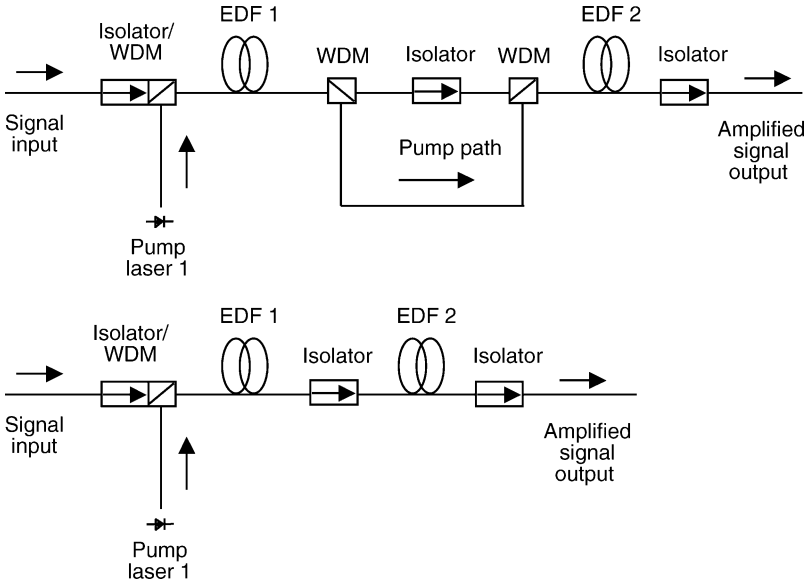

Figure 3 Imbedded Isolator EDFA designs.

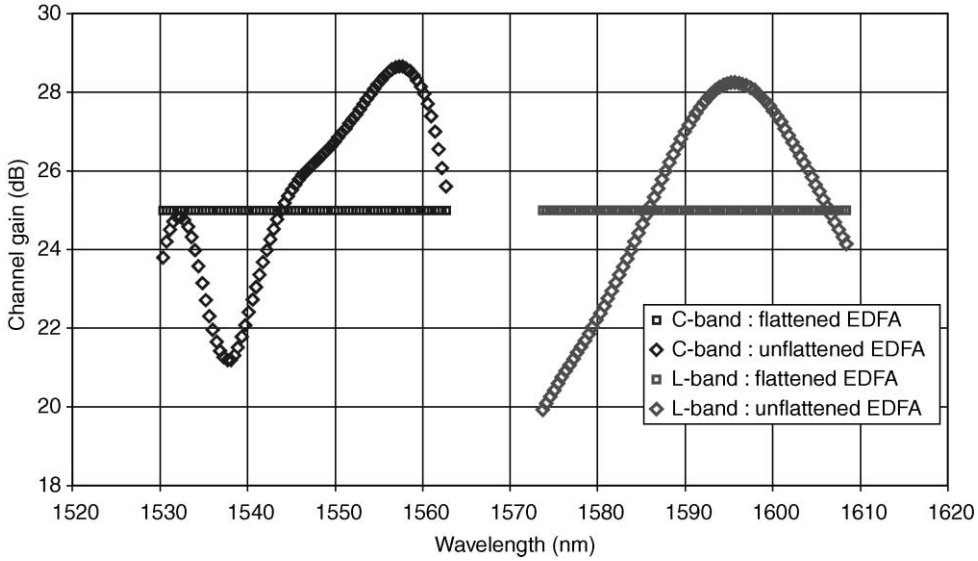

Figure 4 Gain spectrum of a multi-staged optical amplifier with and without gain flattening filters.

flatness error. However, when using these technologies, manufactured EDFAs can have a gain error (flatness) less than 1.0 dB over bandwidths greater than 35 nm.

Early EDFAs for WDM systems used 16 optical channels spaced by 200 GHz in the 1540 to 1560 nm part of the C-band. In this case, the EDF gain profile is relatively smooth and no GFFs are needed to achieve a 1.0 dB gain flatness specification. It is important to note that for a particular level of signal and pump power, a longer length of EDF in the EDFA will produce more gain at the long wavelength end of the spectrum, hence by shortening the EDF length in Figure 4 the result will be relatively flat gain from approximately 1540 to 1560 nm. As EDFA technology has matured, the EDF can be the bandwidth-limiting component in a system, and it has become necessary to use GFFs to realize useable bandwidths of up to 55 nm when using regular silica-based EDF. The most economic EDFAs operate in the C-band where relative to the L-band, pump laser efficiency is highest, EDF lengths are shortest,

and the chromatic dispersion of most installed transmission fiber limits nonlinear optical effects.

In single-stage amplifiers, the gain-flattening filter is at the amplifier output, and this results in lost output power. Wideband gain-flattened amplifiers usually have a multiple EDF stage design, with the GFF component between two EDF stages. The EDF sections that follow the attenuating GFF provide additional amplification, to give high power out of the EDFA module that has large internal losses.

In addition to GFF components inside the EDFA, an attenuator can be used to compensate for input signal power changes, which will produce a spectral gain rotation or tilt. The attenuator reduces the power on all optical channels equally and allows the amplifier to operate in a 'fixed gain' mode. In WDM systems, optical amplifiers may also need mid-stage access where the signal is fed into an external device between the amplifier stages. Reasons for doing this include monitoring, adding or dropping of individual channels, and dispersion compensation. Since additional losses up to 10 dB are introduced in the amplification path, the amplifier design has to be optimized for those losses.

Typical two-stage gain-flattened optical amplifier architecture is shown in Figure 5. Input and output couplers and telemetry WDMs can be included if required. A single pump can be split and shared between stages to save cost. When multiple pumps are needed, the most common configuration is a 980 nm pump laser co-pumping the first stage (EDF1) for low noise and a 1480 nm laser counter-pumping the second spool (EDF2) for high gain. A significant loss element, e.g., a gain-flattening filter, add/drop module or dispersion compensation module, is situated between the stages. Note that mid-stage access can be located before or after the gain flattening or between additional EDF stages. The gain spectrum of multistage gain-flattened EDFAs is shown in Figure 6, showing the gain equalization possible using a multistage amplifier design and gain-flattening filters. Using deeper GFFs can increase the usable bandwidth of the amplifiers, but this requires higher-power pump lasers to maintain the same gain and optical signal-to-noise ratio (OSNR) performance.

The two-stage EDFA shown in Figure 5 highlights a common problem for amplifier design. Given high-grade optical components and pump lasers, what

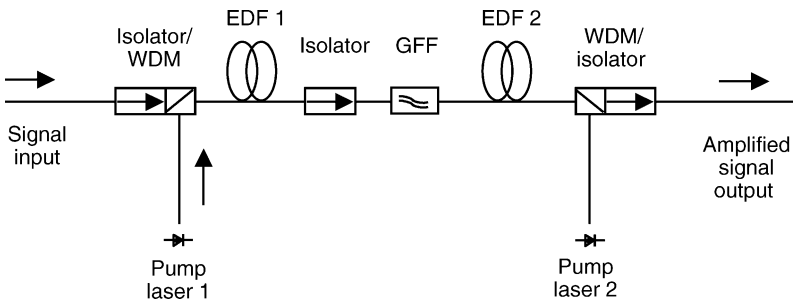

Figure 5 Typical multistage gain-flattened optical amplifier architecture.

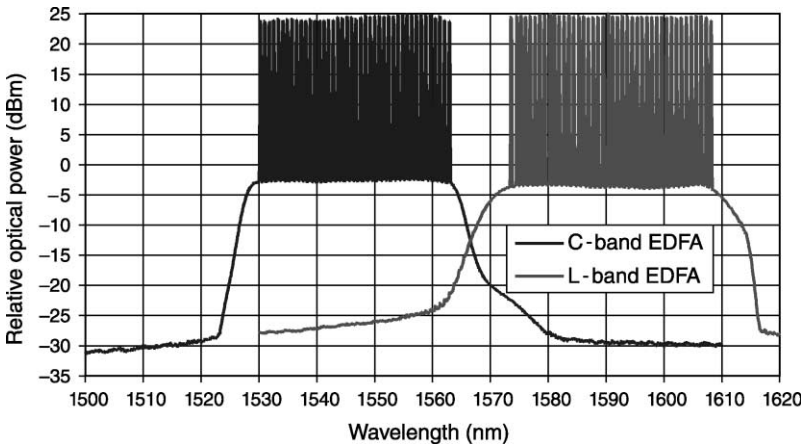

Figure 6 Measured gain and noise spectra of multistaged gain-flattened C-band and L-band EDFAs.

length of erbium-doped fiber should be used to give the best amplifier performance? This question is best answered by using the results of extensive numerical simulations of the optical amplifier.

Figure 7 shows the results of numerical simulation for a two-stage amplifier as a function of the first and second EDF stage lengths. The amplifier was assumed to have EDF with a peak absorption of 5.5 dB/m near 1530 nm, and was pumped with 130 mW at 980 nm in the first stage and 160 mW at 1480 nm in the second stage. The total input power was assumed to be −2.5 dBm for 80 channels distributed from 1530 nm to 1563 nm. Note that each of the 80 channels is separated by 100 GHz, and will generally support a long-distance communications system with each wavelength modulated at 10 GHz.

Figure 7a shows that the optical output power is largest when both EDF stages are approximately 20 meters. For this design, EDF lengths significantly longer than 20 meters will produce less output power, since the pump radiation will have been completely absorbed in the first few meters of EDF. The spectral gain flatness is shown in Figure 7b. For this design, approximately 17 meters of EDF was needed to produce a flat gain spectrum, i.e., each optical channel had the same gain. Other combinations of EDF lengths were not matched to the particular gain-flattening filter and produced large gain variations across the band. In general as the amplifier's total EDF length increases the gain spectrum exhibits a positive tilt (e.g., longer wavelength channels will experience more gain). Figures 7c, d show the average channel and maximum channel NF, respectively. From a system design perspective, a link can be limited by the optical channel with the lowest optical signal-to-noise ratio (OSNR) or highest noise figure, and this is a critical parameter of interest when designing optical amplifiers. In practice the best amplifier design is a compromise between high-gain, low-gain flatness, and low NF. From extensive numerical simulations, for the two-stage gain flattened amplifier example it was for

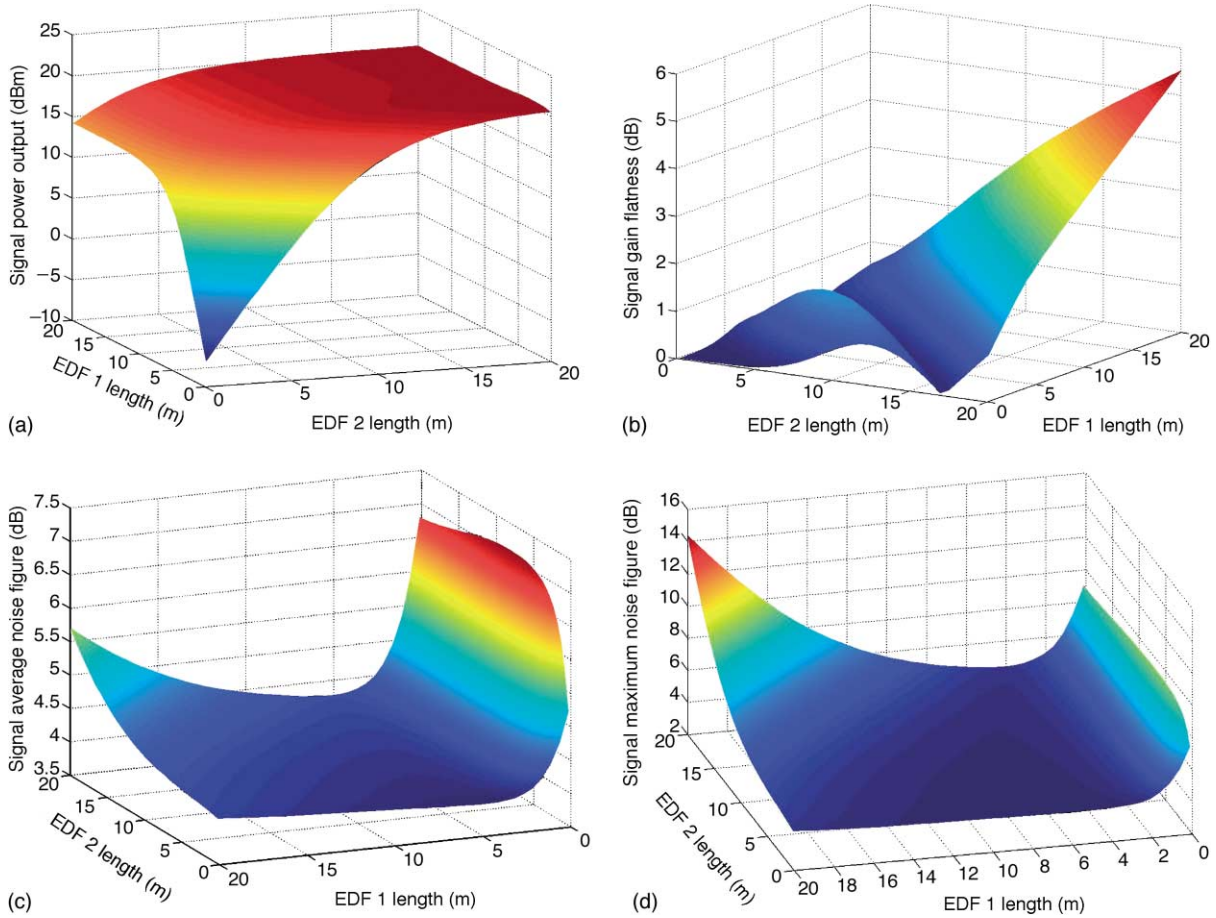

Figure 7 (a) Total output power, (b) spectral flatness, (c) average noise figure, and (d) maximum channel noise figure of a two-stage optical amplifier with a gain-flattening filter.

approximately 4 meters in EDF stage 1, and 13 meters in stage 2.

Successful commercial EDFA products are more than a single amplifier design that can accommodate all applications. In some cases an economical solution is a modular design approach, where smaller capacity, lower-cost amplifiers are initially installed in a network. Additional gain can be added to the basic amplifier for longer-distance spans or as network traffic increases over time. This 'pay as you grow' approach can be done using additional gain stages, or pump lasers, and can be upgraded without interruption of revenue-generating network traffic.

Low-Noise Design of EDFAs

A key design feature of commercial EDFAs is low-noise operation since the degradation of the OSNR limits the reach of the system. The NF of an EDFA can be defined as

$$\mathrm{NF} = \mathrm{SNR_{in}}/\mathrm{SNR_{out}} \qquad [1]$$

The NF can also be calculated from

$$\mathrm{NF} = \frac{1}{G} \times \left[\frac{P_{\mathrm{ASE}}(\nu_s, L)}{h\nu_s} + 1 \right] \qquad [2]$$

where P_{ASE} is the amplified spontaneous emission (ASE) noise power at the signal frequency ν_s for an EDFA of gain G (h = Plancks constant). An alternative equation for the NF for a single section of EDF is

$$\mathrm{NF} = \int_0^L \frac{\gamma_e(\nu_s, z) - \gamma_a(\nu_s, z)}{P_s(z)} \times P_s(0)\mathrm{d}z + 1 \qquad [3]$$

where γ_e and γ_a are the EDF emission and absorption factors at the signal frequency ν_s, at distance z along the amplifying fiber. Equation [3] shows that low NF can result from rapid signal gain in the initial fiber along the EDF. This result indicates that co-propagating pump and signal photons, both into the same end of the EDF, combined with the maximum inversion obtained by using a 980 nm pump, will result in low-noise amplification. The NF is typically expressed in dB units, and using a full quantum mechanical theory, the lowest possible NF for a fully inverted EDF with a large signal gain can be shown to be approximately 3 dB. Actual EDFAs will only approach the '3 dB quantum noise limit' when the signal is significantly lower than the available pump power (e.g., low channel count applications) so that high inversion can be maintained along the EDF length. Optical components in the EDFA prior to the first EDF will attenuate the signal but not the noise, since ASE is only generated in the EDF, and this input stage loss will directly add to the EDFA's NF.

The use of 1480 nm pump lasers can also result in a further NF penalty of 0.3 to 1.5 dB since complete inversion cannot be achieved when the erbium ions are operating as a two-level atomic system and more ASE is generated. The ASE, like the signal gain, has a wavelength-dependent spectral profile and this results in each channel having a different NF. Typically, the optical channel with the largest NF (lowest OSNR) is used to define the EDFA's noise performance. EDFAs with low-input signal power (e.g., −15 dBm) and high gain (e.g., 25 dB) may be described as low noise when the NF is <4 dB. For large total input signal power (e.g., +2.5 dBm for high channel count operation) low noise may be NF < 5 dB.

For an amplifier with multiple EDF sections, the noise figure can be calculated from

$$\mathrm{NF_{System}} = \frac{\mathrm{NF}_1}{L_1} + \frac{\mathrm{NF}_2}{L_1 G_1 L_2} + \ldots + \frac{\mathrm{NF}_N}{L_1 G_1 L_2 G_2 \ldots L_{N-1} G_{N-1}} \qquad [4]$$

where L_i is the signal loss prior to the gain G_i of the EDF stage i. From eqn [4], multistage amplifiers with large inter-stage losses will have numerically larger NFs, but the total module NF is dominated by the first EDF stage. Undersea EDFAs, with a single short EDF section, very small L_i and 980 nm pumping, can have NF <3.5 dB.

Advanced EDFA Functions

An important trend in optical amplifiers, and systems in general, is the move towards dynamic control. Several technologies are being considered and the primary idea is to dynamically control the intensity level of each optical channel or wavelength to correct for any gain/loss inequalities in the network. This is particularly important as channel counts and bit rates rise concurrently with the functionality demanded of optical communication networks. A common requirement in this category is fast amplifier response so that in a network where individual optical channels can be added or dropped there are no power distortions at other surviving wavelengths. In a typical drop event, in less than 1 microsecond, 31 of 32 wavelengths can be completely removed from the input to the EDFA by an add/drop module located elsewhere in the network. This event will cause a total input power decrease of 15 dB and without rapid pump power adjustment the remaining channel will be excessively amplified.

Erbium ions have an excited state lifetime of approximately 10 ms, and this sets the time-scale for the transient signal response. A network transient usually manifests as a sharp optical amplifier (OA) gain fluctuation lasting up to several tens of microseconds that will pulse large signal levels through the entire optical network. Dynamic network loading necessitates controlling temporal gain transients, and this may be achieved by using a microprocessor in the amplifier module. These intelligent EDFA modules can rapidly adjust the pump laser power based on feedback from internal photo detectors to control gain transients.

The need for dynamic control also exists in the frequency domain. Wideband amplifiers have a gain variation among the optical channels of typically up to 1 dB over all operating conditions, and since these EDFAs are concatenated over many spans the electronic receiver circuit at the end of the network will have to detect optical channels with widely varying power levels. This can limit the number of spans that the network can bridge before electronic regeneration becomes necessary. This problem can be corrected using a dynamic gain equalizing filter (DGEF) to actively attenuate individual optical channels levels. A DGEF can be embedded inside an amplifier to create a loss-less component, and can be used to equalize channel powers for an entire network.

The problems of accumulation of gain ripple become more apparent in systems that employ amplifiers based on stimulated Raman scattering. A conventional EDFA amplified system may have 10 spans transmitting 100 optical channels at 10 Gbit/s each over a distance of approximately 800 km before electronic regeneration becomes necessary. To span longer distances with higher capacity, Raman amplifiers are used to amplify the transmission fiber along with EDFAs. This system architecture has the advantage of a higher effective OSNR for the individual spans, and has been demonstrated for distances over 4000 km with 40 Gbit/s channels. However, the variability of the Raman amplifier gain, due to network loading and differing transmission fiber properties, necessitates the use of loss-less DGEFs.

High-capacity transmission uses individual channels that are each modulated up to typical 2.5, 10, or 40 GHz, that requires that the optical amplifiers have low polarization mode dispersion (PMD) and low chromatic dispersion (CD). Polarization mode dispersion distorts the temporal spread of an ultra-short pulse as different polarization states travel at different speeds through the transmission fiber and amplifier components. PMD is particularly a problem in the first generation of installed transmission fiber and through polarization components (e.g., isolators) that are not PMD compensated. Without PMD compensation, 40 Gbit/s transmission, for example, can be limited to very short distances (several km). Fortunately, PMD compensators have been developed for upgrading aged installed networks, and also amplifiers are available with very low PMD.

To achieve long-distance transmission, a chromatic dispersion map is produced for all the optical spans, and by using a dispersion compensating module in each amplifier, the net dispersion across the channel wavelength window is controlled. Although optical amplifiers have approximately 1000 times less optical fiber in them compared to the transmission span that it is amplifying, chromatic dispersion in the amplifier can also be of concern for very long-haul networks. The CD of the amplifier is primarily in the EDF, and is specific to the EDF's geometric and chemical composition. Furthermore, since the erbium ion is a resonant atomic system, there may be a pump and signal power contribution to the dispersion (resonant dispersion) that could degrade network performance. Characterization of these optical effects is typically done on manufactured 'field grade' amplifiers as part of a quality control process.

Conclusion

As optical networks evolve EDFAs will continue to be an enabling technology for higher capacity and more dynamic communications networks. EDFA technology has already advanced to accommodate multiple channels, to span several wavelength windows and to provide features such as dispersion compensation, gain-transient suppression, and dynamic gain flatness. As future network architectures are introduced, to incorporate Raman amplification and additional wavelength windows, the demands placed upon EDFA design will continue to expand.

Introduction

Optical amplifiers have been a key element for enabling the development of optical transmission systems, which have reached total capacity in the order of a few terabits per second. The first type of optical amplifier to see application in the telecom industry has been the erbium-doped fiber amplifier. Following its invention in the late 1980s, the mid-1990s saw its industrial application in submarine and terrestrial transmission systems.

Since then, optical transmission systems have been the predominant source for transmitting information over distances ranging from a few 100 km to more than 10 000 km, connecting cities, countries, and continents.

This article will describe the applications of optical-fiber amplifiers in long-haul transmission systems, focusing on erbium-doped fiber amplifiers and Raman amplifiers, the most popular type of optical amplifiers used in modern transmission optical systems.

Fundamentals of Long-Haul Transmission Systems

This section explains the key elements and parameters of an optical transmission system.

Key Elements

An optical transmission system consists of a transmitter, a receiver, one or more optical amplifiers, and one or more spans of transmission fiber. Figure 1 shows a simplified schematic of a bidirectional transmission system using a fiber pair.

Optical amplifiers are used to compensate for the loss of the transmission fiber and the other optical elements placed along the signal path. Boosters and pre-amplifiers refer to optical amplifiers which are located at, respectively, the input end and output end of the system. In-line amplifiers refer to optical amplifiers located between the transmission fiber spans.

The transmitter includes laser diodes to generate the signal power and optical modulators to transfer the data stream from the electrical input signals to optical signals. The optical signal is transmitted to the receiver after traveling through the transmission fiber. At the receiver are located the photodiodes, which transfer back the information into electrical output signals. In order to increase the total bandwidth of the transmission system, time-division multiplexing (TDM) and wavelength-division multiplexing (WDM) can be used. TDM techniques combine the electrical domain data stream of several electrical channels, which is carried by a single optical channel. An optical channel refers to an optical signal located at a particular wavelength and modulated with the transmission data. TDM increases, therefore, the bit rate supported by the optical channel. Typical bit rates used in modern optical transmission systems are 2.5 Gbit/s and 10 Gbit/s. With WDM, several optical channels are combined, in the optical domain, into a single optical beam, which is launched into the transmission fiber. For this technique, optical multiplexers (Mux) and de-multiplexers (Demux) are required at, respectively, the transmitter and the receiver.

Long-haul transmission systems typically operate at wavelengths around 1.5 μm, where the attenuation of fibers is the lowest. We label C-band the region located between 1530 nm and 1565 nm. Its lower bound is labeled S-band; the upper bound the L-band.

Apart from attenuation, several other effects existing in fiber can be responsible for degrading the quality of the transmission. Among those is chromatic dispersion, which distorts the optical signal as it travels along the transmission fiber. Several types of fiber have been deployed with different chromatic dispersion characteristics. The most common one is the standard single-mode fiber (SSMF), which has a zero-dispersion wavelength – wavelength for which no chromatic dispersion is observed – near 1.3 μm. The dispersion-shifted fiber (DSF) has a zero-dispersion wavelength near 1.55 μm, and the nonzero

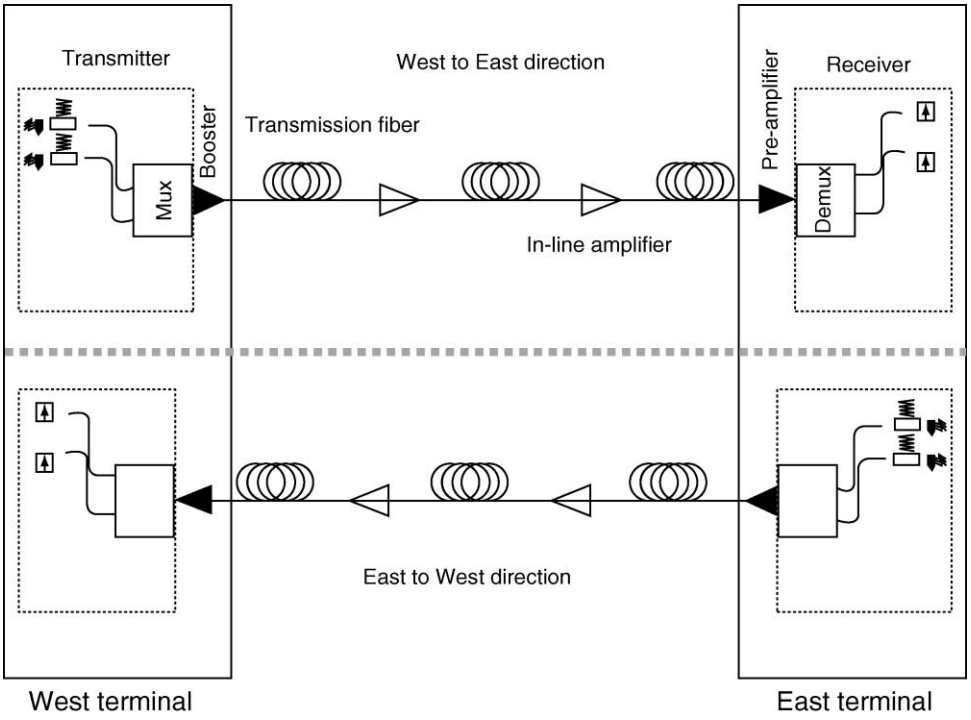

Figure 1 Schematic of a bidirectional long-haul transmission system.

dispersion shifted fiber (NZDSF) has a zero-dispersion wavelength close to 1.5 μm. To remedy this effect, dispersion compensating modules (DCM) are placed along the link. These modules – generally a special type of fiber – have chromatic dispersion with inverted characteristics with respect to those of the transmission fiber.

Key Optical-Amplifier Parameters

Optical amplifiers spontaneously generate optical noise – referred to as amplified spontaneous emission (ASE) – that is added to the modulated signal and consequently degrades the quality of the transmission. It is essential to quantify the level of ASE for a given optical transmission system.

We define the optical signal-to-noise ratio (OSNR) in the bandwidth $\Delta\nu$ as

$$\mathrm{OSNR} = \frac{P_{\mathrm{Signal}}}{P_{\mathrm{ASE}}} \qquad [1]$$

where P_{signal} is the signal power and P_{ASE} is the ASE power in the bandwidth $\Delta\nu$.

The required OSNR at a receiver, to detect the information with high quality, depends on the modulation format and on the other sources of noise or signal degradation existing in the transmission system. If we assume a nonreturn to zero (NRZ) modulation format, and signal detection limited only by ASE noise, an OSNR, in 0.1 nm bandwidth, of about 18 dB, is required at the receiver for a bit-error rate – number of erroneously transmitted bits divided by number of transmitted bits – of 10^{-12}. Introduction of other transmission degradation sources requires a higher OSNR to maintain the same bit-error rate.

The decibel unit (dB) for a given ratio, R, is defined by

$$R_{\mathrm{dB}} = 10\log_{10}R_{\mathrm{linear}} \qquad [2]$$

Similarly we defined the power decibel unit (dBm) as

$$P_{\mathrm{dBm}} = 10\log_{10}P_{\mathrm{mW}} \qquad [3]$$

where P_{mW} is the power in mW.

In order to quantify the amount of ASE generated by an optical amplifier, we define the equivalent input noise factor (n_{eq}), in a linear unit, by

$$n_{\mathrm{eq}} = \frac{P_{\mathrm{ASE}}}{h\nu\Delta\nu G} \qquad [4]$$

where P_{ASE} is the output ASE power in one polarization state in the bandwidth $\Delta\nu$, h the Planck's constant, ν the frequency of the ASE, and G the gain of the amplifier.

We also define the noise figure of the amplifier (NF) – a universal parameter to characterize

amplifier noise – as

$$\mathrm{NF} = 2n_{\mathrm{eq}} + \frac{1}{G} \qquad [5]$$

If an optical component, having a loss T_{in} ($T_{\mathrm{in}} < 1$), is inserted at the input of the amplifier, the total NF of the amplifier becomes $\mathrm{NF}_{\mathrm{total}} = \mathrm{NF}/T_{\mathrm{in}}$. If an optical component, having a loss T_{out} ($T_{\mathrm{out}} < 1$), is inserted at the output of the amplifier, $\mathrm{NF}_{\mathrm{total}} = \mathrm{NF} + 1/G(1/T_{\mathrm{out}} - 1)$. When $G \gg 1$, we have $\mathrm{NF}_{\mathrm{total}} \approx \mathrm{NF}$.

The OSNR in 0.1 nm bandwidth obtained after N fiber spans of loss, $\mathrm{Loss}_{\mathrm{Fiber}}$ (in dB), each having an amplifier, is in decibels:

$$\mathrm{OSNR} = P_{\mathrm{Signal}} - \mathrm{Loss}_{\mathrm{Fiber}} - \mathrm{NF} - 10\log_{10} N + 58 \qquad [6]$$

where P_{Signal} is the signal power at the output of the amplifier.

When the optical signal power is sufficiently high, nonlinear effects also become responsible for the degradation of the system performance. Therefore, choosing the value of the signal power launched into the transmission fiber results in a trade-off between increasing the OSNR, and reducing nonlinear effects.

Optical Fiber Amplifier

An optical fiber amplifier consists of fiber with an active medium and at least one optical pump source, which is launched simultaneously with the signal into the fiber by means of a dichroic coupler.

We define as forward and backward pumping, the case where the pump is launched, respectively, in the same direction as the signal and in the opposite direction to the signal. We define as bidirectional pumping, the case where the fiber is pumped from both ends. The most commonly used pump sources are the semiconductor laser diodes. These lasers may use different technologies to meet the various performance requirements with respect to the amplifier types and applications. The most popular pump diodes are the distributed Bragg reflector (DBR), distributed feedback (DFB), or external-grating stabilized lasers.

Erbium Fiber Amplifier

Fiber doped with the rare-earth Er^{3+} ion can amplify a signal located at 1.5 μm with the appropriate fiber host material and if pumped near 0.98 μm or near 1.48 μm. Silica is the most common material used for the fiber host. Er^{3+} has three energy levels, as described in Figure 2.

0.98 μm pumping occurs between the upper level $^4I_{11/2}$ and the ground level $^4I_{15/2}$, and 1.48 μm pumping occurs between the metastable level $^4I_{13/2}$ and the ground level.

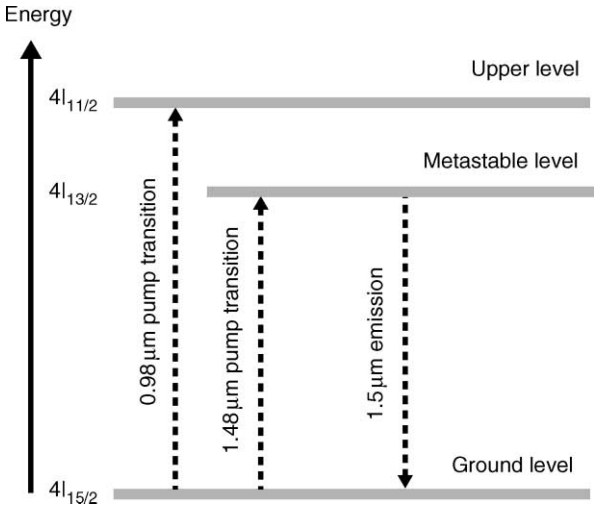

Figure 2 Energy level diagram for Er^{3+} ions.

The signal amplification takes place between the metastable level and the ground level. With 0.98 μm pumping, a rapid energy transfer occurs between the upper level and the metastable level via a phonon-assisted process. The lifetime of the upper level is much lower than the lifetime of the metastable level, about 10 ms. Therefore, with 0.98 μm pumping we can assume a two-level energy transfer, between the metastable and the ground levels, for the description of the amplification process in the Er^{3+} medium.

We define the normalized medium inversion (D) by

$$D = \frac{N_2 - N_1}{N_t} \qquad [7]$$

where N_2 is the population of the metastable level, N_1 the population of the ground level, and $N_t = N_2 + N_1$ the total population. $D = +1$ when the metastable level is fully populated and $D = -1$ when only the ground level is populated.

A simple approach for calculating the gain (G) with erbium-doped fiber amplifiers (EDFA) is given, in decibel units, by

$$G(\lambda) = \big((\alpha(\lambda) + g(\lambda)\big)\frac{D+1}{2} - \alpha(\lambda)L \qquad [8]$$

where λ is the wavelength of the signal, α the absorption coefficient in dB unit length at the signal wavelength, g the emission coefficient in dB unit length at the signal wavelength, and L the length of the erbium-doped fiber (EDF). Here D is the normalized path-average medium inversion of the EDF.

The gain per unit length, $G(\lambda)/L$, is equal to $g(\lambda)$ for $D = +1$ and to $-\alpha(\lambda)$ for $D = -1$.

The absorption and the emission coefficients depend on the EDF host material and the codoping element used for the realization of the EDF. With silicate EDF the most commonly used codoping elements are germanium, aluminum, and phosphorus.

In Figure 3 we show the dependence of the gain per unit length on the normalized path-average medium inversion, for a signal wavelength ranging from 1500 to 1560 nm.

For a more comprehensive description of the EDFA characteristics we use the standard confined-doping model. This model, which is also based on the two-level system, uses the following differential equations:

$$\frac{dP_S^+(z)}{dz} = \left(\frac{N_2}{N_t}(\alpha_S + g_S) - \alpha_s\right)P_S^+(z) \qquad [9]$$

$$\frac{dP_{ASE}^+(z)}{dz} = \left(\frac{N_2}{N_t}(\alpha_S + g_S) - \alpha_s\right) \times P_{ASE}^+(z) + \frac{N_2}{N_t} g_S 2h\nu_S \Delta\nu \qquad [10]$$

$$\frac{dP_{ASE}^-(z)}{dz} = \left(\alpha_s - \frac{N_2}{N_t}(\alpha_S + g_S)\right) \times P_{ASE}^-(z) - \frac{N_2}{N_t} g_S 2h\nu_S \Delta\nu \qquad [11]$$

$$\frac{dP_P^+(z)}{dz} = \left(\frac{N_2}{N_t}(\alpha_P + g_P) - \alpha_P\right)P_P^+(z) \qquad [12]$$

$$\frac{dP_P^-(z)}{dz} = \left(\alpha_P - \frac{N_2}{N_t}(\alpha_P + g_P)\right)P_P^-(z) \qquad [13]$$

where $P_S(z)$, $P_{ASE}(z)$, and $P_P(z)$ in W are, respectively, the signal power, the ASE power, and the pump power along the length (z-axis) of the EDF; $^+$ and $^-$ indicate, respectively, the backward-traveling and the forward-traveling directions; α_s and α_P in m^{-1} are the absorption coefficients at, respectively, the signal and pump wavelengths, g_s and g_p in m^{-1} are the emission coefficients at, respectively, the signal and pump wavelengths, ν_s and ν_p are the frequencies of, respectively, the signal and the pump beams; $\Delta\nu$ is the frequency bandwidth of the ASE; and h is the Planck's constant. N_2/N_1 is the medium inversion along the z-axis of the EDF, and is given by

$$\frac{N_2}{N_t} = \frac{\sum_k \dfrac{P_k(z)\alpha_k\tau}{h\nu_k B_{eff}^2 N_t}}{1 + \sum_k \dfrac{P_k(z)(\alpha_k + g_k)\tau}{h\nu_k B_{eff}^2 N_t}} \qquad [14]$$

where the index k represents all the beams, i.e., signal, ASE, and pump, traveling backward and forward along the EDF, τ is the lifetime of the metastable level, and B_{eff} is the effective erbium-doping area. For a typical silicate EDF, having a peak absorption coefficient of $1\ dBm^{-1}$, we have $\tau = 10$ ms, $B_{eff} = 12\ \mu m^2$, and $N_t = 5 \times 10^{23}\ m^{-3}$.

Using the standard confined-doping model we calculate the dependence of the EDFA noise figure on the normalized path-average medium inversion, as shown in Figure 4. We vary the path-average normalized medium inversion by changing the length of the EDFA, while adjusting the pump power so that the signal gain is kept constant.

The noise figure decreases when the medium inversion increases, and approaches the quantum limit value of 3 dB when the path-average normalized medium inversion is close to unity. Near full inversion

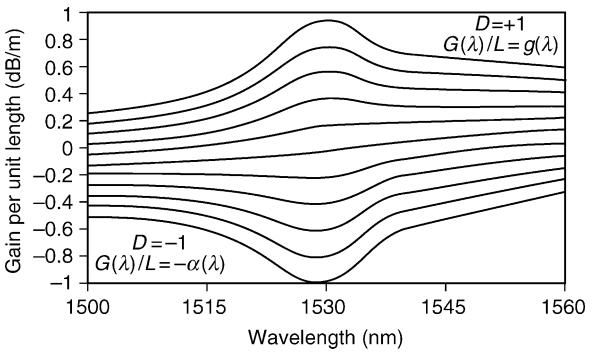

Figure 3 Dependence of the gain per unit length on the normalized path-average medium inversion, D. D ranging from -1 to $+1$ with a 0.2 step (alumino-silicate EDF; peak absorption of 1 dB m^{-1}; peak emission of 0.93 dB m^{-1}).

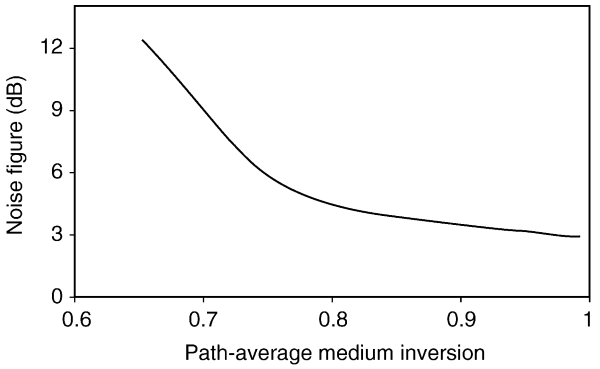

Figure 4 Dependence of the noise figure on the normalized medium inversion (alumino-silicate EDF with peak absorption of 1 dB m^{-1}; EDF lengths ranging from 16 m to 60 m; gain equals to 15 dB; input signal power of -40 dBm at 1530 nm; backward pumping at 980 nm).

may be obtained with a pump located at 0.98 μm because the emission coefficient is null at this pump wavelength. However, this is not the case at 1.48 μm where the ratio g_p/α_p is about 0.3. The maximum medium inversion that can be obtained with 1480 nm is $D = 0.8$. Therefore, higher noise figures are obtained with 1.48 μm pumping than with 0.98 μm pumping. The pumping direction also has an effect on the noise figure, in particular with 0.98 μm. Since at 0.98 μm the emission coefficient is null, when backward pumping configuration is used the 0.98 μm pump is quickly absorbed along the EDF length. This leads to a low-medium inversion at the input end of the EDF, resulting in high noise figures. However, in order to achieve forward pumping, a dichroic coupler must be placed at the input end of the EDF, thus inducing an additional loss at the input of the amplifier. This increases the noise figure and, therefore, to some extent, counterbalances the NF improvement associated with forward pumping.

Raman Fiber Amplifier

Stimulated Raman scattering, an optical-phonon based nonlinear effect present in silica fiber, is used to convert energy from a pump located at a frequency ν_p, to a signal located at a lower frequency ν_s. The efficiency of the so-called Raman amplification depends on the frequency shift $\Delta\nu_r = \nu_p - \nu_s$. Figure 5 shows the dependence of the Raman gain on the frequency shift in standard single-mode fibers. The exact Raman gain spectrum depends on the doping elements used during the fabrication process of the fiber. With standard telecommunications fibers the Raman gain is maximum for $\Delta\nu_r$ close to 13 THz.

Raman amplification can be achieved within the transmission fiber of the system – distributed amplification – or within a specific fiber, such as a dispersion compensation fiber – discrete amplification. Contrary to EDFA, Raman amplification has a very fast response time – in the order of a few hundred femtoseconds – and is strongly dependent on the polarization state of the signal and the pump, the highest gain efficiency being obtained when the polarization states of the signal and the pump are parallel. Because of the nonpolarization-maintaining nature of standard telecommunications fibers, depolarized pump sources are preferable for Raman amplification. To avoid pump fluctuation being transferred to the signal, Raman amplifiers generally use backward pumping, which virtually averages the fluctuation. Forward pumping can also be employed with Raman amplifiers but with careful control of the pump characteristics.

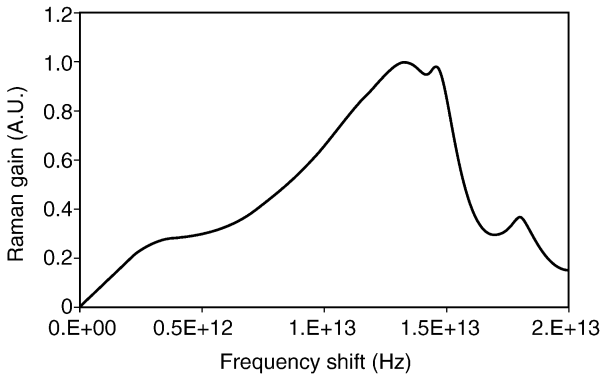

Figure 5 Raman gain spectrum in standard single mode fiber.

If the signal is sufficiently low the pump depletion can be neglected. In that case the gain of the Raman amplifier is given by

$$G = \exp\left(\frac{g_R P_P}{A_{eff}\alpha_p}(1 - \exp^{-\alpha_p L}) - \alpha_S L\right) \qquad [15]$$

where P_p is the launched pump power, L is the length of the fiber, g_R is the Raman gain coefficient, and A_{eff} is the effective area of the fiber. We assume for the simulation examples given in this article that the peak value of g_R is equal to 6×10^{-14} m/W.

A more comprehensive model for Raman amplification is given by the following set of differential equations:

$$\frac{dP_S^+(z)}{dz} = -\alpha_s P_S^+(z) + \left(\frac{g_R}{A_{eff}}\right)(P_p^+(z) + P_p^-(z))P_S^+(z) + r_S P_S^-(z) \qquad [16]$$

$$\frac{dP_S^-(z)}{dz} = \alpha_s P_S^-(z) - \left(\frac{g_R}{A_{eff}}\right)(P_p^+(z) + P_p^-(z))P_S^-(z) - r_S P_S^+(z) \qquad [17]$$

$$\frac{dP_{ASE}^+(z)}{dz} = -\alpha_s P_{ASE}^+(z) + \left(\frac{g_R}{A_{eff}}\right)(P_p^+(z) + P_p^-(z)) \times [P_{ASE}^+(z) + 2h\nu_S\Delta\nu] + r_S P_{ASE}^-(z) \qquad [18]$$

$$\frac{dP_{ASE}^-(z)}{dz} = \alpha_s P_{ASE}^-(z) - \left(\frac{g_R}{A_{eff}}\right)(P_p^+(z) + P_p^-(z)) \times [P_{ASE}^-(z) + 2h\nu_S\Delta\nu] - r_S P_{ASE}^+(z) \qquad [19]$$

$$\frac{dP_p^+(z)}{dz} = -\alpha_p P_p^+(z) - \left(\frac{\nu_p}{\nu_S}\right)\left(\frac{g_R}{A_{eff}}\right)P_p^+(z) \times (P_S^+(z) + P_S^-(z) + P_{ASE}^+(z) + P_{ASE}^-(z)) + r_P P_p^-(z) \qquad [20]$$

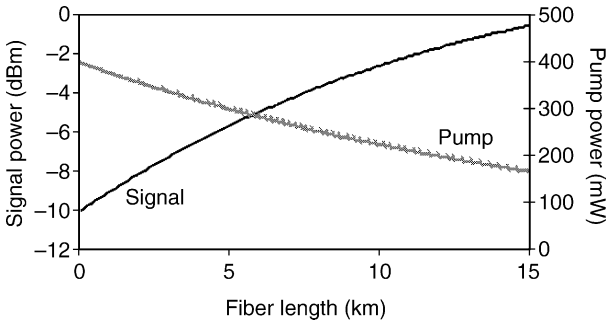

Figure 6 Evolution of the signal power and pump power along fiber length with Raman amplification (standard single-mode fiber; fiber length of 15 km; input signal power of −10 dBm at 1550 nm; forward pumping with 400 mW at 1450 nm; total amplifier gain of 9.5 dB).

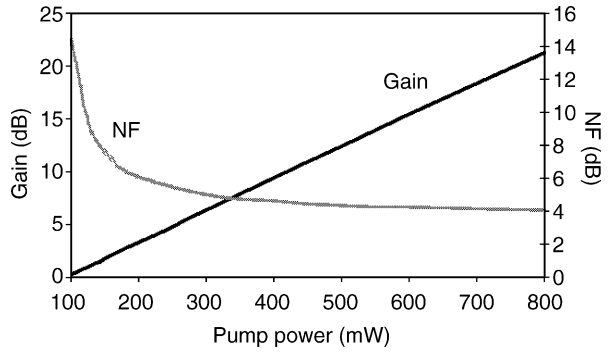

Figure 7 Dependence of the Raman amplifier gain and the noise figure on the pump power (standard single-mode fiber; fiber length of 15 km; input signal power of −10 dBm at 1550 nm; forward pumping at 1450 nm with power ranging from 100 mW to 800 mW).

$$\frac{dP_p^-(z)}{dz} = \alpha_p P_p^-(z) + \left(\frac{\nu_p}{\nu_S}\right)\left(\frac{g_R}{A_{eff}}\right) P_p^-(z) \times \left(P_S^+(z) + P_S^-(z) + P_{ASE}^+(z) + P_{ASE}^-(z)\right) - r_p P_p^+(z) \quad [21]$$

where r_S and r_p are the Rayleigh backscattering coefficients at, respectively, the signal wavelength and the pump wavelength.

An example of the evolution of the signal power and pump power along fiber length is given by Figure 6.

Figure 7 shows the dependence of the Raman amplifier gain and noise figure on the pump power.

Distributed and Discrete Amplification

A system uses distributed amplification when the transmission fiber is used as the medium for generating the optical signal amplification. It uses discrete amplification when an optical amplifier is located between the transmission fiber spans.

Discrete Amplification

Both EDFA and Raman amplifiers can be used to provide discrete amplification. Discrete amplifiers can be used as booster, pre-amplifier, or in-line amplifier. They can also be used to compensate for the loss of additional elements such as DCM, which may be located between the fiber spans. In Figure 8 we show the path of the signal when a discrete amplification is used to compensate for the loss of the transmission fiber and for the loss of a DCM. In this example, we assume that the discrete amplifier is made of two amplifiers. The first-stage amplifier compensates mainly for the loss of the transmission fiber, while the second-stage amplifier compensates mainly for the loss of the DCM.

If a 'lossy' element is inserted between two amplifiers, the noise figure of the composite amplifier increases the total noise figure of the dual-stage amplifier.

The total noise figure of a dual-stage amplifier, NF_{total}, is given by

$$NF_{total} = NF_1 - \frac{1}{G_1} + \frac{NF_2}{G_1 T_{mid}} \quad [22]$$

where NF_1 is the noise figure of the first-stage amplifier, G_1 is the gain of the first-stage amplifier, NF_2 is the noise figure of the second-stage amplifier, and T_{mid} is the loss of the optical element inserted between the two amplifiers ($T_{mid} < 1$).

Distributed Amplification

When fibers are deployed it is generally assumed, at least for terrestrial networks, that it can be used with different types of transmission systems, which may or

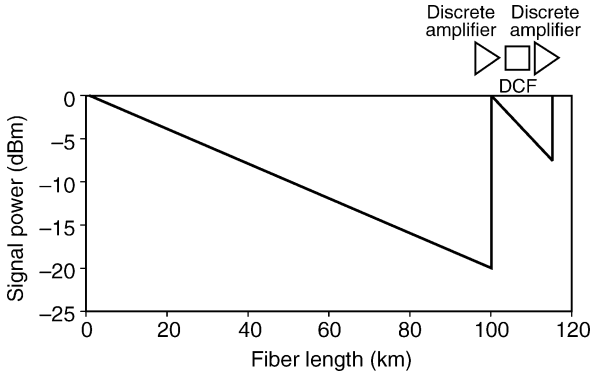

Figure 8 Schematic of a transmission system using discrete amplification to compensate for the loss of the transmission fiber and the dispersion compensating module.

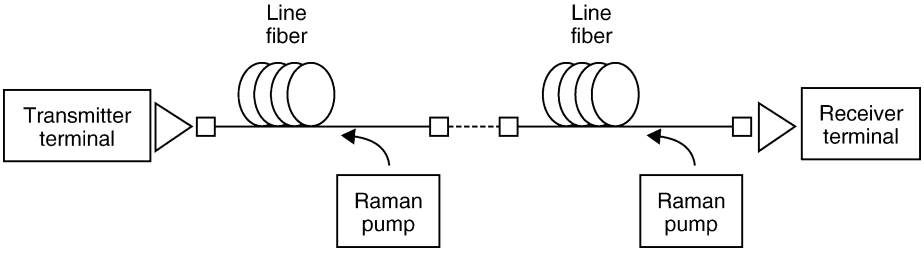

Figure 9 Schematic of a transmission system using distributed Raman amplification.

may not use distributed amplification. Doping the transmission fiber with erbium is not a practical solution since the absence of a pump would result in high fiber loss. On the other hand, Raman amplification can be achieved with conventional fibers, and is consequently the preferred solution to generate distributed amplification. Raman amplification is then obtained by launching a pump signal into the transmission fiber. Figure 9 shows the schematic of a transmission system using distributed Raman amplification with backward pumping.

Even if distributed amplification can be used to compensate fully for the loss of the transmission fiber, discrete amplifiers are generally required to compensate for the loss of the transmitter and receiver terminals. In order to compare distributed amplification with discrete amplification we define the equivalent noise figure as follows:

$$\mathrm{NF_{Equ}} = \frac{1}{G_{\mathrm{On/Off}}}\left(\frac{\mathrm{Pase}}{h\nu\Delta\nu} + 1\right) \qquad [23]$$

where Pase is the total ASE power at the output end of the transmission fiber and where the on/off gain, $G_{\mathrm{On/Off}}$ is given by

$$G_{\mathrm{On/Off}} = \frac{P^{\mathrm{On}}_{\mathrm{signal}}}{P^{\mathrm{Off}}_{\mathrm{signal}}} \qquad [24]$$

where $P^{\mathrm{On}}_{\mathrm{signal}}$ and $P^{\mathrm{Off}}_{\mathrm{signal}}$ are the signal power levels at the output end of the transmission fiber when the distributed amplifier is, respectively, turned on and off.

To illustrate the meaning of the on/off gain, we show in Figure 10 the evolution of the signal power along a fiber with and without Raman pump power. In this case, the on/off gain is 20 dB.

The equivalent noise figure, which has no real physical meaning, is equal to the noise figure of an imaginary discrete amplifier that would be located at the output end of the transmission fiber and would lead to the same OSNR. Figure 11 shows the dependence of the equivalent noise figure on the Raman gain, with no Rayleigh backscattering and with a Rayleigh backscattering level of $-74\ \mathrm{dB\ m^{-1}}$.

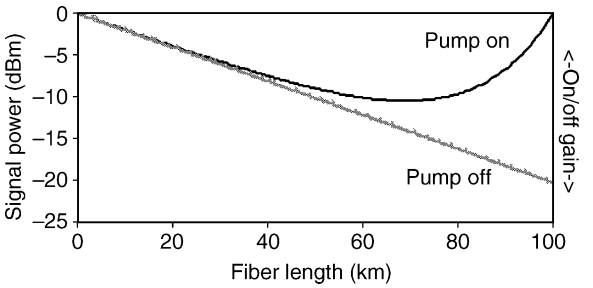

Figure 10 Evolution of signal power along the fiber length with and without pump power (standard single-mode fiber; fiber length of 100 km; fiber attenuation of 0.2 dB/km at signal wavelength; input signal power of 0 dBm at 1550 nm; backward pumping 400 mW at 1450 nm).

Once the on/off gain is higher than ~10 dB the equivalent noise figure becomes negative and it decreases when the on/off gain further increases. However, once the on/off is higher than 20 dB, Rayleigh backscattering limits the minimum equivalent noise figure that can be achieved. The lowest equivalent noise figure is observed for an on/off gain of ~33 dB. In addition, Rayleigh backscattering causes the reflected portion of the signal to be superimposed onto the transmitted signal, leading to multipath interference (MPI), which level increases with the gain. This results in an additional source of noise for the signal, and consequently degrades the system performance.

Hybrid Amplification

Discrete and distributed amplification can be used simultaneously in a same-transmission system. An example of the evolution of the signal power with hybrid amplification is represented in Figure 12, for the case where distributed Raman amplification and a dual-stage discrete amplifier are used to compensate for the loss of the transmission fiber and for the loss of a DCM.

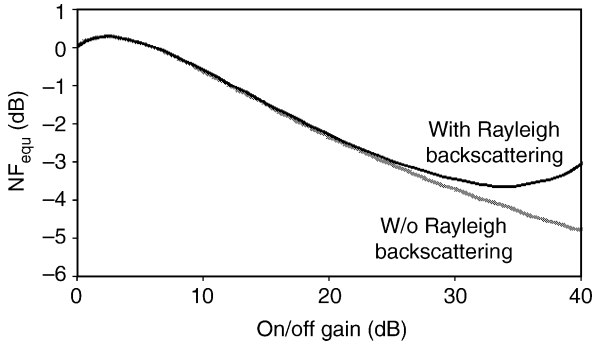

Figure 11 Equivalent noise figure versus distributed on/off gain (standard single-mode fiber; fiber length of 250 km; fiber attenuation of 0.2 dB/km at 1550 nm; input signal power of 0 dBm at 1550 nm; backward pumping ranging from 0 to 1 W at 1450 nm).

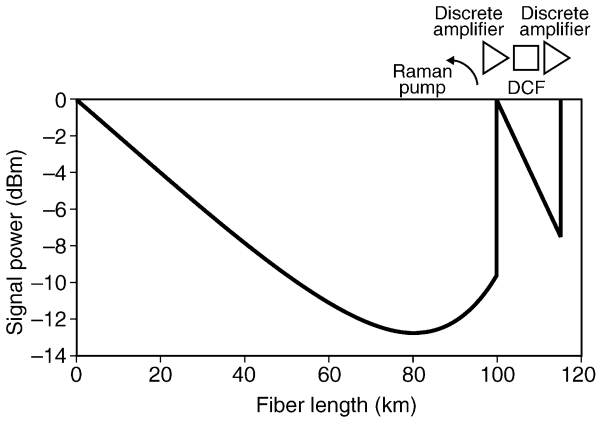

Figure 12 Evolution of the signal power using discrete and distributed amplification (standard single-mode fiber of 100 km; fiber loss of 20 dB at signal wavelength; DCM loss of 8 dB; input signal power of 0 dBm at 1550 nm; Raman backward pumping with 200 mW at 1450 nm; Raman on/off gain of 10 dB).

Similar to the case of distributed amplification, the total equivalent noise figure of a hybrid amplifier can be defined by

$$NF_{Equ}^{Total} = NF_{Equ}^{Distributed} + \frac{NF^{Discrete} - 1}{G_{On/Off}} \qquad [25]$$

where $NF_{Equ}^{Distributed}$ is the equivalent noise figure of the distributed amplifier and $NF^{Discrete}$ is the noise figure of the discrete amplifier.

In Figure 13 we show the dependence of the total equivalent noise figure on the on/off gain for a hybrid amplifier with fixed discrete noise figure. The dependence of the distributed equivalent noise figure on the on/off gain is also plotted on the same graph.

Since the equivalent noise figure of the distributed amplifier is relatively low, the total equivalent noise figure is lower than the noise figure of the discrete amplifier once distributed amplification is used. Moreover, as the on/off gain becomes large, the total equivalent noise figure of the hybrid amplifier converges toward the distributed equivalent noise figure.

Wavelength-Division Multiplexing

The transmission of WDM signals over long distances requires meticulous control of the spectral characteristics of the amplifier gain. The amplifier gain excursion induces a power excursion between the channels of the WDM signal, which increases with the number of spans. Consequently, the available bandwidth for WDM transmission narrows with the total distance of the link. This is illustrated in Figure 14, where the power excursion observed after an amplifier chain is plotted for different numbers of amplifiers, a fiber span being included between each amplifier. With this example, the 1 dB-bandwidth drops from 9 nm after one span to 1.5 nm after 50 spans.

For a comprehensive analysis of the spectral gain characteristic of EDFA and Raman amplifiers we generalize the single-channel model described in the amplifier section of this article to the multichannel case. The generalization of the models is obtained by adding a frequency dimension to each beam propagating in the amplifier, as described in Table 1, where each k element represents the signal, the ASE noise or the pump, λ is the wavelength of the kth beam, $\Delta\nu$ is the frequency separation between the pump beam p, and the signal beam s.

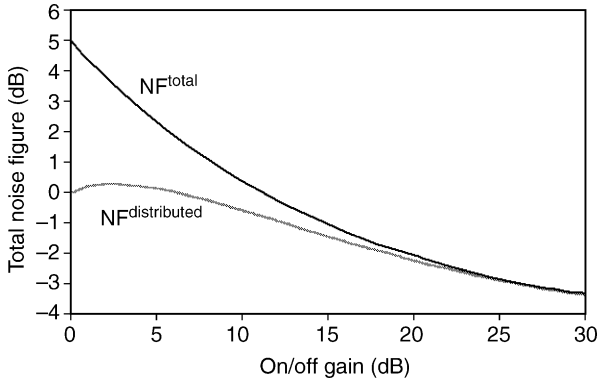

Figure 13 Total noise figure of the hybrid amplifier and noise figure of the distributed amplifier versus on/off gain (noise figure of the discrete amplifier equals to 5 dB; standard single-mode fiber of 100 km; fiber loss of 20 dB at signal wavelength; input signal power of 0 dBm at 1550 nm; Raman backward pumping ranging from 0 mW to 600 mW at 1450 nm).

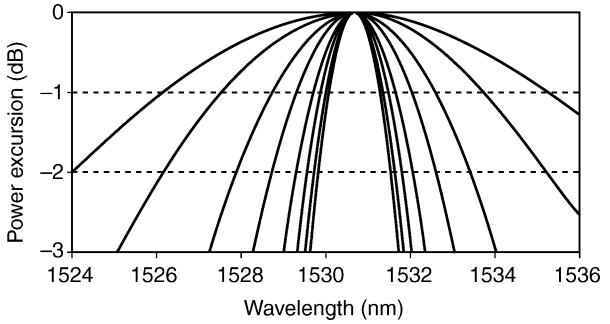

Figure 14 Dependence of the power excursion on the number of fiber spans. Number of spans equals, respectively, to 1, 2, 5, 10, 20, 30, 40, and 50 (amplifier with 15 m long alumino-silicate EDF; peak absorption of 1 dB m^{-1}; $D = 0.6$; fiber loss of 8.5 dB; flat fiber loss spectrum).

Table 1 Correspondence between parameters used for the EDFA and Raman amplifier models with the single-channel and the multichannel approaches (the multichannel approach is also used to describe the power evolution of pump beam when WDM pump scheme is used)

	Single-channel model	*Multichannel model*
Power	$P_k^{+,-}(z)$	$P_k^{+,-}(\lambda, z)$
Sum of power	$P_k^{+}(z)$ $+P_k^{-}(z)$	$\sum_\lambda P_k^{+}(\lambda, z)$ $+P_k^{-}(\lambda, z)$
Absorption coefficient	α_k	$\alpha(\lambda)$
Emission coefficient	g_k	$g(\lambda)$
Raman gain coefficient	g_R	$g_R(\Delta\nu_{p,s})$

With EDFAs, the main factors in the gain flatness are the path-average medium inversion, the EDF codopant composition, and fiber host material. Depending on the bandwidth and the wavelength of the WDM signal, the way the EDF is optimized may vary.

In the following example, we focus on the path-average medium inversion for the case of C-band applications. Figure 15 shows the output spectrum of a WDM signal amplified by an alumino-silicate EDFA having, respectively, a medium inversion of $D = +0.4$ and $D = 0$. The peak-to-peak gain excursion is, respectively, 2 dB and 14 dB for $D = +0.4$ and $D = 0$.

Application with C-band WDM signals requires amplifiers operating with high-medium inversion. As can be extrapolated from Figure 15, if the WDM signal is centered around 1560 nm, a lower medium inversion is more suitable. Indeed, as shown in Figure 3, when the medium inversion is close to zero the peak gain wavelength changes from 1530 nm to 1560 nm and higher; the optical window for L-band applications.

Regarding the doping elements, we show in Figure 16 the gain spectrum for a germano-silicate and an alumino-silicate EDF, respectively. The peak-to-peak gain excursion is 8 dB with the germano-silicate EDF compared to 2 dB with the alumino-silicate EDF.

With Raman amplifiers, the gain flatness can be adjusted by using wavelength-multiplexed pumps. In Figure 17 we show the power spectrum when a Raman amplifier is pumped with three wavelength-multiplexed pumps located, respectively, at 1430 nm, 1455 nm, and 1480 nm. The maximum power excursion between the channels is 2 dB.

For comparison, we also show in Figure 18 the power spectrum of the Raman amplifiers when only

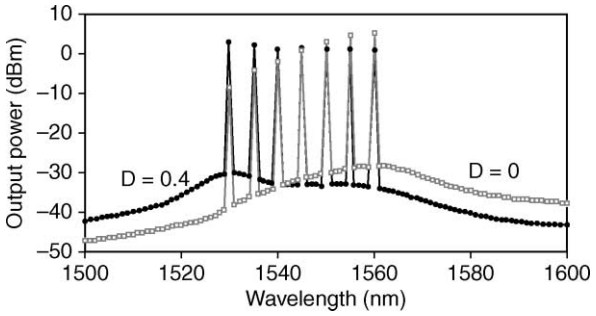

Figure 15 Gain spectrum of an alumino-silicate EDF for $D = 0.4$ and $D = 0$ (C-band WDM signal made of 7 channels equally spaced ranging from 1530 nm to 1560 nm; flat input power of −10 dBm per channel; gain of channel located at 1545 nm of 10 dB for $D = 0.4$ and $D = 0$; EDF with peak absorption of 1 dB m^{-1}; EDF length of 30 m for $D = 0.4$; EDF length of 100 m for $D = 0$).

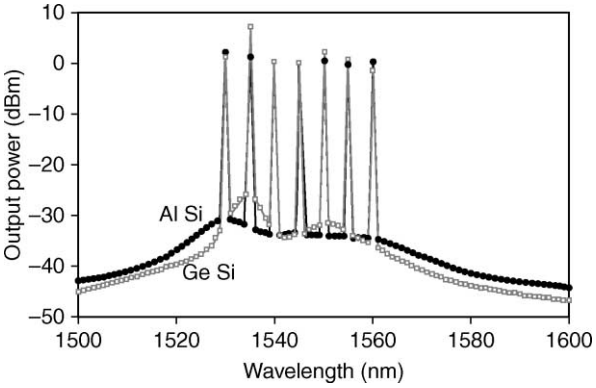

Figure 16 Gain spectrum of an alumino-silicate EDF and of a germano-silicate EDF for $D = 0.4$ (C-band WDM signal made of 7 channels equally spaced ranging from 1530 nm to 1560 nm; flat input power of −10 dBm per channel; gain of channel located at 1545 nm of 10 dB for $D = 0.4$ and $D = 0$; alumino-silicate EDF of 30 m with peak absorption of 1 dB m^{-1}; germano-silicate EDF of 40 m with peak absorption of 1 dB m^{-1}).

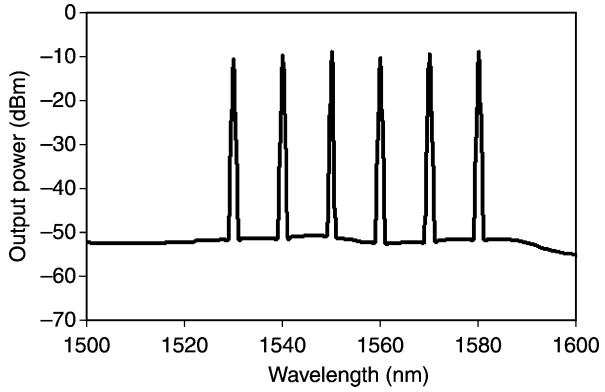

Figure 17 Output power spectrum of a Raman amplifier pumped with three wavelength-multiplexed pumps (standard single-mode fiber of 100 km; WDM signal made of 6 channels equally spaced ranging from 1530 nm to 1580 nm; pumping in forward direction with 100 mW per pump located at 1430 nm, 1455 nm, and 1480 nm).

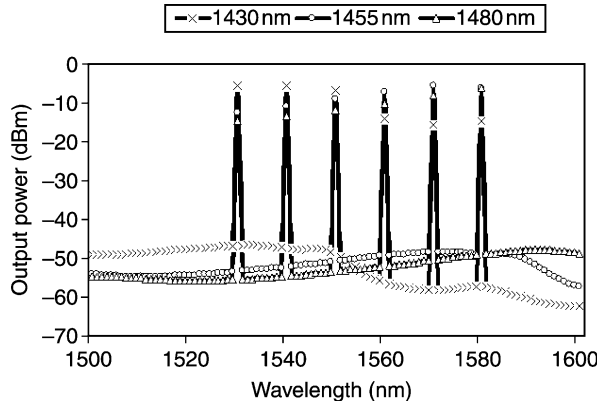

Figure 18 Output power spectrum of Raman amplifiers pumped at three different wavelengths (standard single-mode fiber of 100 km; WDM signal made of 6 channels equally spaced ranging from 1530 nm to 1580 nm; pumping in forward direction with 300 mW at, respectively, 1430 nm, 1455 nm, and 1480 nm).

one of the three multiplexed pumps is used, with the same total pump power. The power excursion becomes 10 dB for the 1430 nm pump, 7 dB for the 1455 nm pump, and 8.5 dB for the 1480 nm pump, which are much higher values than are obtained with the multiplexed pump scheme.

To further reduce the gain excursion of the amplifiers an external gain equalizing filter can be used. The filter, which is located next to the amplifier, is manufactured so that its attenuation spectrum matches the gain spectrum of amplifier, as illustrated in Figure 19. Gain equalizing filters are generally made with thin film filters or fiber Bragg gratings (FBG).

In order to obtain amplification over ultra-wide bandwidths, amplifiers of smaller bandwidths, e.g., C-band and L-band EDFAs, can be operated in parallel by means of Mux and Demux. Another option is to use a Raman amplifier with multiple pumps having their wavelengths distributed over a very large bandwidth.

Long-Haul Transmission System Types

Long-haul optical transmission systems are appropriate for different types of applications. We distinguish here three types of transmission system: the submarine systems; the terrestrial systems; and the unrepeatered systems. Each of these applications requires a careful design of the system, with particular attention to the optical amplifiers. In this section we focus on the key points of their design.

Submarine Systems

Submarine systems are used to transmit information across the oceans, i.e., over distances of up to several thousand kilometers. The transmission fiber and the in-line optical amplifiers, which are packaged in the repeater modules, are deployed undersea at the same time. The drastic constraints imposed on the reliability of the repeaters lead to their high cost, and consequently minimizing their number in a link is essential. The optimum span length, and therefore the number of in-line amplifiers, depends on the total distance of the transmission system. To illustrate this point, we derive from eqn [6] which number of spans of a particular length can be used for a given received OSNR, launched signal power, amplifier noise figure, and span loss per km. Based on the number of spans and span length, we then calculate the maximum distance that can be reached. The result is represented in Figure 20.

With the assumption made here regarding the amplifier characteristics, in order to reach distances of more than 5000 km, span lengths close to 50 km are required.

Terrestrial Systems

Terrestrial systems are used to connect traffic from cities to cities and from cities to submarine-system landing sites. Their total distances vary from a few hundred kilometers to several thousand kilometers. Generally with terrestrial systems, the deployments of the transmission fibers and the transmission systems are done at different times. During its lifetime, the same fiber plant might be used with a different generation of transmission system. Furthermore, because of the geographical constraints that can be imposed on the

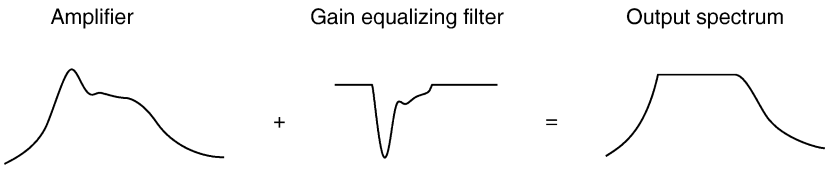

Figure 19 Combination of optical amplifier and gain equalizing filter to provide a flat gain amplifier.

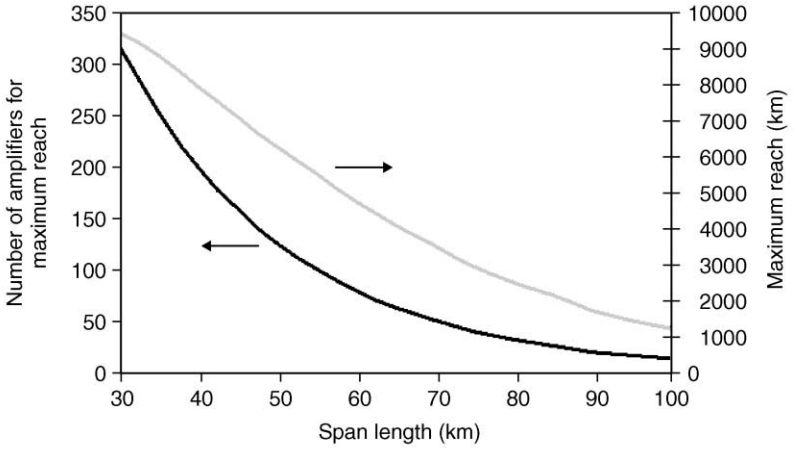

Figure 20 Dependence of the maximum distance and span number of a system on its span length (signal power at the output of the amplifier of −2 dBm; amplifier noise figure of 5 dB; fiber loss of 0.2 dB/km; required OSNR of 20 dB/0.1 nm).

locations of the terminals and the in-line optical amplifiers, the different span lengths may greatly vary in a given link. Consequently, an important characteristic of the terrestrial systems is their capability to operate with different span parameters.

For terrestrial systems using large numbers of WDM channels, maintaining the gain excursion of the optical amplifiers as little as possible under different operating conditions is crucial. Approaches to limit the gain excursion under these variations can be taken. With EDFAs of a given length, the medium inversion depends on its operating gain. The EDFA can be forced to operate at constant gain, independent of the span loss, by adding an adjustable attenuator to the amplifier, e.g., in the middle of a dual-stage amplifier, such that the sum of the attenuator loss and the span loss remains constant. With Raman amplifiers, the control of the gain excursion can be realized by adjusting the power of the pumps when a wavelength-multiplexed pumping scheme is used. Another possibility is to insert dynamically adjustable gain flattening devices along the link. The automatic adjustment of the gain flatness requires the need of a feedback generally provided by an optical channel power monitor.

Unrepeatered Systems

Unrepeatered systems are used to connect mainland sites separated by a water area, such as islands or cities located on the coast. Their main characteristic is that they do not use any electronic component along the transmission fiber; therefore optical amplifiers cannot be placed under water. The length of such systems is typically of a few hundred kilometers, meaning that, even for those systems where very low loss fiber is used, the loss of the transmission fiber is in the order of several tens of dB. To allow sufficiently high OSNR at the receiver, several options can be used. Among them are the use of very high-power boosters, distributed Raman amplification, and remotely pumped discrete amplification. Remote amplification is obtained by inserting, along the submerged fiber cable, a piece of EDF. A 1.48 μm pump is launched into the EDF from the mainland via the transmission fiber or via a dedicated fiber running along the transmission fiber. Figure 21 shows a schematic of a possible configuration for unrepeatered systems when a very high-power booster, distributed Raman amplification, and remote discrete amplification are used simultaneously.

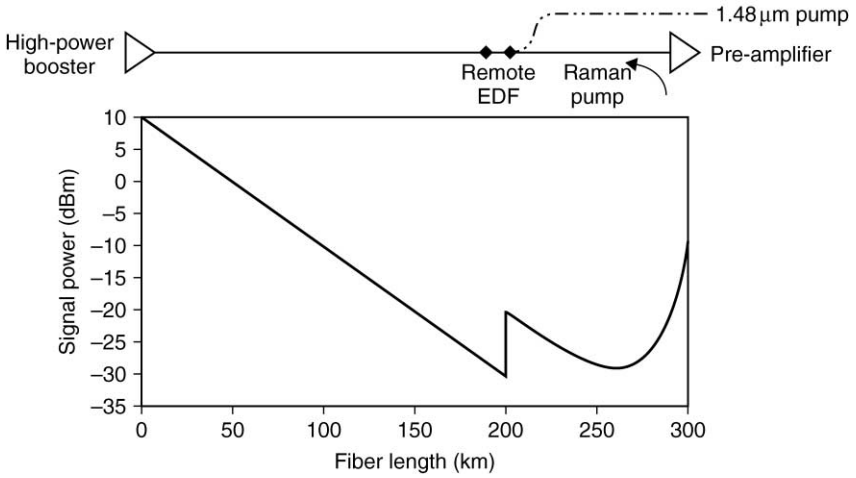

Figure 21 Schematic of unrepeatered systems using high-power booster, remote EDFA, and distributed Raman amplification.

The total equivalent noise figure, NF_{Equ}^{Total}, of an unrepeatered transmission system, using remote discrete amplification and distributed amplification, is given by

$$NF_{Equ}^{Total} = T NF^{Remote} + \frac{1}{G_{Remote}} \times \left(NF_{Equ}^{Distributed} + \frac{NF^{Discrete} - 1}{G_{On/Off}} - T \right) \quad [26]$$

where NF^{Remote} and G_{Remote} are, respectively, the noise figure and the gain of the remote amplifier; T is the loss of the transmission fiber between the remote amplifier and the pre-amplifier ($T < 1$); $NF_{Equ}^{Distributed}$ and $G_{On/Off}$ are, respectively, the equivalent noise figure and on/off gain of the distributed amplifier; and $NF^{Discrete}$ is the noise figure of the pre-amplifier.

Assuming that the gain and noise figures of the remote EDFA are, respectively, 10 dB and 7 dB, that the remote EDFA is located at 100 km from the pre-amplifier, that the fiber loss per km is 0.2 dB/km, that the Raman distributed amplifier provides 30 dB of on/off gain with an equivalent noise figure of −3 dB, and that the pre-amplifier noise figure is 5 dB, the equivalent total noise figure of the unrepeatered system is −10 dB.

List of Units and Nomenclature

A_{eff}	effective area
ASE	amplified spontaneous emission
B_{eff}	effective erbium doping area
D	normalized medium inversion
dB	ratio in decibel
dBm	power in decibel
DBR	distributed Bragg reflector
DCM	dispersion compensating modules
Demux	optical de-multiplexers
DFB	distributed feedback
DSF	dispersion-shifted fiber
EDF	erbium-doped fiber
EDFA	erbium-doped fiber amplifiers
FBG	fiber Bragg gratings
g_R	Raman gain coefficient
G	gain
$G_{On/Off}$	on/off gain
h	Planck's constant
Length	meter (m)
MPI	multi-path interference
Mux	optical multiplexers
n_{eq}	equivalent input noise factor
NF	noise figure of the amplifier
NRZ	non-return to zero
NZDSF	non-zero dispersion shifter fiber
N_2/N_1	medium inversion
OSNR	optical signal-to-noise ratio
Power	watt (W)
SSMF	standard single-mode fiber
TDM	time-division multiplexing
Time	second (s)
WDM	wavelength-division multiplexing
τ	lifetime

Introduction

Glass fibers for optical communications are made of fused silica, an amorphous material, to which dopant materials of various kinds can be added to produce changes in refractive index. A number of third-order nonlinear processes can occur; these can grow to appreciable magnitudes over the long lengths available in fibers, even though the nonlinear coefficients in the materials are relatively small. The effects are particularly important in single-mode fibers, in which the small mode field dimensions result in substantially high light intensities with relatively modest input powers.

Nonlinear optical effects, such as stimulated Raman scattering (SRS), stimulated Brillouin scattering (SBS), and four-wave mixing (FWM), can cause some problems such as nonlinear loss, pulse distortion, and cross-talk between signals in wavelength division multiplexed (WDM) transmission systems. However, these effects are also useful for efficient amplification and frequency conversion of injected signals, as well as for generation of new frequencies. In this chapter the main properties of fiber Raman amplifiers (FRAs), fiber Brillouin amplifiers (FBAs), and fiber parametric amplifiers (FPAs) will be reviewed, regarding their applications in the field of fiber optic communications.

Fiber Raman Amplifiers

Stimulated Raman scattering is likely to occur in fibers, producing appreciable amplification for down-shifted signals when moderate pump power levels are used. This is largely because the process is phase-matched, so that the long interaction lengths available in fibers will enhance the process. Additionally, the small mode field cross-section yields high intensities for relatively modest power levels.

In the SRS process one has simultaneously the absorption of a photon from the pump beam at frequency ω_p and the emission of a photon at the signal (Stokes) frequency, stimulated by the incident signal beam at frequency ω_s (Figure 1a). The difference in energy is taken up by a high energy

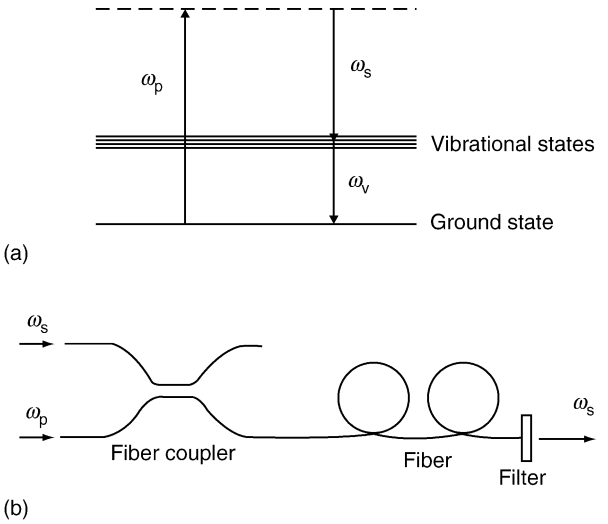

Figure 1 (a) Energy-level illustration of the process of stimulated Raman scattering and (b) schematic diagram of a fiber Raman amplifier.

phonon (molecular vibration) at frequency ω_v. Thus, SRS provides for energy gain at the signal frequency at the expense of the pump.

Figure 1b shows schematically a fiber Raman amplifier. The pump and the signal beams are injected into the fiber through a WDM fiber coupler. The case illustrated in Figure 1a shows the two beams co-propagating inside the fiber, but the counter-propagating configuration is also possible. In fact, the SRS can occur in both directions, forwards and backwards. It was confirmed experimentally that the Raman gain is almost the same in both cases.

Raman Gain and Bandwidth

Figure 2 shows the Raman gain coefficient for fused silica as derived from the spontaneous Raman spectrum. At the peak, the Raman gain coefficient for silica fibers is 9.4×10^{-14} m W^{-1} for a pumping wavelength $\lambda_p = 1.0\,\mu$m and varies as λ_p^{-1}. At this wavelength, a shift of 15 THz corresponds to 50 nm. The most significant feature of the Raman gain in silica fibers is that $\bar{g}_R$ extends over a large frequency range (up to 40 THz) with a broad dominant peak near 13 THz. This behavior is due to the amorphous nature of silica glass, whose molecular vibrational energy levels merge together to form a band.

The use of oxide glasses as dopants for fiber fabrication is suitable to enhance the Raman gain coefficient. For example, in the case of pure GeO_2, the Raman gain coefficient is about 9.2 times that for pure SiO_2 glass. In fact, doping the core of an SiO_2 Raman fiber amplifier with GeO_2 has two beneficial effects. First, the index difference Δ is raised, which increases the effective waveguiding and in turn reduces the effective cross-sectional area A_e. As a consequence, the rate of SRS is increased. Secondly, the Raman gain coefficient increases above that of pure SiO_2 in proportion to the concentration GeO_2, and is given by

$$g_R = (1 + 80\Delta)\bar{g}_R \qquad [1]$$

where $\bar{g}_R$ is the Raman coefficient for pure SiO_2.

In spite of the positive aspects mentioned above, doping with GeO_2 also increases the fiber losses, due to the concomitant rise in Rayleigh scatter and in the number of dopant-dependent loss centers. Thus, greatly increasing the GeO_2 concentration will not be worthwhile if the increased fiber losses outweigh the improvement in amplifier gain.

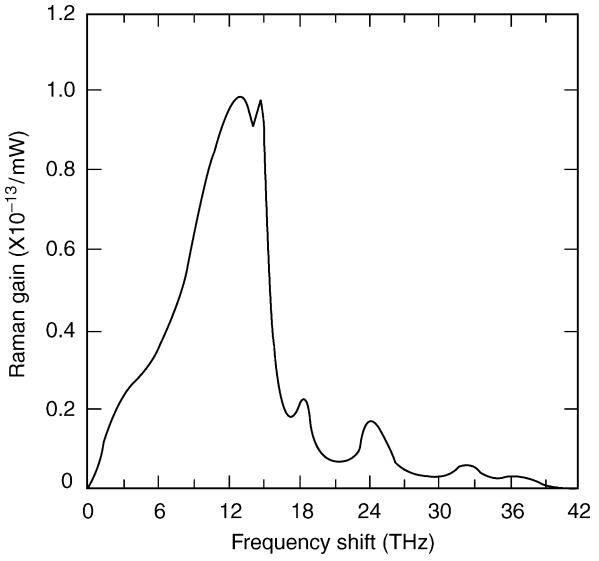

Figure 2 Measured Raman gain spectrum for fused silica at a pump wavelength $\lambda_p = 1.0\,\mu$m. The Raman gain scales inversely with λ_p. Reproduced with permission from Stolen RH and Ippen EP (1973) *Applied Physics Letters* 22: 276. © 1973 American Institute of Physics.

Gain Saturation

The interaction between the pump and Stokes waves is governed by the following coupled equations:

$$\frac{dP_s}{dz} = -\alpha_s P_s + \frac{g_R}{A_e} P_p P_s \qquad [2]$$

$$\frac{dP_p}{dz} = -\alpha_p P_p - \frac{\omega_p}{\omega_s}\frac{g_R}{A_e} P_s P_p \qquad [3]$$

where A_e is the effective cross-sectional area of the fiber mode, α_s and α_p are absorption coefficients which account for the fiber loss at the signal and pump frequencies, respectively, and the signal wave is considered to be co-propagating with the pump wave. Assuming that $\alpha_s = \alpha_p = \alpha$ (which is a reasonable approximation around the 1.5 μm wavelength region in a low loss fiber), the following approximate solutions of eqns [2] and [3] can be written when $P_p(0) \gg P_s(0)$:

$$P_p(z) = \frac{P_p(0)\exp(-\alpha z)}{1 + F(z)} \qquad [4]$$

$$P_s(z) = \frac{P_s(0)\exp\left(\Gamma(1 - e^{-\alpha z}) - \alpha z\right)}{1 + F(z)} \qquad [5]$$

where

$$\Gamma = \frac{g_R P_p(0)}{\alpha A_e} \qquad [6]$$

and

$$F(z) = \frac{\omega_p P_s(0)}{\omega_s P_p(0)} \exp\left(\Gamma(1 - e^{-\alpha z})\right) \qquad [7]$$

The dimensionless parameter $F(z)$ accounts for the effects of pump depletion and the attendant saturation of the gain seen by the signal.

Figure 3 shows the output signal power $P_s(L)$ versus the input signal power $P_s(0)$ for a Raman amplifier with length $L = 8$ km and several values of the input pump power. Typical values $g_R = 6.7 \times 10^{-14}$ m W^{-1}, $\alpha = 0.2$ dB km^{-1}, $A_e = 30 \times 10^{-12}$ m^2, $\lambda_p = 1.46$ μm and $\lambda_s = 1.55$ μm were assumed. The transfer characteristics are linear for $P_p(0) = 0.1$, 0.2, and 0.4 W, but the effects of pump depletion become discernible for input signal levels $P_s(0) > -15$ dB m when $P_p(0) = 0.6$ W. For a pump power $P_p(0) = 0.8$ W the linear behavior of the Raman amplifier cannot be observed, even for signal power levels as low as -25 dB m.

Since, in the absence of Raman amplification, the signal power at the amplifier output would be $P_s(L) = P_s(0) \exp(-\alpha L)$, the amplifier gain is given by

$$G_R = \frac{P_s(L)}{P_s(0) \exp(-\alpha L)} = \frac{\exp(g_R P_p(0) L_e / A_e)}{1 + F(L)} \qquad [8]$$

where

$$L_e = \frac{1}{\alpha}[1 - \exp(-\alpha L)] \qquad [9]$$

is the effective interaction length and L is the actual fiber length. The gain given by eqn [8] is seen to be a function of the input signal power (i.e., a saturation nonlinearity) through the term $F(L)$.

When $F(L) \gg 1$ we have from eqn [5], that

$$P_s(L) = \frac{\omega_s}{\omega_p} P_p(0) \exp(-\alpha L) \qquad [10]$$

In this case, the amplifier output reaches the pump level irrespective of the input signal level. This implies that any spontaneous Raman scatter in the fiber will be amplified up to power levels comparable to that of the pump. This is obviously inadmissible in an amplifier application, thus this operating regime must be avoided.

On the other hand, when $F(L) \ll 1$ we have, from eqn [5], that

$$P_s(L) = P_s(0) \exp(g_R L_e P_p(0)/A_e - \alpha L) \qquad [11]$$

In this case, the amplifier gain is

$$G_R = \frac{P_s(L)}{P_s(0) \exp(-\alpha L)} = \exp(g_R L_e P_0 / A_e) \qquad [12]$$

From eqn [12], the Raman gain in decibels is expected to increase linearly with the pump input power. Raman gains were experimentally confirmed to be almost the same for forwards and backwards pumping.

Figure 4 illustrates the variation of the amplifier gain (full curves, left scale) and the saturation parameter $F(L)$ (dashed curves, right scale) with the pump power $P_p(0)$ for a fixed input signal power $P_s(0) = 0$ dBm and amplifier lengths $L = 2$, 4, and 8 km. The full curve corresponding to $L = 2$ km shows a linear dependence of the gain on the pump power. However, the other two full curves show how the pump depletion limits the achievable gain. The black point on these curves marks the value of the pump power at which the depletion parameter F

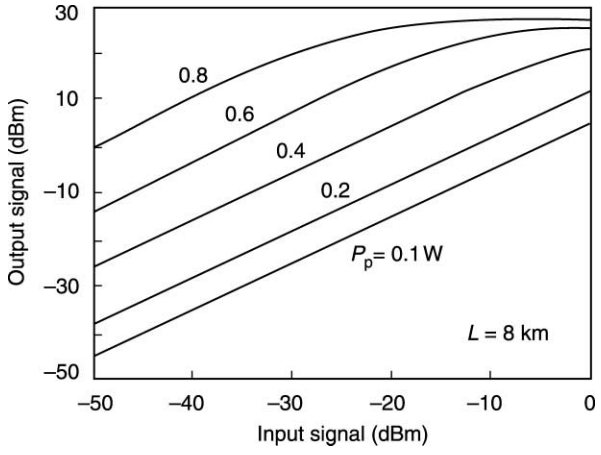

Figure 3 Transfer characteristics for a Raman amplifier with a length $L = 8$ km and several values of the input pump power.

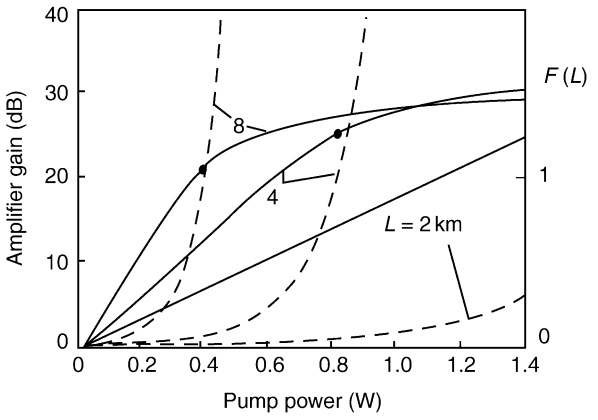

Figure 4 Raman amplifier gain (full curves, left scale) and parameter $F(L)$ (dashed curves, right scale) against input pump power for three values of the amplifier length.

becomes equal to unity. Only operating at pump powers sufficiently below each point ensures linear operation of the amplifier, whilst choosing to operate the amplifier significantly above that point will mean $F \gg 1$ and spontaneous scatter will be amplified to intolerable levels.

Noise Light Power

The dominant noise light in fiber Raman amplification is due to the amplified spontaneously Raman scattered light. In fact, a part of the pump energy is spontaneously converted into Stokes radiation extending over the entire bandwidth of the Raman gain spectrum and is amplified together with the signal. The output thus consists not only of the desired signal but also of background noise extending over a wide frequency range (~10 THz or more).

It has been shown that, for both forwards and backwards pumpings, the noise light power is equivalent to a hypothetical injection of a single-photon per unit frequency at the fiber input end for forwards pumping, and at some distance away from the fiber output for backwards pumping. Assuming that $G_R \gg 1$ and $\alpha_L \gg 1$, the noise light powers for forwards pumping, $P_{fasp}(L)$, and backwards pumping, $P_{basp}(L)$, are approximately given by

$$P_{fasp}(L) \approx h\nu_s \Delta\nu_R (G_R - 1) \exp(-\alpha L) \qquad [13]$$

$$P_{basp}(L) \approx h\nu_s \Delta\nu_R (G_R - 1)/\ln G_R \qquad [14]$$

where $\Delta\nu_R$ is the Raman gain bandwidth, h is Planck's constant, and ν_s is the signal frequency. We can observe from eqn [13] that the noise light power in the case of forward pumping decreases as the fiber length is increased. However, in the case of backwards pumping, it depends mainly on the Raman gain, being nearly independent of fiber length and loss.

FRA Performance and Applications

One main limitation affecting the operation of fiber Raman amplifiers is the requirement of a relatively high-power laser as a pump source. The experiments near 1.55 μm are usually carried out using color-center lasers for this purpose. However, such lasers are too bulky for communication applications and the use of compact high-power laser diodes (LDs) becomes desirable. This objective has recently been achieved with the advent of high-power multimode LDs. In some cases, the output lights from various LDs are combined to attain the necessary pump power.

In a Raman amplifier, SRS has to compete frequently with other nonlinear effects. For example, since the intrinsic gain coefficient for SBS is two orders of magnitude larger than that for SRS, in some cases the SBS may occur at lower pump powers and may affect significantly the SRS process. In particular, the Raman gain may not only be reduced but also become unstable. However, the SBS can be suppressed taking into account its narrow linewidth, which is typically less than 100 MHz. Therefore, if a pump laser with linewidth broader than the Brillouin bandwidth is employed, the SBS effect would not be significant. When a semiconductor laser is used as pump source, its spectral linewidth can be artificially increased by direct frequency modulation, resulting in effective SBS suppression.

Considering its broad bandwidth (>5 THz), fiber Raman amplifiers can be used to amplify several channels simultaneously in a multichannel communication system. The same characteristic also makes such amplifiers suitable for amplification of short optical pulses.

Considering a repeaterless transmission system, the FRA can be used in three different configurations: forwards pumping, backwards pumping, and bi-directional pumping. In the first case, the signal amplification occurs near the fiber input, where the signal power is relatively high. This configuration for the Raman amplification does not generally affect the transmission quality and can compensate for the transmission loss by approximately the value of the Raman gain. For example, 10 dB Raman gain provides an increase in transmission distance of 50 km when the fiber attenuation is 0.2 dB km^{-1}. In the case of backwards pumping, the signal amplification occurs near the fiber output end before photodetection, where the signal power may be very weak, comparable with the Raman noise power. This scheme for the Raman amplification can considerably reduce the minimum detectable signal power, which results in a corresponding increase of the transmission distance. However, the transmission quality is affected due to backwards noise light. The bi-directional pumping configuration uses both forwards and backwards pumping simultaneously and its performance can be estimated from those for the respective unidirectional schemes considered above.

The FRAs can also be used in nonregenerative all-optical multirepeater systems. In this case, the transmission loss is compensated for by both forwards and backwards Raman gain providing the periodically injected pump light. This scheme can be used to overcome the fiber loss in soliton-based communication systems. In this case, the pulse broadening due to chromatic dispersion of the

fiber is also eliminated, which provides the possibility of achieving ultralong distance distortionless transmission.

Fiber Brillouin Amplifiers

The process of SBS can be described as a classical three-wave interaction involving the incident (pump) wave of frequency ω_p, the Stokes wave of frequency ω_s, and an acoustic wave of frequency ω_a. The pump creates a pressure wave in the medium owing to electrostriction, which in turn causes a periodic modulation of the refractive index. This process is illustrated schematically in Figure 5. Since the acoustic wavefronts are moving away from the incident pump wave, the scattered light is shifted downward in frequency to the Stokes frequency:

$$\omega_s = \omega_p - \omega_a \qquad [15]$$

The response of the material to the interference of the pump and Stokes fields tends to increase the amplitude of the acoustic wave. Therefore, the beating of the pump wave with the acoustic wave tends to reinforce the Stokes wave, whereas the beating of the pump wave and the Stokes waves tends to reinforce the acoustic wave. This explains the appearance of the stimulated Brillouin scattering process.

In spite of the apparent similarity between SBS and SRS, these processes differ in three important aspects: i) Brillouin amplification occurs only when the pump and signal beams counter-propagate inside the fiber; ii) the Stokes shift for SBS is smaller by three orders of magnitude compared with that of SRS; and iii) the Brillouin gain spectrum is extremely narrow, with a bandwidth <100 MHz. These characteristics significantly affect the performance and the fiber Brillouin amplifiers.

Brillouin Gain and Bandwidth

Physically, each pump photon in the SBS process gives up its energy to create simultaneously a Stokes photon and an acoustic phonon. Since both the energy and the momentum must be conserved in this process, the frequencies of the three waves must satisfy eqn [15], whereas the wave vectors are related by

$$\vec{k}_p = \vec{k}_s + \vec{k}_a \qquad [16]$$

where $\vec{k}_p$ and $\vec{k}_s$ are the wave vectors of the pump and signal beams, respectively. The frequency ω_a and the wave vector $\vec{k}_a$ of the acoustic wave satisfy the dispersion relation:

$$\omega_a = |\vec{k}_a| v_a = 2v_a |\vec{k}_p| \sin(\theta/2) \qquad [17]$$

where v_a is the acoustic velocity, θ is the angle between the pump and signal waves, and $|\vec{k}_p| \approx |\vec{k}_s|$ was used. Equation [17] shows that ω_a vanishes in the forward direction ($\theta = 0$), whereas it is maximum in the backward direction ($\theta = \pi$). The frequency shift ν_B in the backward direction is given by

$$\nu_B = \frac{\omega_a}{2\pi} = \frac{2nv_a}{\lambda_p} \qquad [18]$$

where eqn [17] was used with $|\vec{k}_p| = 2\pi n/\lambda_p$, λ_p is the pump wavelength, and n is the refractive index. Considering $n = 1.45$ and $v_a = 5.96$ km s^{-1} as typical values for silica fibers, we obtain $\nu_B = 11.1$ GHz at $\lambda_p = 1.55$ μm.

Assuming a monochromatic pump, the spectrum of the scattered light depends on the uniformity of the fiber parameters. For a uniform medium the spectrum is Lorentzian with a width $\Delta\nu_B$ determined by the acoustic attenuation. For 1.5 μm light the width is about 17 MHz. However, both the frequency shift ν_B and the gain bandwidth $\Delta\nu_B$ can vary from fiber to fiber because of the guided nature of light and the presence of dopants in the fiber core. In particular, the inhomogeneities in the core section along the length determine an increase of the amplifier bandwidth, which can exceed 100 MHz, although typical values are 50–60 MHz for $\lambda_p \approx 1.55$ μm.

The peak value of the Brillouin gain coefficient is given by

$$g_B(\nu_B) = \frac{2\pi n^7 p_{12}^2 \gamma}{c\lambda_p^2 \rho_0 v_a \Delta\nu_B} \qquad [19]$$

where p_{12} is the longitudinal elasto-optic coefficient, ρ_0 the average material density, n the refractive index, c the vacuum speed of light, and γ is a numerical factor that depends on the polarization properties of the optical fiber, which assumes the value $\frac{1}{2}$ for long lengths of nonpolarization-preserving optical fiber. By using the parameter values typical of fused silica, g_B is estimated to be about 2.5×10^{-11} m W^{-1}, which is two orders of magnitude larger than the Raman gain coefficient at $\lambda_p = 1.55$ μm.

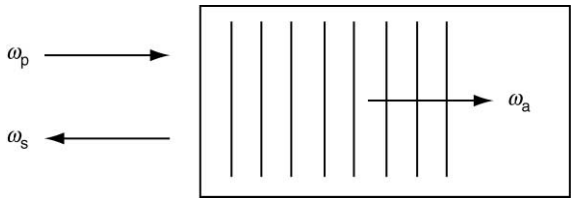

Figure 5 Schematic illustration of the stimulated Brillouin scattering process.

The expression for the Brillouin gain in eqn [19] assumes that the spectral width of the pump beam ($\Delta\nu_p$) is much narrower that the Brillouin linewidth ($\Delta\nu_B$). When such condition is not verified, the Brillouin gain is reduced according with the relation:

$$\tilde{g}_B(\nu_B) = \frac{\Delta\nu_B}{\Delta\nu_B + \Delta\nu_p} g_B(\nu_B) \qquad [20]$$

For this reason, fiber Brillouin amplifiers need to be pumped by narrow-linewidth semiconductor lasers ($\Delta\nu_p < 10$ MHz).

Gain Saturation

The slowly varying steady-state Fourier amplitudes of the Stokes (E_s) and pump (E_p) electric fields are related by the following coupled-wave equations:

$$\frac{\partial E_s}{\partial z} = \left[j\frac{K_1 K_2 |E_p|^2}{\delta - j\Gamma} + \frac{\alpha}{2} \right] E_s \qquad [21]$$

$$\frac{\partial E_p}{\partial z} = -\left[j\frac{K_1 K_2 |E_s|^2}{\delta + j\Gamma} + \frac{\alpha}{2} \right] E_p \qquad [22]$$

where Γ^{-1} is the acoustic phonon lifetime resulting in a spontaneous Brillouin scattering linewidth $\Delta\nu_B = \Gamma/\pi$, $\alpha = \alpha_s \approx \alpha_p$ is the absorption coefficient, and the coupling constants are

$$K_1 = \frac{K_2 \rho_0 n^2 \varepsilon_0}{2\nu_a}, \qquad K_2 = \frac{n^3 p_{12} \omega_s (\hat{e}_p \times \hat{e}_s)}{2c\rho_0} \qquad [23]$$

ε_0 being the free-space permittivity and $\hat{e}_p$ and $\hat{e}_s$ the unit vectors in the directions of the pump and Stokes optical fields, respectively. In eqns [21] and [22] it is assumed that the pump wave is launched at $z = 0$ and propagates in the $+z$ direction, whereas the signal wave is launched at $z = L$ and propagates in the $-z$ direction. The parameter $\delta \equiv \omega_p - \omega_s - \omega_a$ takes into account a possible detuning of the signal from the SBS gain line center.

Equations [21] and [22] can be written in terms of optical power as follows:

$$\frac{dP_s}{dz} = \alpha P_s - \frac{g_B(\delta)}{A_e} P_p P_s \qquad [24]$$

$$\frac{dP_p}{dz} = -\alpha P_p - \frac{g_B(\delta)}{A_e} P_s P_p \qquad [25]$$

where A_e is the effective core area and $g_B(\delta)$ is the Brillouin gain coefficient, given by

$$g_B(\delta) = \frac{\Gamma^2}{\delta^2 + \Gamma^2} g_B(\nu_B) \qquad [26]$$

where $g_B(\nu_B)$ is given by eqn [19].

Considering that $a \ll 1$, the following approximate solutions of eqns [24] and [25] can be written:

$$P_s(z) = P_s(0) D(z) e^{\alpha z} \qquad [27]$$

$$P_p(z) = P_p(0) D(z) H(z) e^{-\alpha z} \qquad [28]$$

where

$$D(z) = \frac{[P_p(0) - P_s(0)]}{[P_p(0) H(z) - P_s(0)]} \qquad [29]$$

and

$$H(z) = \exp\left\{ g_B [P_p(0) - P_s(0)][1 - \exp(-\alpha z)]/(A_e \alpha) \right\} \qquad [30]$$

The Brillouin amplifier gain is given from eqn [27] as

$$G_B = \frac{P_s(0)}{P_s(L) e^{-\alpha L}} = \frac{1}{D(L)} \qquad [31]$$

Figure 6 shows the output signal power $P_s(0)$ versus the input signal power $P_s(L)$ for a Brillouin amplifier with length $L = 8$ km and several values of the input pump power. Typical values $g_B(0) = 2.5 \times 10^{-11}$ m W^{-1}, $\alpha = 0.2$ dB km^{-1}, $A_e = 30 \times 10^{-12}$ m^2 were assumed. The transfer characteristics are linear for $P_p(0) = 0.2$ mW, but the effects of pump depletion become discernible

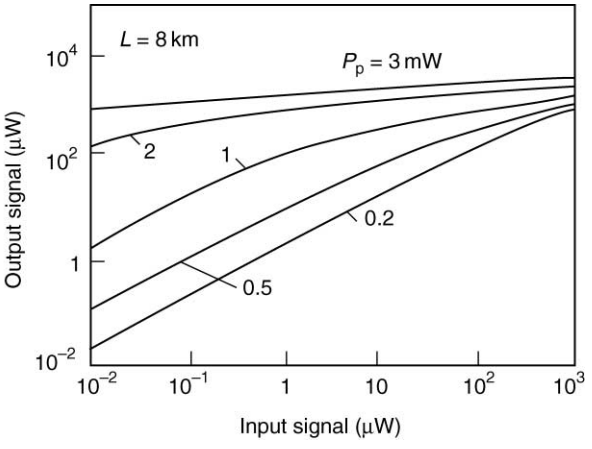

Figure 6 Transfer characteristics for a Brillouin amplifier with a length $L = 8$ km and several values of the input pump power.

for input signal levels $P_s(0) > 2\ \mu W$ when $P_p(0) = 1$ mW. For a pump power $P_p(0) = 2$ mW, linear behavior of the Brillouin amplifier cannot be observed even for signal powers as low as 10 nW.

The dependence of the Brillouin amplifier gain on the input pump power is illustrated in Figure 7 for several amounts of the signal detuning and two values of the signal power. The fiber length is $L = 5$ km and the gain bandwidth is $\Delta\nu_B = 30$ MHz, whereas the other parameter values are equal to those assumed in Figure 6. The saturated gain shows a significant dependence on the input signal power. An input signal of 1 nW, which is comparable to the original value of spontaneous emission, can be amplified by about 60 dB for a pump power $P_p(0) \approx 5$ mW. However, the amplifier gain can be considerably reduced when the signal is detuned from the gain peak. For example, for an input signal power $P_s(L) = 1$ nW and a pump power $P_p(0) \approx 3$ mW, a detuning of 15 MHz (which corresponds to a reduction of the gain coefficient to half of its maximum value) determines a reduction of about 25 dB on the amplifier gain.

Substituting eqn [28] for $P_p(z)$ in eqn [21], the following result is obtained for the Stokes field at the amplifier output:

$$E_s(0) = E_s(L)\sqrt{G_B}\,\exp\{-\alpha L/2 - j\phi\} \qquad [32]$$

where

$$\phi = \frac{\delta}{2\Gamma}\ln(G_B) \qquad [33]$$

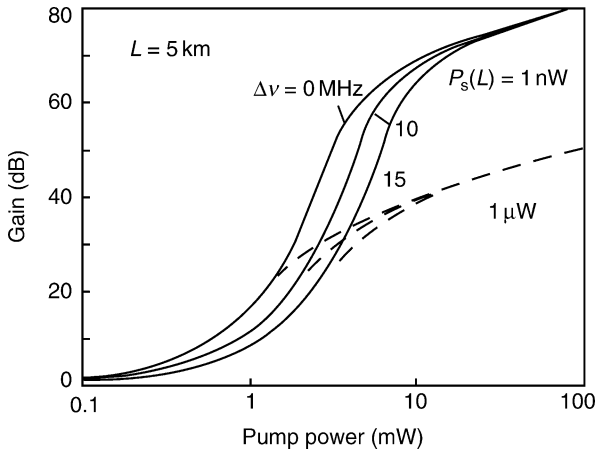

Figure 7 Brillouin amplifier gain against the input pump power for an amplifier length $L = 5$ km and different amounts of detuning from the gain center. The full curves and the dashed curves correspond to input signal powers $P_s(L) = 1$ nW and $P_s(L) = 1\ \mu$W, respectively. represents a nonlinear phase change, which depends on the SBS gain, input signal power, and frequency detuning. This nonlinear phase shift can impose a stringent limit on the pump- and signal-frequency stability when FBAs are used in some phase-sensitive detection schemes.

Noise Light Power

To describe the spontaneous emission noise we must add a spontaneous emission term to the equations describing the evolution of the Stokes and pump waves. The amplified spontaneous scattered power per unit frequency is then obtained in the form:

$$P_{asp}(\nu, z) = (h\nu/A_e)g_B(\delta)(N+1)G(\nu, z) \times \int_z^L P_p(z')[G(\nu, z')]^{-1}dz' \qquad [34]$$

where

$$G(\nu, z) = \exp\left\{\int_z^L [P_p(z)g_B(\delta)/A_e - \alpha]dz\right\} \qquad [35]$$

is the gain function, h is Planck's constant, and N is the thermal equilibrium number of acoustic phonons, given by

$$N = \frac{1}{\exp(h\nu_B/kT)^{-1}} \approx kT/h\nu_B \approx 500 \qquad [36]$$

where k is the Boltzmann constant and T is the absolute temperature. The total amplified signal and spontaneous powers are given by integration of $P_s(\nu, z)$ over the gain profile.

Similarly to the behavior of the gain, the noise power depends significantly on the signal magnitude in the saturation regime and becomes particularly high for low signal powers. This high noise level, which is about 20 dB above that of an ideal amplifier, imposes some limitations on the use of FBA as a receiver preamplifier.

FBA Performance and Applications

Fiber Brillouin amplifiers can provide high gains at low pump powers. However, the gain bandwidth is small and the amplified spontaneous emission noise is substantially larger than that observed with other amplifiers, leading to a noise figure that is quite large (>15 dB). This fact limits their usefulness as a preamplifier. Use as in-line amplifiers at high signal levels is possible in some configurations. Some problems in this application are concerned with the narrow bandwidth and the small saturation power of

the FBAs. In particular, the Brillouin linewidth strictly limits the bandwidth of data signals that can be amplified in a FBA.

The Brillouin gain bandwidth can be intentionally extended by more than one order of magnitude by applying frequency modulation to the pump laser. Of course, the bandwidth enhancement is accompanied by a reduction of the peak gain. Consequently, a higher pump power will be necessary to achieve the same gain.

The narrow bandwidth of the FBAs can be used to advantage in coherent lightwave systems to amplify selectively the carrier of a phase- or amplitude-modulated wave, thus allowing homodyne detection, using the amplified carrier as local oscillator. The scheme should work well at bit rates $>100\ \text{Mb s}^{-1}$ because the modulation sidebands then fall outside the amplifier bandwidth, and the optical carrier can be amplified selectively. However, an inevitable accompaniment of this narrow-band amplification is the nonlinear phase shift induced by the pump on the signal, given by eqn [33]. This phase shift imposes the most stringent limit on pump- and signal-frequency stability when FBAs are used for self-homodyne detection. In the case of amplitude-shift keyed (ASK) signals, for example, a phase stability of about 0.1 rad for the amplified signal carrier may be required, which corresponds to a pump-signal frequency offset <100 kHz. The nonlinear phase shift can be used with advantage in some self-homodyne schemes which require some specific adjustment of the carrier phase. In the case of a self-homodyne coherent receiver for phase-shift keyed (PSK) signals, for example, a quadrature phase correction is required. Typically, this requires a detuning of only a few MHz from the SBS gain peak, well within the Brillouin gain bandwidth.

Another application of the narrow linewidth associated with the Brillouin gain, is as a tunable narrow-band filter for channel selection in a densely packed multichannel communication system. A channel can be selectively amplified through Brillouin amplification by launching a pump beam at the receiver end so that it propagates inside the fiber in a direction opposite to that of the multichannel signal. Different channels can be selectively amplified by tuning the pump laser. The adjustable bandwidth and high out-of-band rejection can be used to advantage in this case. In another approach, the fiber Brillouin amplifier can be used to selectively amplify multiple subcarrier-multiplexed (SCM) channels carried by a single optical carrier within a WDM signal, or to amplify a backward-propagating supervisory signal.

Fiber Parametric Amplifiers

In both stimulated Raman scattering and stimulated Brillouin scattering, the optical fiber plays an active role through the participation of molecular vibrations or acoustic phonons. However, in many other nonlinear phenomena, the fiber plays a passive role except for mediating the interaction among several optical waves. Since these phenomena involve the light-induced modulation of some medium parameter, they are known as parametric processes.

The parametric processes can be classified as second-order or third-order processes, depending on whether the second-order susceptibility or the third-order susceptibility is responsible for them. Concerning the second-order parametric processes, they are not significant in silica fibers, due to the small value of the second-order susceptibility. In contrast, some third-order parametric processes, namely third-harmonic generation, four-wave mixing, and parametric amplification, can exhibit relatively high conversion efficiencies. The parametric gain in optical fibers can be used to make fiber parametric amplifiers, which find some interesting applications for squeezing and optical fiber communications.

Phase-Matching in Parametric Processes

The efficiency of the four-wave mixing process depends on the relative phase among the interacting optical waves. A high efficiency requires matching of the frequencies as well as of the wave vectors. The latter requirement is often referred to as phase-matching. In contrast with SRS and SBS, where phase-matching is automatically fulfilled as a result of the active participation of the nonlinear medium, the phase-matching condition in parametric processes requires a specific choice of the frequencies and the refractive indices.

Considering the case in which two photons at energies ω_1 and ω_2 are annihilated with simultaneous creation of two photons at frequencies ω_3 and ω_4, the matching of the frequencies imposes the condition:

$$\omega_1 + \omega_2 = \omega_3 + \omega_4 \qquad [37]$$

On the other hand, the phase-matching is given by the condition $\Delta k = 0$, where

$$\begin{aligned}\Delta k &= k_3 + k_4 - k_1 - k_2 \\ &= (\tilde{n}_3\omega_3 + \tilde{n}_4\omega_4 - \tilde{n}_1\omega_1 - \tilde{n}_2\omega_2)/c \end{aligned} \qquad [38]$$

where the $\tilde{n}_i$ are the effective refractive indices of the fiber modes. It is relatively easy to satisfy the phase-matching condition when $\omega_1 = \omega_2$. In this case, a strong pump at $\omega_1 = \omega_2 \equiv \omega_p$ generates a

low-frequency sideband at ω_3 and a high-frequency sideband at ω_4, when we assume $\omega_4 > \omega_3$. These sidebands are referred as the Stokes and anti-Stokes bands, respectively, which are also often called the signal and idler bands. The frequency shift of the two sidebands is given by

$$\Omega_s = \omega_p - \omega_3 = \omega_4 - \omega_p \qquad [39]$$

The effective indices $\tilde{n}_i$ in eqn [38] can be written as

$$\tilde{n}_i = n_i + \Delta n_i \qquad [40]$$

where Δn_i is the change of index refraction due to waveguiding. As a consequence, considering the eqn [40] and the case $\omega_1 = \omega_2$, eqn [38] can be written in the form:

$$\Delta k = \Delta k_m + \Delta k_w \qquad [41]$$

where

$$\Delta k_m = (n_3\omega_3 + n_4\omega_4 - 2n_1\omega_1)/c \qquad [42]$$

results from the material dispersion and

$$\Delta k_w = (\Delta n_3\omega_3 + \Delta n_4\omega_4 - (\Delta n_1 + \Delta n_2)\omega_1)/c \qquad [43]$$

results from the waveguide dispersion. We must note that although the two pump waves have the same frequency, Δn_1 and Δn_2 are, in general, different if these waves propagate in different modes.

The material contribution Δk_m can be expressed in terms of the frequency shift Ω_s given by eqn [39], if we use an expansion of Δk_m about the pump frequency $\omega_p = \omega_1 = \omega_2$. By retaining up to terms quadratic in Ω_s in this expansion, one obtains

$$\Delta k_m = \beta_2\Omega_s^2 \qquad [44]$$

where $\beta_2 = d^2k/d\omega^2$ is the group-velocity dispersion (GVD) coefficient at the pump frequency. In the description of the evolution of the Stokes and anti-Stokes waves, an effective propagation constant appears, given by

$$\kappa = \Delta k + \Delta k_{NL} = \Delta k_m + \Delta k_w + \Delta k_{NL} \qquad [45]$$

In eqn [45], Δk_{NL} represents a nonlinear contribution, given by

$$\Delta k_{NL} = 2\gamma P_p \qquad [46]$$

where $P_p = P_1 = P_2$ is the power in each pump wave and

$$\gamma = \frac{\bar{n}_2\omega}{cA_e} \qquad [47]$$

is the nonlinearity coefficient, $\bar{n}_2$ being the nonlinear-index coefficient.

Parametric Gain

The evolution of the Stokes and anti-Stokes waves are governed by the following coupled equations:

$$\frac{dE_3}{dz} = 2j\gamma P_p \exp(-j\kappa z)E_4^* \qquad [48]$$

$$\frac{dE_4^*}{dz} = -2j\gamma P_p \exp(j\kappa z)E_3 \qquad [49]$$

The general solution of eqns [48] and [49] is given by

$$E_3(z) = \left(c_1\exp(g_P z) + c_2\exp(-g_P z)\right)\exp\left(-j\kappa z/2\right) \qquad [50]$$

$$E_4^*(z) = \left(c_3\exp(g_P z) + c_4\exp(-g_P z)\right)\exp\left(j\kappa z/2\right) \qquad [51]$$

where the coefficients c_i are determined from the boundary conditions and the parametric gain g_P is given by

$$g_P = \sqrt{(2\gamma P_p)^2 - \left(\frac{\kappa}{2}\right)^2} \qquad [52]$$

In the range

$$-6\gamma P_p \le \Delta k \le 2\gamma P_p \qquad [53]$$

the radicand in eqn [52] is positive, so a gain occurs. The maximum gain is achieved when $\kappa = 0$ and it is given by

$$g_{Pmax} = \Delta k_{NL} = 2\gamma P_p = \bar{g}_P\frac{2P_p}{A_e} \qquad [54]$$

where

$$\bar{g}_P = \frac{\omega_p\bar{n}_2}{c} \qquad [55]$$

Considering that $\bar{n}_2 = 3.2\times10^{-20}\ m^2\ W^{-1}$ and assuming a pump wavelength $\lambda_p = 1\ \mu m$, we find that the gain coefficient $\bar{g}_P$ is larger by a factor of 2 than the peak of the Raman gain coefficient g_R. Consequently, the threshold for the parametric process is lower than with the Raman effect. However, the Raman effect dominates in general for long fibers, since it is difficult to maintain phase matching because of fluctuations of the core diameter. One can define a coherence length, given by

$$L_{coh} = 2\pi/\kappa_{max} \qquad [56]$$

where κ_{max} is the maximum tolerable phase mismatch. Significant four-wave mixing occurs only if $L < L_{coh}$.

In the case of a monomode fiber, Δk_w is very small and can be ignored. For λ_p below the zero of dispersion $\lambda_D \approx 1.3\ \mu m$ ($\beta_2 > 0$), one has to keep both Δk_m and Δk_{NL} small by using small frequency shifts Ω_s and low pump powers. When Δk_m dominates, we have

$$L_{coh} \approx \frac{2\pi}{|\Delta k_m|} = \frac{2\pi}{\beta_2 \Omega_s^2} \qquad [57]$$

In the visible range, one has $\beta_2 \approx 50 - 60\ ps^2\ km^{-1}$, and $L_{coh} \approx 1\ km$ for $f_s = \Omega_s/2\pi \approx 50\ GHz$. For a pump wavelength above the zero dispersion ($\beta_2 < 0$), the negative value of Δk_m must be compensated by Δk_{NL}. For phase matching one has

$$\kappa = 0 \approx \Delta k_m + \Delta k_{NL} = \beta_2 \Omega_s^2 + \Delta k_{NL} \qquad [58]$$

From this, we obtain

$$\Omega_s = \sqrt{2\gamma P_p/|\beta_2|} \qquad [59]$$

which coincides with the frequency shift characteristic of the modulation instability.

Amplifier Gain and Bandwidth

Four-wave mixing can be used, for example, in a fiber-optical parametric amplifier. In fact, the main difference between the four-wave mixing experiments and the parametric-amplification experiments is whether a signal at the phase-matched frequency is co-propagated with the pump or not. In the absence of a signal, the signal and idler waves are generated from amplifications of noise.

Let us consider the situation in which a signal wave with a power P_3 is launched at $z = 0$, and simultaneously an idler wave appears, with $P_4(z = 0) = 0$. In this case, considering the solution given by eqs [50] and [51] and taking into account eqn [52], we can write the following results for the signal and idler powers:

$$P_3(z) = P_3(0)\left[1 + \left(1 + \frac{\kappa^2}{4g_P^2}\right)\sinh^2(g_P z)\right] \qquad [60]$$

$$P_4(z) = P_3(0)\left(1 + \frac{\kappa^2}{4g_P^2}\right)\sinh^2(g_P z) = P_3(z) - P_3(0) \qquad [61]$$

The single-pass gain of the parametric amplifier becomes

$$G_P = \frac{P_3(L)}{P_3(0)} = 1 + \frac{P_4(L)}{P_3(0)} = 1 + \left(1 + \frac{\kappa^2}{4g_P^2}\right)\sinh^2(g_P L)$$
$$= 1 + \frac{(2\gamma P_p)^2}{g_P^2}\sinh^2(g_P L) \approx \left(1 + \frac{\kappa^2}{4g_P^2}\right)\sinh^2(g_P L) \qquad [62]$$

The approximation holds for $g_P L \gg 1$. According to eqn [52], amplification ($g_P > 0$) occurs only in the case:

$$|\kappa| < 4\gamma P_p \qquad [63]$$

Since $|\kappa|$ must be small, this also means good phase-matching. If one has complete phase-matching ($\kappa = 0$) and still $g_P L \gg 1$,one obtains exponential behavior for the amplifier gain:

$$G_P = \sinh^2(g_P L) \approx \frac{1}{4}\exp(2g_P L) = \frac{1}{4}\exp(4\gamma P_p L) \qquad [64]$$

From Eqs [44] and [45], we have that the phase mismatch κ and the frequency shift Ω_s are related by

$$\kappa = \beta_2 \Omega_s^2 + \Delta k_w + \Delta k_{NL} \qquad [65]$$

From eqn [65] we have

$$\frac{\Delta\kappa}{\Delta\Omega_s} = 2|\beta_2|\Omega_s \qquad [66]$$

In order to estimate the amplification bandwidth $\Delta\Omega_s$, we set

$$\Delta\kappa = \kappa_{max} = 4\gamma P_p \qquad [67]$$

From Eqs [66] and [67] we obtain

$$\Delta\Omega_s = \frac{2\gamma P_p}{|\beta_2|\Omega_s} = \frac{2}{|\beta_2|\Omega_s L_{NL}} \qquad [68]$$

where $L_{NL} = (\gamma P_p)^{-1}$ is the nonlinear length. Considering typical values $|\beta_2| = 20\text{–}60\ ps^2\ km^{-1}$, $\Omega_s/2\pi = 10\text{–}100\ THz$, and $L_{NL} \sim 1\ m$, we obtain a bandwidth in the range ~10–100 GHz. This bandwidth lies between that of a fiber Raman amplifier (~5 THz) and a fiber Brillouin amplifier (~100 MHz).

For $|\kappa| > 4\gamma P_p$ the parametric gain becomes imaginary and there is no longer amplification, but rather a periodical power variation of the signal and idler waves. In particular, if $|\kappa| \gg 4\gamma P_p$, then

$g_P \approx j\kappa/2$ and the parametric amplifier gain is

$$G_P = (2\gamma P_p L)^2 \frac{\sin^2(\kappa L/2)}{(\kappa L/2)^2} \quad [69]$$

A convenient measure for the width in this case corresponds to a wavevector mismatch $\Delta\kappa = 2\pi/L$, where L is the fiber length. Using eqn [66], we then have

$$\Delta\Omega_s = \frac{\pi}{L|\beta_2|\Omega_s} \quad [70]$$

Amplifier Performance and Applications

Parametric amplification can induce considerable crosstalk in WDM communication systems. Such crosstalk affects the system performance, particularly for channel spacings less than 10 GHz. Considering a channel spacing of 5 GHz and -20 dB allowed crosstalk, calculations show that the input power per channel should be smaller than 1 mW for a 15 km-long monomode fiber, and 0.1 mW for 100 km-long fiber. However, this effect can be avoided by an appropriate frequency separation of the channels.

Besides the limitation mentioned above, parametric amplification may be useful in the field of optical fiber communication systems. In fact, parametric amplifiers have a bandwidth of ~100 GHz, which is smaller that the bandwidth of fiber Raman amplifiers (~5 THz) but still sufficiently large for many applications. On the other hand, the frequency shift in FPAs can be as large as ~100 THz, which must be compared with the pump-signal frequency shift of ~13 THz of FRAs. These characteristics of FPAs allow a considerable flexibility in the choice of the pump source.

Parametric amplifier gains above 40 dB, with a 30-m-long fiber for input signal powers less than 1 mW and a pump power $P_p \approx 70$ W, were already measured. Such large gain values show clearly the potential of fiber parametric amplifiers provided phase-matching can be achieved. In fact, this condition puts stringent limits on the control of frequency shift Ω_s between the pump and signal waves. One method to satisfy the phase-matching requirement consists in using large birefringence of polarization-preserving fibers. Several parametric amplifiers using this kind of fiber have been demonstrated. Moreover, the possibility to realize a parametric laser was also demonstrated, by placing the fiber inside a Fabry–Perot cavity.

Fiber-optic parametric amplifiers have also attracted considerable attention in the context of a phenomenon known as squeezing. In contrast to coherent light containing equal minimum noise fluctuations in cophasal and quadrature components, in squeezed states one of these components acquires a noise fluctuation below the quantum-noise level at the expense of the other component. This phenomenon can occur in a parametric amplifier for certain values of the relative phase between the signal and idler waves. In fact, spontaneous emission at the signal and idler frequencies generates photons with random phases. Four-wave mixing increases or decreases the number of specific signal-idler photon pairs, depending on their relative phases. The noise reduction below the quantum-noise level can be verified using a phase-sensitive detection scheme in which the phase of the local oscillator is conveniently adjusted. The phase-sensitive nature of parametric amplifiers can also be usefully exploited to reduce the timing jitter in soliton communication systems.

List of Units and Nomenclature

A_e	effective fiber core area, m^2
c	vacuum speed of light, m s^{-1}
E_p	amplitude of the pump wave electric field, V m^{-1}
E_s	amplitude of the signal wave electric field, V m^{-1}
g_B	Brillouin gain coefficient, m W^{-1}
G_B	Brillouin amplifier gain
g_P	parametric gain, m^{-1}
G_P	parametric amplifier gain
g_R	Raman gain coefficient, m W^{-1}
G_R	Raman amplifier gain
$\vec{k}_a$	wave vector of the acoustic wave, rad m^{-1}
$\vec{k}_p$	wave vector of the pump wave, rad m^{-1}
$\vec{k}_s$	wave vector of the signal wave, rad m^{-1}
L	amplifier length, m
L_{coh}	coherence length, m
L_e	effective amplifier length, m
L_{NL}	nonlinear length, m
n	refractive index
$\bar{n}_2$	nonlinear-index coefficient, m^2 W^{-1}
p_{12}	longitudinal elasto-optic coefficient
P_{asp}	amplified spontaneous scattered power, W
P_p	pump power, W
P_s	signal (Stokes) power, W
ν_a	acoustic velocity, m s^{-1}
ν_B	Brillouin frequency shift, s^{-1}
α_p	absorption coefficient at the pump frequency, m^{-1}

α_s	absorption coefficient at the signal frequency, m^{-1}
β_2	group-velocity dispersion coefficient, $s^2\ m^{-1}$
γ	nonlinearity coefficient, $W^{-1}\ m^{-1}$

Introduction

There has been rapid growth in the deployment and capacity of optical fiber communication networks over the past 25 years. This growth has been made possible by the development of new optoelectronic technologies that can be utilized to exploit the enormous bandwidth of optical fiber. Today, systems are operational which operate at bit rates in excess of 100 Gb/s. Optical technology is the dominant carrier of global information. It is also central to the realization of future networks that will have the capabilities demanded by society. These capabilities include virtually unlimited bandwidth to carry communication services of almost any kind, and full transparency that allows terminal upgrades in capacity and flexible routing of channels. Many of the advances in optical networks have been made possible by the optical amplifier.

Optical amplifiers can be divided into two classes: the optical fiber amplifier and semiconductor optical amplifier (SOA). The former dominates conventional system applications such as in-line amplification to compensate for optical link losses. However, due to advances in optical semiconductor fabrication techniques and device design, the SOA is showing great promise for use in evolving optical communication networks. It can be utilized as a general gain element but also has many functional applications, including optical switching and wavelength conversion. These functions, where there is no conversion of optical signals into the electrical domain, are required in transparent optical networks.

We will review SOA basics, technology (materials and structures), signal transmission performance (pattern effects, crosstalk, and ultrashort pulse amplification), and some important functional applications (optical switching and wavelength conversion).

Basic Principles

The SOA is based on similar technology as a laser diode. Optical gain is achieved by electrically pumping a suitable semiconductor material, such that a

population inversion occurs between the material conduction and valence bands. An incoming photon can then be amplified when the resulting stimulated emission exceeds losses due to stimulated absorption and internal material losses. SOAs can be designed to operate in either the 1300 nm or 1550 nm optical communication windows. The principle of operation of an SOA with low residual reflectivities ($R \approx 0$) is shown in Figure 1. An input optical power experiences a single-pass gain $G = \exp(gL)$ after traveling through the SOA active waveguide of length L. The net gain coefficient $g = \Gamma g_m - \alpha_{int}$, where Γ is the optical confinement factor (the fraction of the propagating signal power confined to the SOA waveguide), g_m the material gain, and α_{int} the optical loss coefficient. g_m is a function of the injected carrier (electron) density and wavelength. The single-mode active waveguide can support two orthogonal polarization modes: transverse electric (TE) and transverse magnetic (TM).

The amplification process also adds broadband noise, amplified spontaneous emission (ASE) to the output signal. The amplifier noise figure (NF) is a measure of the signal-to-noise ratio (SNR) degradation of the signal after amplification. It is defined as the ratio of the SNR of the input to that of the output when the input noise is shot noise limited. Expressions for the output SNR are usually calculated assuming that the SOA is followed by a narrowband optical filter and an ideal photodetector, such that the main source of detector noise is the beat noise between the signal and the ASE falling within the filter bandwidth. In this case the SOA noise figure is given by

$$\mathrm{NF} = 2n_{sp}K \qquad [1]$$

with the excess noise factor K given by

$$K = \frac{(1 + RG)(G - 1)\Gamma g_m}{(1 - R)G(\Gamma g_m - \alpha_{int})} \qquad [2]$$

where n_{sp} is the effective population inversion parameter. To achieve a low NF, the internal losses must be small and a value of n_{sp} close to one is required. A favorable value of n_{sp} is achieved by operating the SOA at high gain.

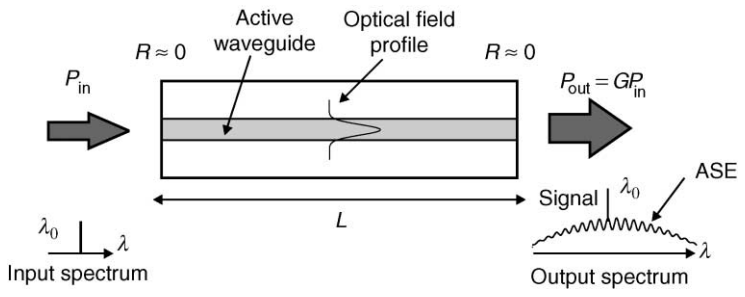
A low R is required to prevent the SOA from oscillating at high gains. The residual reflectivity is manifest as ripples in the amplifier gain spectrum and ASE spectrum.

SOA Structures

The key parameters required for a practical SOA are:

- low reflectivity ($<10^{-4}$) to ensure low gain ripple (<0.5 dB);
- low optical loss coefficient to achieve a high gain;
- high material gain to allow low drive current operation;
- low polarization sensitivity (<0.5 dB) because the polarization state of the optical signal coming from a link fiber is usually random;
- high saturation output power (P_{sat}), defined as the output power at which the gain is reduced by 3 dB; and
- low fiber-to-chip coupling losses (<3 dB per facet).

A schematic diagram of a commercial SOA chip is shown in Figure 2. The active waveguide consists of a 0.2 μm thick InGaAsP bulk active layer sandwiched between 0.1 μm thick InGaAsP separate confinement heterostructure (SCH) layers. The central section of the active waveguide is 600 μm long with a constant width of 1.4 μm. The mode-expanding active waveguide tapers are 150 μm long with a width that changes linearly from 1.4 μm to 0.4 μm at the tip. The tapers allow optical coupling to an underlying passive waveguide enabling efficient coupling to the input and output optical fibers. The structure provides a high confinement factor because of the refractive index mismatch between the layers in the gain section. The p-n junction formed by the p-InP



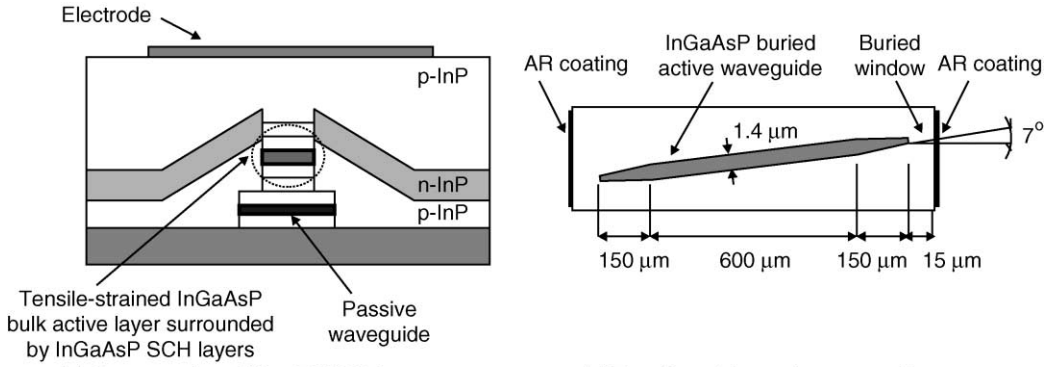


Figure 1 SOA basic structure.

Figure 2 SCH SOA with tensile-strained bulk active layer.

Table 1 Typical specifications of a commercial SOA

Wavelength of peak gain	1550 nm
Peak fiber-to-fiber gain	22 dB
Noise figure	6.5 dB
Saturation output power	10 dBm
Polarization sensitivity	0.2 dB
Gain ripple	0.1 dB
3 dB bandwidth	40 nm
Drive current	200 mA

and n-InP layers acts as a current block, thereby providing good confinement of the injected carriers from the drive current to the active layer. Very low-reflectivity ($<10^{-6}$) is obtained by combining buried windows with antireflection-coated tilted facets (7° tilt angle).

Because of the active waveguide asymmetry, the TE confinement factor is larger than the TM confinement factor. g_m is isotropic in bulk material. The introduction of tensile strain, due to the lattice mismatch between the active layer and SCH layers, causes the bulk material band structure to change in such a way that the TM material gain is greater than the TE material gain. The introduction of the correct amount of tensile strain compensates for the difference in the TE and TM confinement factors leading to low polarization dependence.

Other SOA structures that can achieve low polarization dependency are based on active waveguides with near square cross-section having almost the same TE and TM confinement factors or the combination of compressively strained quantum wells (higher TE gain) and tensile strained quantum wells (higher TM gain). Typical specifications and characteristics of a commercial SOA are listed in Table 1 and shown in Figure 3.

As Figure 3 shows, gain saturation in conventional SOAs is manifest at output signal powers well below P_{sat}. Because the gain recovery time (carrier lifetime) in SOAs is fast (typically 0.1–1 ns), this can lead to pattern effects in single-channel systems and severe crosstalk in wavelength division multiplexed (WDM) systems. This problem can be greatly reduced by the use of a gain-clamped SOA (GC-SOA). In a GC-SOA, lasing action is produced, at a wavelength remote from the operating wavelength range, by the introduction of wavelength specific feedback. Once lasing begins, the carrier density in the SOA active layer is clamped at a fixed value. Changes in the input signal power lead to opposing changes in the lasing mode power. This has the effect of keeping the carrier density fixed (i.e., clamped), thereby making the signal gain relatively insensitive to changes in the total input power. A common method of providing this feedback is the use of distributed Bragg reflectors (DBRs) as shown in Figure 4. A typical GC-SOA gain versus output power characteristic is shown in Figure 5.

Basic Applications of SOAs in Optical Communication Systems

The three basic applications of SOAs in optical communication systems are: booster amplifier, in-line amplifier, and preamplifier. The main requirements of SOAs for such applications are listed in Table 2.

A booster amplifier is used to increase the power of a high power signal. Boosting laser power in an optical transmitter can be used to overcome external modulator losses, compensate for splitting and tap losses in optical distribution networks and to increase the power budget of optical links. The most critical requirement of a booster amplifier is a high P_{sat}, to obtain a high output signal power and minimize pattern effects. SOAs with P_{sat} in excess of 10 dBm are now available commercially.

The sensitivity of a conventional optical receiver is limited by thermal noise. The sensitivity is the

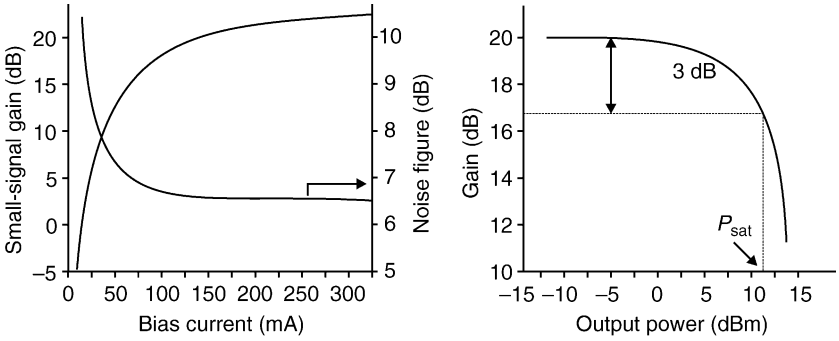

Figure 3 Typical commercial SOA small-signal gain and noise figure versus bias current and gain versus output power characteristics.

minimum signal power required at the receiver input to achieve a desired bit-error-rate (typically 10^{-9}). An optical preamplifier can be used to increase the power level of an optical data signal prior to detection and demodulation, leading to an increase in sensitivity. The performance of a preamplified optical receiver is dependent on the detector signal-to-noise ratio, $\text{SNR} = i_{\text{sig}}^2 / \bar{i}_{\text{noise}}^2$. The signal photocurrent i_{sig} is proportional to the amplified signal power. The mean square noise current $\bar{i}_{\text{noise}}^2$ includes circuit noise (thermal noise and detector dark current noise), signal shot noise, spontaneous emission shot noise, signal-spontaneous beat noise, and beat noise between the spectral components of the spontaneous emission. The best improvement in SNR occurs when the SOA is operated in the signal-spontaneous beat noise limit. In this regime, the signal power is sufficiently large such that the dominant receiver noise is the signal-spontaneous beat noise that falls within the signal bandwidth. This usually requires that the spontaneous emission from the SOA be reduced using a narrowband optical filter. The noise figure is a critical parameter in this application and should be as low as possible.

In long-haul optical transmission systems, in-line optical amplifiers can be used to compensate for link losses thereby increasing the spacing between optical regenerators. The main advantages of in-line SOAs are transparency to data rate and modulation format (unsaturated operation), bidirectionality, WDM capability, simple mode of operation, low power consumption, and compactness. The latter two advantages are important for remotely located optical components. To avoid noise accumulation in the link, it may be necessary to follow each SOA by a narrowband optical filter, but this can prevent capacity enhancements using WDM.

An example of a single channel optical transmission system utilizing booster, in-line, and

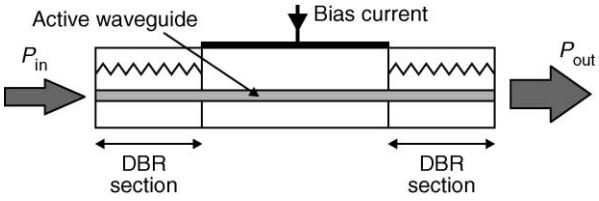

Figure 4 Schematic structure of a GC-SOA.

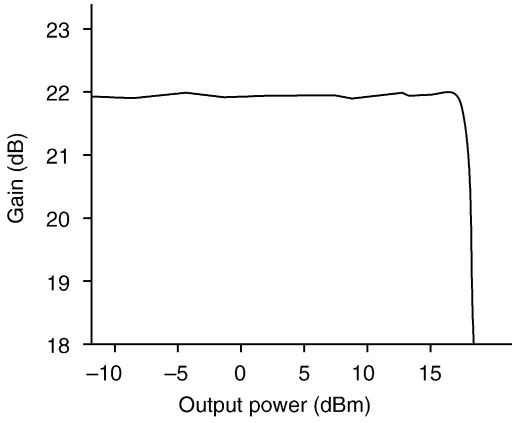

Figure 5 Typical GC-SOA gain versus output power characteristic.

preamplifier SOAs is shown in Figure 6. The transmitter comprised a 1309 nm gain-switched laser diode directly modulated with a 10 GHz sinusoid to produce a train of 40 ps wide pulses at a repetition rate of 10 GHz. At 1309 nm fiber dispersion is small and the maximum transmission distance is mainly limited by the link losses. The laser output was connected to an external modulator, driven by a 2^{31}-1 pseudo-random bit sequence (PRBS) to produce an optical data stream with an extinction ratio of 13 dB. A booster SOA was used to increase

Table 2 Requirements of basic SOA applications

Requirement	*Booster amplifier*	*In-line amplifier*	*Preamplifier*
High gain	Yes	Yes	Yes
High P_{sat}	Yes	Yes	Not critical
Low noise figure	Not critical	Yes	Yes
Low polarization sensitivity	Not critical	Yes	Yes
Optical filter	Not necessary	Not critical	Yes

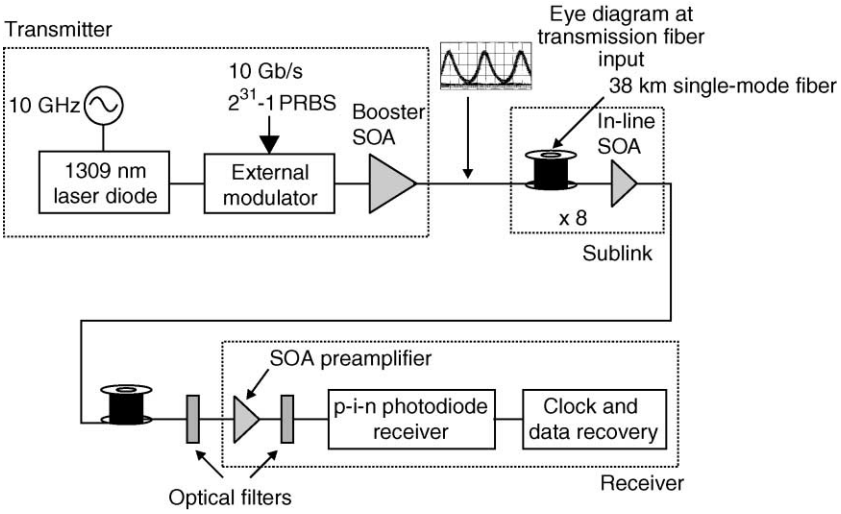

Figure 6 10 Gbit/s transmission experiment utilizing booster, in-line and preamplifier SOAs. (Adapted from Kuindersma *et al.* (1996) 10 Gbit/s RZ transmission at 1309 nm over 420 km using a chain of multiple quantum-well semiconductor optical amplifier modules at 38 km intervals. European Conference on Optical Communications 1996.)

the average transmitted power to between 0 and 2 dBm (7–9 dBm peak power). The transmission fiber length was 420 km with 12 in-line SOAs, used to compensate for fiber loss, spaced at 38 km intervals. At the receiver the signal was passed through a 1 nm bandpass filter, to reduce the accumulated spontaneous emission, amplified by an SOA preamplifier and filtered by a 1 nm bandpass filter. The signal was then detected by a p-i-n photodiode followed by an electronic clock and data recovery circuit. The SOA preamplifier and filter increased the receiver sensitivity from −14 dBm to −31 dBm for a BER of 10^{-10}. The receiver penalty after 420 km was 5 dB. In this experiment, the main limitation on transmission distance was the accumulation of spontaneous emission within the optical filter bandwidth.

Pattern Effects and Crosstalk

When an SOA is operated in the unsaturated regime, the amplifier gain is independent of the number of input signals and signal data rate. Outside this regime, the SOA will cause distortion because at high input powers, the gain saturates and compresses. Dynamic gain saturation occurs on the same time scale as the gain recovery time. This leads to pattern effects where the power of an incoming bit affects the gain experienced by subsequent bits. This is particularly important when the bit rate is of the same order as the inverse of the gain recovery time as shown in Figure 7. In WDM systems cross-gain modulation (XGM) between the channels can lead to severe interchannel crosstalk.

A further complication in WDM systems using SOAs is interchannel crosstalk caused by four-wave mixing (FWM). FWM is a coherent nonlinear process between two optical fields within the SOA, resulting in gain modulation at the beat frequency between the fields, and in the process generating new sidebands. In WDM systems with equally spaced wavelengths, the net effect of FWM is the generation of crosstalk terms interfering with the desired signals. Although the crosstalk can be relatively low in power terms, it can produce significant power penalties due to the coherent beat noise phenomena. The level of FWM crosstalk increases as the channel spacing decreases and the channel output power increases.

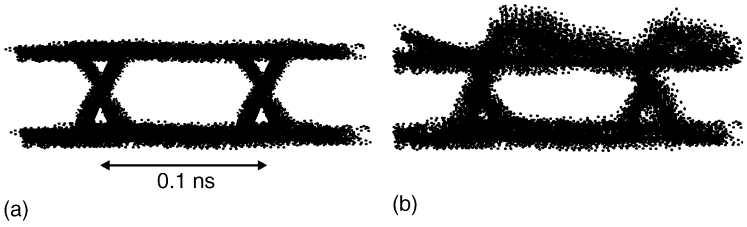

Figure 7 Typical eye diagrams of 10 Gb/s nonreturn to zero data (a) before and (b) after amplification by an SOA. ASE noise is present in the output eye diagram.

FWM crosstalk is of particular importance in dense WDM systems where the inter channel spacing is less than 100 GHz. Figure 8 shows a typical SOA output spectrum for an 8-channel multiplex with FWM-generated crosstalk signals.

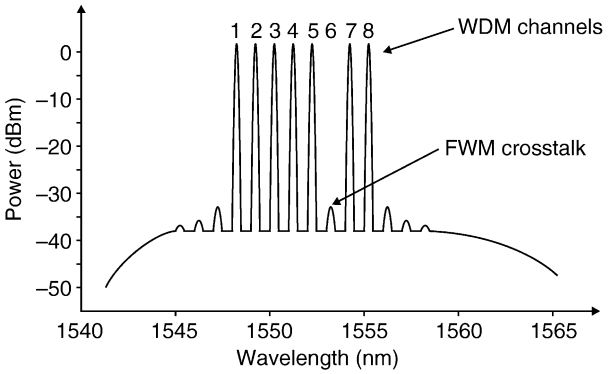

Figure 8 Typical SOA output spectrum for an 8-channel WDM multiplex with 100 GHz spacing. Channel 6 has been dropped to show the FWM crosstalk signal caused by channels 5 and 7.

Ultrashort Pulse Amplification

Optical time division multiplexing is an efficient method for increasing the bit rate of optical transmission systems. This requires the time interleaving of short optical pulses. The transmission distance is limited by the fiber group velocity dispersion, which is proportional to the pulse spectral width. Soliton transmission is also possible where the pulse shape is preserved as it propagates in the fiber.

Because an SOA has a very large bandwidth (typically 5 THz) it is capable of amplifying pulses as short as 100 fs. An input pulse can be amplified without significant distortion if the pulse energy is much less than the saturation energy E_{sat} of the SOA. Typical SOA saturation energies are of the order of a few pico Joules. As the pulse energy approaches E_{sat}, considerable spectral broadening and distortion can result. For an input pulse width τ_p (full width at half maximum) of the order of 10–100 ps spectral broadening is primarily due to self phase modulation (SPM). SPM is caused by gain saturation, which leads to intensity-dependent changes in the SOA active layer refractive index in response to carrier density variations. The degree of spectral broadening and distortion also depends on the input pulse shape. If τ_p is much less than the carrier lifetime, the output pulse power $P_{out}(t)$ and phase $\phi_{out}(t)$ are given approximately by

$$P_{out}(t) = P_{in}(t)\exp[h(t)] \qquad [3]$$

$$\phi_{out}(t) = \phi_{in}(t) - \frac{1}{2}\alpha h(t) \qquad [4]$$

with

$$h(t) = \left[1 - \left(1 - \frac{1}{G_0}\right)\exp\left(\frac{-U_{in}(t)}{E_{sat}}\right)\right]^{-1} \qquad [5]$$

$$U_{in}(t) = \int_{-\infty}^{t} P_{in}(\tau)\mathrm{d}\tau \qquad [6]$$

where $P_{in}(t)$ and $\phi_{in}(t)$ are the input pulse power and phase, respectively. G_0 and α are the amplifier unsaturated gain and linewidth enhancement factor, respectively. Typical values for α are in the range 2–10 and depend on the amplifier active region material and operating conditions. The output pulse spectrum can be obtained from

$$S(\omega) = \left|\int_{-\infty}^{\infty} [P_{out}(t)]^{1/2}\exp[i\phi_{out}(t) + i(\omega - \omega_0)t]\mathrm{d}t\right|^2 \qquad [7]$$

where $\nu_0 = \omega_0/2\pi$ is the pulse optical frequency. The output pulse chirp (frequency variation) is given by

$$\Delta\nu_{out}(t) = -\frac{1}{2\pi}\frac{\partial\phi_{out}}{\partial t} = \Delta\nu_{in}(t) + \frac{\alpha}{4\pi}\frac{\partial h}{\partial t} \qquad [8]$$

where $\Delta\nu_{in}(t)$ is the input pulse chirp. Using the above theory the shape, chirp and spectrum of an amplified zero-chirp (transform limited) Gaussian

pulse of input power

$$P_{\text{in}}(t)=\frac{E_{\text{in}}}{\tau_0\sqrt{\pi}}\exp\left(-\frac{t^2}{\tau_0^2}\right)$$

is shown in Figure 9. E_{in} is the pulse energy and $\tau_{\text{p}}\approx 1.665\tau_0$. The amplified pulse is asymmetric because the leading edge of the pulse experiences a larger gain than the trailing edge. The amplified pulse spectrum is broader than the input pulse and also develops a multipeak structure. This is due to the SPM-induced frequency chirp imposed on the pulse as it propagates through the amplifier. In this case the chirp is linear around the peak of the pulse power spectrum. It can be compensated by transmitting the pulse through an optical fiber with anomalous group-velocity dispersion. In practice optical pulses can be far from Gaussian and can also have an initial chirp. In this case the induced chirp and resulting pulse spectrum can be more complex and more difficult to compensate.

When the input pulse width is less than ~10 ps, the above theory is no longer adequate and other nonlinear effects within the SOA such as carrier heating and spectral hole burning must be taken into account. The resulting pulse power and spectral distortions induced by an SOA on such pulses can be very complex.

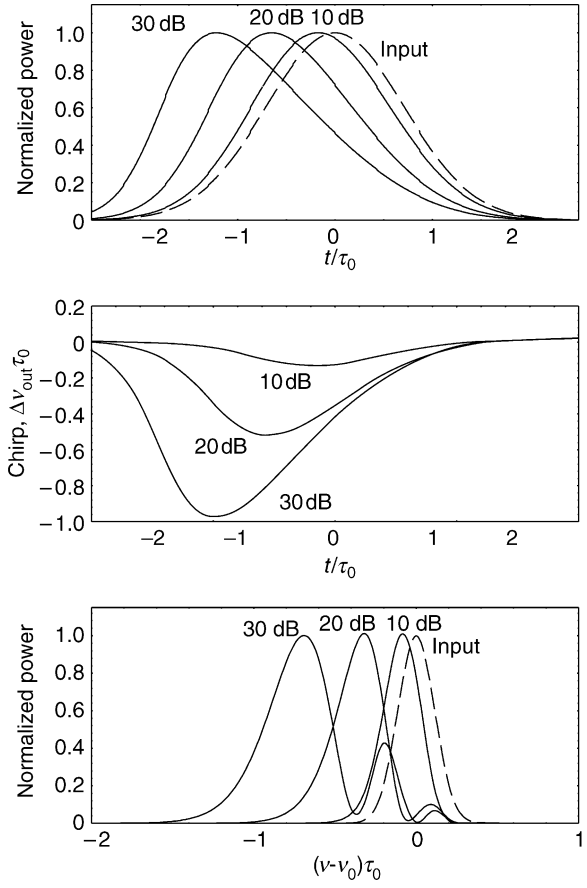

Figure 9 Amplified pulse shape, frequency chirp and spectrum for a transform-limited Gaussian input pulse with $E_{\text{in}}/E_{\text{sat}} = 0.1$ and $\alpha = 5$. ν is optical frequency. The parameter is the amplifier unsaturated gain.

Functional Applications

SOAs can be used to perform functions that are particularly useful in optically transparent networks. Recent advances in photonic integrated circuit and optoelectronic device packaging technology have made the deployment of SOA functional elements feasible. Two of the most important applications of SOAs are optical switching and wavelength conversion.

An example of a 2 × 2 SOA switch module used for optical routing is shown in Figure 10. Larger switch matrices can be constructed using this basic element. The module is based on a hybrid structure consisting of four integrated SOAs mounted on a silicon submount. The SOA-array is aligned to input and output polymer waveguides through V-grooves and alignment indentations. An incoming data packet can be routed to any output port by switching on the appropriate SOA. Switching times of the order of 1 ns are possible.

Ultrafast switching (<100 fs) can be achieved by incorporating SOAs in non-linear loop mirror structures, such as the terahertz optical asymmetric demultiplexer (TOAD) shown in Figure 11. Switching is achieved by placing an SOA offset from the center of an optical fiber loop mirror and injecting data into the loop via a 50:50 coupler. The two

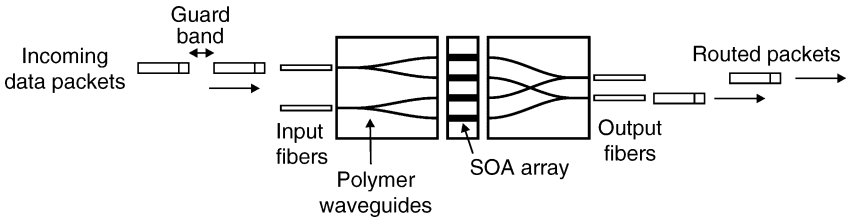

Figure 10 2 × 2 hybrid SOA switch module.

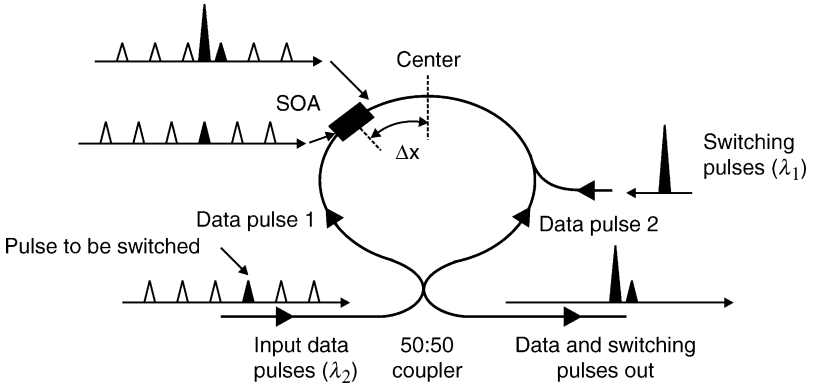

Figure 11 Ultrahigh speed optical switching using a TOAD.

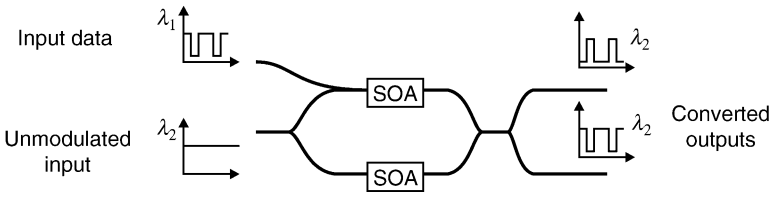

Figure 12 SOA Mach–Zehnder wavelength converter.

counter-propagating data pulse streams arrive asynchronously at the SOA. A switching pulse is timed to arrive after one data pulse but just before its replica. The switching pulse power is adjusted to impart a phase change of π radians onto the replica, so the data pulse is switched out when the two counter-propagating components interfere on their return to the coupler. The TOAD can also be used to demultiplex high-speed time division multiplexed pulse streams.

All-optical wavelength converters will play an important role in broadband optical networks. Their most important function will be to avoid wavelength blocking in optical cross-connects in WDM networks. Wavelength converters increase the flexibility and capacity of a network using a fixed set of wavelengths and can be used to centralize network management. In packet switching networks, tunable wavelength converters can be used to resolve packet contention and reduce optical buffering requirements.

Wavelength conversion in SOAs can be achieved using XGM, cross-phase modulation (XPM), or FWM. The design of an SOA wavelength converter based on XPM requires that one or more SOAs be incorporated into an interferometer, an example of which is the Mach–Zehnder interferometer (MZI) shown in Figure 12. An input data signal at wavelength λ_1 is used to modulate the upper SOA refractive index, which controls the phase shift experienced by a second unmodulated input signal at λ_2 in one of the interferometer arms. When the input data signal is low (logic 0), the arms are in phase and the λ_2 signal appears at the top output. When the input pump signal is high (logic 1) it produces an extra π phase shift between the two arms, causing them to be totally out of phase and the λ_2 signal to appear at the bottom output. Both outputs contain a copy of the original data signal imposed onto the new wavelength. Up and down conversion is possible. The lower SOA is used to equalize the gain experienced by the λ_2 signal in each of the arms. An optical filter is required at the output to remove λ_1. Such wavelength converters can operate at very high bit rates (>10 Gb/s). An important advantage of the MZI structure is that it also gives 2R regeneration (re-amplification and reshaping) of the input data signal with wavelength conversion. This is because the interferometer non-linear response increases the converted signal extinction ratio compared to the input data. All-optical 3R (2R + retiming) regenerators are of great interest in future optical communication networks to restore degraded transmission signals. SOA-based interferometric structures can be used to achieve 3R (2R + retiming) regeneration at data rates >80 Gb/s.

Introduction

Scientists are well known for the diversity of their interests. One topic that captures the interest of virtually all scientists, and people in general, is money. Not only are people engaged in obtaining money, but they are also fascinated about the manufacture of money and the protection of its value.

The relationship between manufacturing techniques and the protection of value documents (currency, stock shares, bonds, etc.) is not accidental. Technology has always been employed to counter the contemporary threats of counterfeiters. These threats vary, depending on the skill set and resources available to the criminal, as well as the counterfeiting strategy adopted. While we refer to banknotes repeatedly in this chapter, the information applies, as well, to passports, stamps, tax banderoles, identification cards, visas, licenses, checks, and bankcards. Banknotes can be considered the most challenging application for optical anticounterfeiting technologies. Stamps, banderoles, and checks are single-use items, and do not have to be as durable as currency. Identification cards, passports, and the like are used many times but are generally in protective covers and are examined by trained personnel. Currency must endure the rigors of commerce and travel, while still being easily authenticated by the average citizen.

The ever-increasing availability of low-cost computer hardware and software, along with color photocopiers and printers, has stimulated the use of optical and electro-optical technologies that were previously applied in a limited fashion or not at all. These optical techniques include: transmitted light devices, such as watermarks and threads; luminescent materials; reflective, interference, and diffraction schemes; modulation techniques (Moiré, for example); and light polarization effects.

Each of these concepts either has been or is likely to be applied to value documents to prevent counterfeiting. Each has its own set of potential benefits and

application challenges. Also, some of these effects have been successfully applied to commercial decorative products. It is important to understand the difference between commercial and security uses. Effects aimed at commercial uses are mainly decorative or aesthetic, whereas security devices are functional and integrated into a security strategy. To ensure economic success, decorative products must be easily manufactured and widely distributed. In contrast, security products are carefully controlled in both their availability and the diffusion of manufacturing expertise.

Historical Perspective

Paper currencies (banknotes) have been printed for hundreds of years. Their history has been marked by a succession of technical changes in an effort to prevent counterfeiting. Sophisticated manufacturing techniques, such as intaglio printing and watermarks, along with special papers, made it difficult for counterfeiters to produce acceptable imitations. Intaglio is the centuries old method of printing, using incised or engraved metal plates. The tremendous pressure of the intaglio press forces the paper into an ink-coated plate engraving, forming patterns of ink on the paper.

In the eighteenth and nineteenth centuries, banknote printers often used unique engravings of guilloche patterns (intricate, overlapping curves), vignettes, and portraits as anticounterfeiting devices. These sophisticated patterns effectively discouraged early, relatively unskilled, counterfeiters. The development of photography and lithographic printing in the late nineteenth century created new opportunities for counterfeiting. Photochemical technology made it possible to produce suitable reproductions using print shop facilities throughout the world.

Photochemical techniques had significant limitations, however. The printed notes were passable but not high-quality imitations of genuine intaglio notes. Making lithographic plates required specific skill, considerable equipment, and left behind meaningful evidence (films, plates, press blankets, etc.) for police to find.

Until the 1980s, counterfeiting detection methods by governmental officials were relatively uncomplicated, as three general perpetrators could be classified in fairly predictable ways (Table 1).

Until the advent of home computers, optical scanners, color printers, and copiers, the challenge for law enforcement was difficult but focused. Amateur counterfeiting was virtually nonexistent. The effort required to make a few notes was daunting, the risk high, and potential profit meager. This meant that anticounterfeiting police efforts could be concentrated on criminal counterfeiters. Government-sponsored counterfeiting was certainly known (both the Germans and the British attempted to de-stabilize their opponents' national economies during World War II), but this was more an issue of foreign policy, diplomacy, and espionage and not the main province of national police.

The situation changed quickly and radically in the late 1980s. Color photocopiers had improved in cost, quality, and size to the point that commercial establishments were buying hundreds of machines. The 1990s introduced numerous new technologies to seduce the casual counterfeiter. These included home computers, graphics editing software, color printers, and low-cost scanners.

The amateur counterfeiter now had an array of sophisticated tools that could copy, edit, and reproduce virtually any kind of document. Banknotes made by the techniques of 'digifeiting' (a term coined by Dr. Sara Church of the US Treasury Department) were not of high quality, but passable in small quantities in low risk situations. It was now possible, economical, and relatively safe to make one or a dozen bills, especially in low denominations.

Police efforts were now severely challenged as the proliferation of amateur counterfeiters made investigation and prosecution costly. Especially in the United States, average citizens were lured by the prospect of augmenting their incomes by printing one or two notes a week. When apprehended, effective prosecution and punishment of such small-stakes criminals was expensive and unpopular.

Large-production criminal counterfeiting was augmented by new digital and electro-optical

Table 1

Class of threat	*Typical volume of notes*	*Resources and skills (1980)*
Amateur	Small (<100)	Retail paper, ink. Household chemistry
Criminal	Medium to large (1000 to 1 000 000)	Litho press, darkroom, plate making, cutting equipment. Skilled printing personnel
State-sponsored	Large (millions)	Intaglio press, currency paper. Skilled engravers and printers, Major distribution networks

breakthroughs. Lithographic plates could now be made without cameras or chemistry. Laser ablated plates made directly on the printing press (such as Heidelberg/Presstek) accurately duplicated features as small as 10 or 15 microns. Further, computer-to-plate technology with erasable plates presented an unusual opportunity for counterfeit production in small press shops.

The use of new electronic and optical tools by amateur and criminal counterfeiters coincided with a rise in state-sponsored counterfeiting. The United States, in particular, was victimized in the early 1990s by high-quality, intaglio-printed notes. One such note, dubbed the 'super $100' was allegedly produced in huge volumes in the Middle East and circulated widely in Europe.

Various means of detecting counterfeits were promoted but remain largely ineffective today. The so-called 'detector pen' applies a small amount of iodine solution onto a banknote. The iodine reacts with starch (often used to stiffen paper to give it a banknote 'feel'), turning the pen mark from light brown to black. Unfortunately, the presence or absence of starch in the paper is not a foolproof criterion. US currency paper contains no starch, while the currencies of other countries, such as Canada, have a starch component.

Concurrent with the availability of new high-tech counterfeiting tools, optical science has been hard at work to create protection schemes, utilizing the latest optical effects and manufacturing technologies. These new technologies have been largely outside the skill set and resources of amateur, criminal, and even state-sponsored counterfeiters.

An analysis of all the types of optical materials used for anticounterfeiting purposes as well as for decorative purposes shows that all are based on the control of electromagnetic radiation in the ultraviolet (UV), visible, and infrared. Exploiting various degrees of light transmission, reflectance, absorption, or scatter controls this radiation. In particular, all anticounterfeit devices fall into one or more of five basic categories: light patterning, light re-emission, light diffraction, polarization, or light interference. Characteristics of an effective anticounterfeiting solution include:

- quick verification by the average person;
- ability to function in a variety of lighting situations;
- deterrence of scanning and electronic photocopying;
- compatibility with existing banknote production schemes and equipment;
- ability to be verified by machines;
- durable and reliable despite strenuous handling conditions;
- tight control of materials and manufacturing processes.

Devices Based on Light Patterning

Watermarks

Images can be created in the paper substrate during the manufacturing process. Watermarks have been in use for at least 500 years and are produced by the arrangement of the paper fibers in the cylinder-mold paper machine or by impression in wet paper in the Fourdrinier paper machine. Because they are not on the surface of a document, watermarks are not readily visible in reflected light, but become apparent when light is transmitted through the paper substrate. Credible counterfeits, however, have been produced using images created by imprinting paper with waxy or oily substances. The fatty 'ink' is not readily detected on the surface of the document and serves to change the light transmission characteristics of the paper.

Watermarks serve chiefly to authenticate the paper substrate and to deter the practice of 'raising' notes, that is, bleaching a genuine low-denomination note and re-printing it as a higher value. The most effective watermarks are produced by the cylinder-mold process and use an image that is a duplicate of that image printed in ink (Figure 1) elsewhere on the document. This gives the examiner a reference point to compare the watermark as, for example, on all high-denomination US currency.

Watermarks are an effective counterfeiting deterrent when the general population is educated about their presence and their function. The limited opportunity to expose banknotes to a source of transmitted light (outdoors or in a dimly lit restaurant, for example) somewhat reduces their effectiveness.

Threads

Thin strips of polymer or metallized polymer can be imbedded in the paper substrate during the paper-making process. Such strips are approximately 12 microns thick and 1–5 millimeters wide. These strips are known as threads because Crane & Company developed the original concept in the 1860s, using colored silk thread. Typically, threads are installed border-to-border in the narrow direction of the banknote. Because they are inside the paper, they are not seen in reflected light, but are readily visible when light is transmitted through the substrate. Such threads are effective deterrents against counterfeiting achieved by scanning or photocopying, as the scanner uses only reflected light and cannot duplicate the buried thread. Threads have evolved into several varieties:

Figure 2 Windowed thread. Reproduced with permission from De La Rue International Limited.

Figure 3 Fluorescent thread embedded into US $100 note. Reproduced with permission from Crane and Co., Inc.

- De-metallized threads: Thin polymer coated with an opaque metal. The metal is selectively removed to create text or images.
- 'Window' threads: Metallized polymer that is 'woven' in and out of the paper to permit observation in both reflected and transmitted light (Figure 2).
- Fluorescent threads: Polymer impregnated with ultraviolet inks that emit a specific color under UV irradiation (Figure 3). See the section 'Devices Based on Light Re-emission' later in this article.
- Diffractive threads: Metallized polymer strips that have been embossed with diffractive or holographic patterns and attached by hot-stamping or adhesive to the surface of the note. See the section 'Devices Based on Light Diffraction.'

Potential drawbacks to the use of threads are durability and the temptation of the general public to try to extract them from the banknote. Also, some threads can be simulated by printing or by attaching a polymer film to the surface of the banknote.

Laser Perforation

A modern 'watermark' concept is laser perforation of the banknote substrate. Precise patterns of microscopic holes (ca. 100 microns diameter) can be drilled using a high-power laser apparatus. The 200-Franc Swiss banknote features denomination numbers that are not readily visible in reflected light. However, when a light source is held behind the note, the numerals fabricated by laser perforation are clearly visible (Figure 4). In addition to being easily authenticated by non-expert observers with no special viewing apparatus, laser perforation has forensic advantages. The penetrations made by laser beams have a particular shape, spacing, and dimension, which are not easily mimicked. By clever adaptation of laser scanning software, holes of different shapes can be made and inter-mixed for additional security complexity. As a result, manual

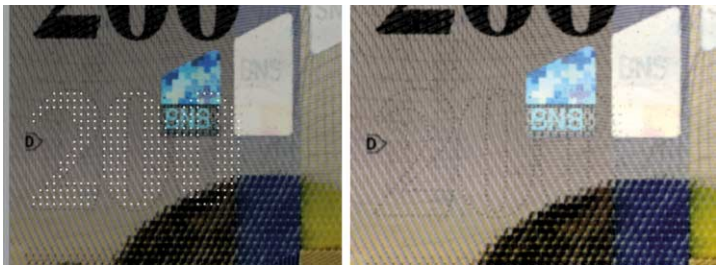

Figure 4 Microperf® laser holes in banknote. Left image in transmitted light; right image in reflected light. Reproduced with permission from Orell Füssli Security Printing Ltd.

pin pricks and mechanically pierced holes can be discriminated as forgeries.

Reflective Foils

One of the earliest defenses against photocopying and digital scanning was the use of reflective metallic foils affixed to the surface of the document. Such foils yield >80% reflection during scanning and the resultant scanned image is usually a black field.

Attachment of foils to currency paper or documents is carried out by applying a thermoset adhesive under heat and pressure and releasing the optical film from its carrier web by means of a separate polymeric release layer. This process is known as hot-stamping. Alternatively, an ultraviolet curing adhesive can be used to affix the foil to the paper substrate using a cold roll-on process.

Foiling may impede the amateur counterfeiter; since decorative foiling of stationery and packaging is well known, it presents little challenge to the professional perpetrator.

Planchettes

Planchettes are small flakes or fragments a few millimeters in diameter and 10–25 microns thick. These are often colorful or reflective materials and can feature a variety of effects including iridescence, diffraction, fluorescence, magnetic properties, or thermochromic properties. These fragments are attached to the banknote substrate by an adhesive (Figure 5). Planchettes discourage scanning and photocopying, since the copier cannot duplicate their special properties. Unfortunately, planchettes have been found to be non-durable and easy to simulate. The generally random placement makes it difficult for an examiner to authenticate a genuine note.

Thermochromic Inks

Inks that react to temperature changes have been employed on checks and identity cards. Thermochromic inks fluctuate from one color to another when the temperature of the printed image is raised. While it is possible for body temperature to activate this change, the effect is more certain if infrared heat is used. Since the process requires several seconds to activate (depending on the heat source), thermochromic materials have not been widely used on banknotes where immediate authentication is necessary.

Figure 5 Peruvian 100 Nuevo Soles note showing iridescent planchettes. Reproduced with permission from Flex Products, Inc.

Colored Fibers

Extremely fine fibers (ca. 15 microns diameter) have been incorporated into currency papers for decades. The United States, for example, uses a few hundred grams of red and blue fibers per ton of paper in making currency. While of some forensic interest, the amount and size of the fibers makes them nearly undetectable by the average citizen.

Alternatively, fibers may be impregnated with fluorescent materials, or with absorbers that selectively absorb the wavelengths of light typically used in copy machines, producing obvious forgeries when copied.

Moiré Effects

Images can be created with very fine details that produce aliasing errors when digitized. Aliasing is the creation of new and spurious patterns through the superposition of two patterns whose periodicities are unequal. It represents interaction between the spatial frequency of the genuine document and the sampling frequency of the copying device. Aliasing is commonly known as moiré in the printing industry. Typical moiré generating patterns are constructed as closely spaced concentric circles, often found around the eyes in portraits on banknotes. When scanned digitally, the resulting copy will contain spurious images (scan traps) that are easily identified as fraudulent.

For example, if a genuine document is designed in a 1000 dpi (dots per inch) printing process it can later be scanned on a 1000 dpi scanner and, theoretically, all the data can be reproduced accurately. If, however, the scanner and the document are not in synchrony, the scanner will miss pieces of data, depending on the registration error, resulting in a digitized image that does not resemble the original.

In the scanned section of a US $5 note (Figure 6), one can see patterns of curved lines intersecting in the background, whereas the authentic image consists of fine parallel lines that do not intersect. The curvature and intersections are artifacts of the moiré created by digital scanning.

Modulation Techniques

Images produced by offset lithography are based on patterns (screens) of fine dots. By varying dot density, an array of shadings and tones can be created. More progressive modulation techniques, such as amplitude modulation (varying dot sizes) and frequency modulation (varying dot spacing) are often used to produce high-resolution images. To deter counterfeiting, banknotes can be printed using pixels, which are lines of equal length but assorted angular orientation. This technique is known as screen angle modulation (SAM).

SAM techniques can be used to defeat digital scanners by preventing the scanning of all available information due to under-sampling, or by concealing hidden patterns which are not demodulated by the human eye, but can be detected with suitable filters (Figure 7). A variant of this technology, called Scrambled Indicia®, has been used to protect US postage stamps (Figure 8).

Devices Based on Light Re-emission

Ultraviolet Fluorescent Inks

Ultraviolet (UV) inks are widely used on banknotes as semicovert deterrents. Images printed in UV inks are challenging to detect in normal lighting situations but are readily visible under UV (black light) illumination. Such printed images require a special light source for authentication and are subject to degradation over time from the handling and chemical exposure of banknotes. Typically, these products are sensitive to either short UV at 254 nanometers or long UV at 366 nanometers.

UV inks provide good protection against photocopying but can be readily simulated by more advanced counterfeiters.

UV Fibers

Several countries mix minute quantities of UV luminescent fibers into the paper substrate. In most cases, these are randomly placed and invisible to the naked eye.

Devices Based on Light Diffraction

Diffractive structures range from simple periodic surface relief structures (textured surfaces) to multilevel holographic structures that form a continuum of products ranging from decorative coatings to anti-counterfeit devices. Figure 9 shows a generalized structure for all known types of reflective-based relief structures.

Most devices are based on reflection; however, in a few instances where clear polymer is used, devices may also be based on diffractive light transmission. The sizes, shapes, and orientation of the grooves vary according to the exact device. The opaque aluminum layer insures that the design works in reflected light. Most of these structures exhibit a rainbow effect where the color moves from short to long wavelength as the viewing angle increases. This rainbow effect can be found for all types of structures with grooves that have sizes near that of light wavelengths. The color shifts in a direction opposite to that of a thin film interference structure. Further, the rainbow effect can only be seen in a direction perpendicular to the groove direction. In the special case where the groove dimensions are less than the wavelength of light, the

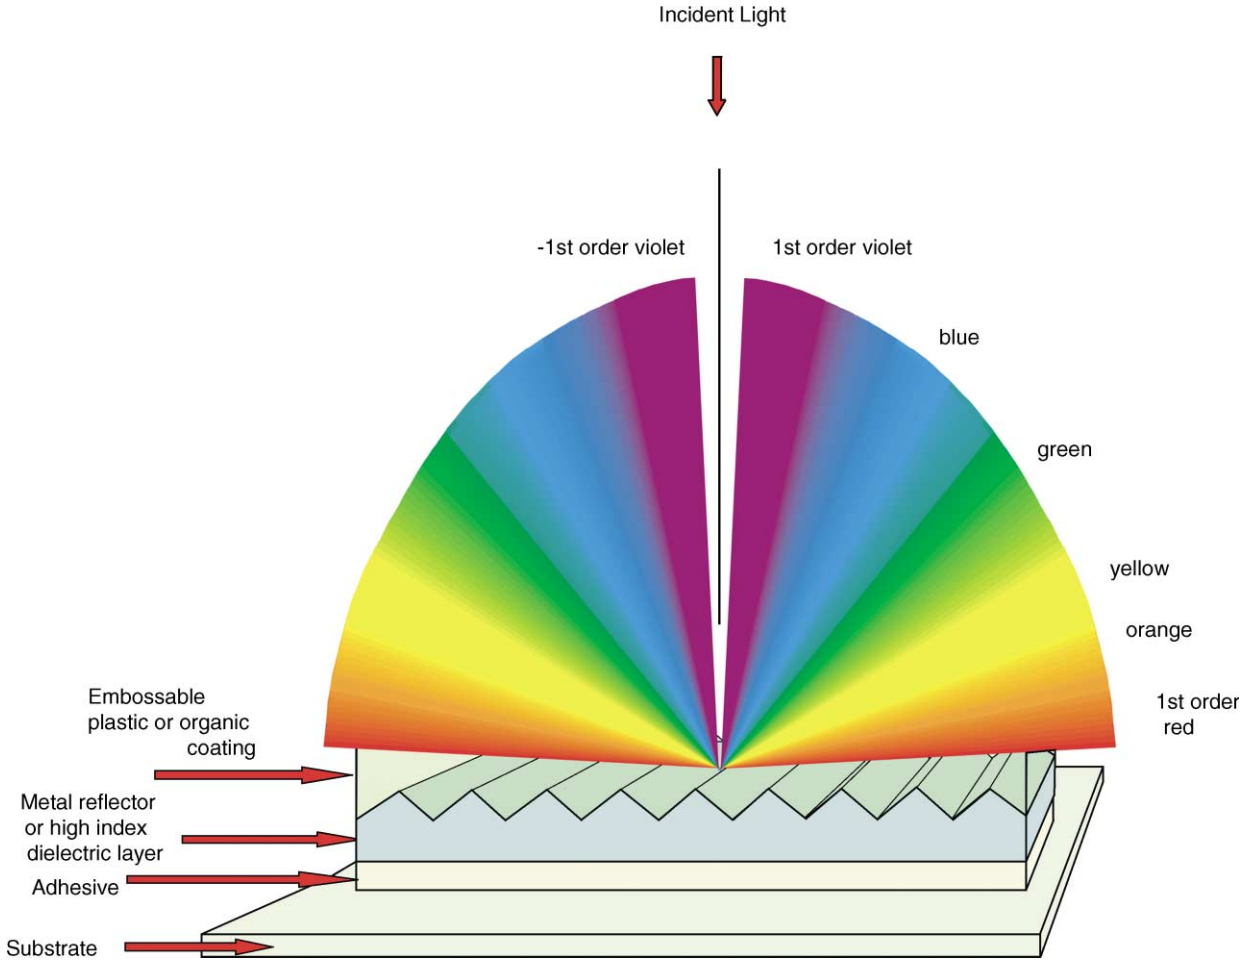

Figure 9 Cross-section of diffraction device. Courtesy of Flex Products, Inc.

rainbow effects disappear and are replaced by another type of diffraction (zero-order diffraction), where only specific colors are seen in reflection. Groove height and width for all diffraction products range from 0.1 to 10 microns.

For a unique set of discrete angles and for a given spacing d, the diffracted light from each facet is in phase with the light diffracted from any other facet, so they combine constructively:

$$Gm\lambda = \sin\alpha + \sin\beta \qquad [1]$$

where $G = 1/d$ is the groove density or pitch, α is the angle between the incident light and the normal to the grating, β is the angle between the diffracted beam and the normal to the grating and m is an integer called the diffraction order.

For $m = 0$, $\beta = -\alpha$ for all λ, the grating acts as a mirror and the wavelengths are no longer separated. This is called specular or zero-order reflection.

In contrast to grating structures (linear grooves) that only modify light intensities, holographic structures are complex surface contours that modify both the phase and intensity of the reflected light. Light reflecting off a metallized holographic structure is capable of producing an image in either two dimensions (2D) or three dimensions (3D). Heat and pressure may emboss the relief structure into a metallized polymeric film by hot-stamping. Alternatively, an embossing metal roller presses the relief image into a thermoplastic film or thin ultraviolet curable coating. The embossed structure is subsequently metallized with opaque aluminum or with a high-index dielectric material such as zinc sulfide or zirconium dioxide. The latter layers allow printed information on the substrate to show, while at the same time provide a holographic image. However, such high-index holograms are not as bright, since some of the reflective light is lost in transmission. Polymethylmethacralate (PMMA), polycarbonate (PC), polyvinyl chloride (PVC), and polyester (type G) are typical materials that can accept such an embossing.

Thick metallized embossed plastic films of ca. 50 microns are used for decorative labels. Thin metallized embossed hardcoats of ca. 7 microns, which can be released from carrier sheets or embossed thin plastic films, are used for the security field.

Holograms used for high-security applications have one characteristic that distinguishes them from ordinary holograms or other diffractive devices used for decorative purposes. This characteristic finds itself in the complication of images, multilevel images at different focal depths, different images that appear at various viewing angles, images of 3D objects superimposed with synthetic 2D images, micro-images, or images that appear to move as the device is tilted back and forth. Specific types of diffractive structures are described below. The list starts with simple holograms used in decorative markets and progresses to high-security devices.

Diffractive grating: A structure comprised of square or sinusoidal linear grooves that breaks light into its component colors. An assemblage of abutting islands, each randomly oriented and with its own parallel grooves, gives the viewer a twinkling color effect (Figure 10).

2D hologram: A relief structure that, upon viewing with a point source of light, shows a 2D image of objects, text, logos, or lines that emerge over a background. Such holograms are often referred to as 'cartoon images' since they are images of original drawings (Figure 11). Because of their simplicity and frequent use as decorative packaging, these holograms are generally not used in the security market.

Multilevel 2D hologram: A relief structure that shows a simulated 3D effect. This is accomplished by creating an image with two or more layers of flat artwork, with each layer at a slightly different focal depth (Figure 12). These images are well suited for labels, cards, and other decorative products. They have also been used on coupons, gift certificates, and tickets.

3D hologram: A relief structure that reconstructs a 3D image from a real or computer-synthesized 3D object (Figure 13). A 3D dove has been used on the VISA credit card as a security device for many years, though many now consider it more of a marketing logo than a security feature.

2D/3D hologram: A relief structure that reconstructs an image showing both a 3D and a 2D object, created from a 3D sculpture and flat art drawings (Figure 14). The artwork is created in such a way that the images appear at different depths of view.

Stereo-hologram: A relief structure that reconstructs a 3D image such that upon tilting from side to side one can see around the object, and additional features can then be viewed. At any given angle, it appears to be a 3D hologram. The image is created through multiple exposures of a 3D object during the holographic mastering process.

True color hologram: In contrast to the holograms described above, a true color hologram is created by diffraction angle control of the colors red, green, and blue from a 3D object or color transparency. The relief structure, when viewed in white light, reveals a picture in true color, as opposed to the rainbow effect seen in regular 2D and 3D holograms (Figure 15).

High-definition security hologram: A relief structure that produces an image composed of multiple elements, such as fine line text and complex patterns that simulate movement as the device is tilted back and forth. Different images also appear at different angles (Figure 16). These images occur because different images are recorded in the holographic mastering process at different angles. The complicated imagery and the use of multiple images is the major holographic technique in use today for anticounterfeiting.

High-definition diffraction gratings: The relief structure in Figure 17 shows a multitude of elements, each with colors that change upon tilting. It consists of a very fine line grating structure, 1000 lines or greater per millimeter. These gratings are sometimes combined with holographic images that change depictions upon tilting, thus providing a high level of security.

Kinegrams®: This grating structure, based on computer-generated graphic images, is composed of light diffracting microstructures of less than one micron, with blaze (saw-tooth) contours that when viewed display optokinematic movements. This security device was first used in 1987 on Austrian 5000 Schillings. When the orientation of the blaze grating changes across the device, two distinct images are possible, depending on the view with respect to the blaze angles. The images do, however, require an aluminum reflective layer deposited onto the relief structure in order to generate the highly reflective colored images.

A 180° rotation of the device can lead to a marked change in the diffraction properties and, consequently, the image properties. This stands in contrast to holographic symmetrically based structures that yield identical images. An example of a Kinegram® security device is shown in Figure 18. The letter 'K' on the front facet of the cube is filled with an asymmetric structure, whereas the background is realized by using the same structure rotated by 180°. When viewed from one side, the letter 'K' appears bright on a dark background. Upon rotation in its plane by 180°, the contrast between the letter 'K' and the background is reversed.

Zero-order diffraction grating: This relief structure is quite different from holographic or normal grating structures, as it is based on an abrupt change in the

Figure 18 The Kinegram® security device as seen in two views differing from each other by a rotation of 180° in its plane, while illumination and viewing conditions remain unchanged. Reproduced with permission from OVD Kinegram Corporation.

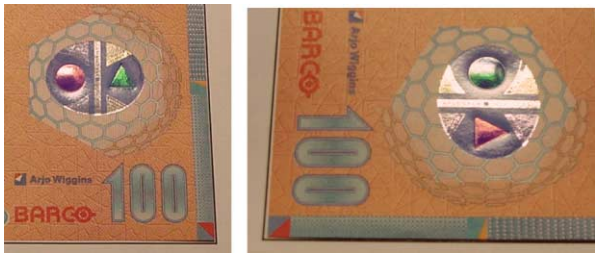

Figure 19 Zero-order diffraction images in a DID® security device: two views 180° apart in planar rotation. Reproduced with permission from Hologram Industries.

refractive index from approximately 2.3 to 1.5. Rather than employing an aluminized layer for reflection, the structure uses a thin, high-index layer ($n = 2.3$, for example) embedded in an organic polymer with a refractive index of about 1.5. The high-index layer appears as a parallel series of lines, approximately 0.2 microns wide, with another parallel series of lines beneath the first set, but oriented under the spacing of the first set of lines at a depth of about 0.2 microns.

This structure not only changes color as the device is tilted back and forth but also as it is rotated. In rotation, the color changes from red to green (Figure 19). Further, the light is polarized as it reflects. When a linear polarizer is inserted between the eye and the device, the color changes to black. The colors seen are based on specular zero-order reflection, unlike standard diffraction gratings where the reflected color is based on first-order reflection. The preeminent effect is when the device is placed over a black background. Over a white background the colors are subtler. Viewing reflection in zero order allows one to see the reflected colors in both point and diffuse lighting. The combination of polarization effects and color in rotation is ideally suited to high-security applications.

Devices Based on Light Interference

Thin-Film Foils

There are two types of thin-film interference devices. The first is based on an all-dielectric filter, and the second is based on a Fabry–Perot resonance cavity structure of the type absorber/dielectric/reflector. The all-dielectric filter uses pairs of high and low refractive index materials at a quarter-wave thickness. A typical filter is the one used initially on Canadian currency that employed the design: ZrO_2 1QW/SiO_2 3QW/ZrO_2 1QW/SiO_2 3QW/ZrO_2 1QW, where the QW (quarter-wave optical thickness) is centered at 585 nm. This design exhibits a gold-to-green color shift with viewing angle.

A Fabry–Perot filter also has a gold-to-green color shift and typically uses the design Cr 5 nm/MgF_2 4QW @ 604 nm/Al (opaque). This filter has slightly higher color saturation than the all-dielectric filter. The design is opaque and, therefore, the color observed is independent of the substrate color onto which it is affixed. This stands in contrast to the all-dielectric filter that must be laid over a black background for optical color saturation. If the all-dielectric filter is placed on a white background, the transmitted light passing through the optical filter will reflect off the white background and combine with the filter's reflection to give white light. However, with a varied colored background, the reflected color will vary depending on the combination of reflected color from the substrate and the reflected color from the filter.

The gamut of reflected colors from a metal–dielectric foil covers all four-color quadrants in the CIE Lab color space. Brightness of the foil depends on the materials used and on the design. Figure 20 shows the theoretical gamut of colors as plotted on the a^* b^* plane for the design, using the materials Cr, MgF_2 and Al.

Foils based on thin film interference layers contain a reflectance peak property moving from long wavelength to short wavelength as the viewing angle is increased. This is true across the UV, through the visible and into the near-infrared. To the human eye, the color moves from red to blue. The anti-counterfeit foil shown in Figure 21 exemplifies this effect.

Shifts from long to short wavelength occur because the path light difference (see the bold line in Figure 22) between the rays of light that reflect from the surface and the reflector are a function of the cosine of the incidence angle.

The path length difference is shown by the term $2d \cos \theta$, where θ is the angle of incidence within the

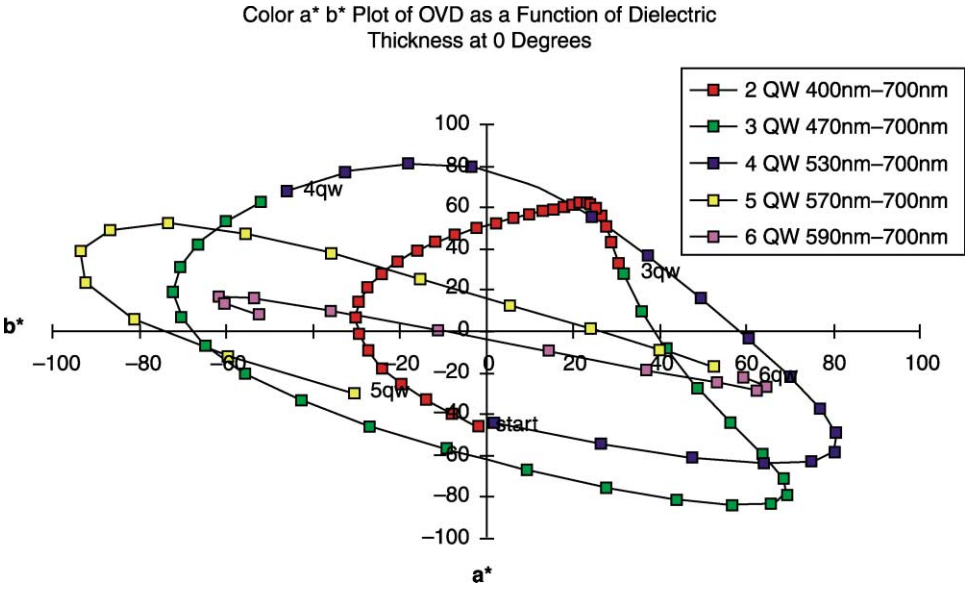

Figure 20 Gamut of colors at 0° incidence viewing under Illuminant C produced from Fabry–Perot designs as a function of quarter-wave optical thickness. Courtesy of Flex Products, Inc.

Figure 21 Anticounterfeit interference foil on brake shoes. Reproduced with permission from November AG.

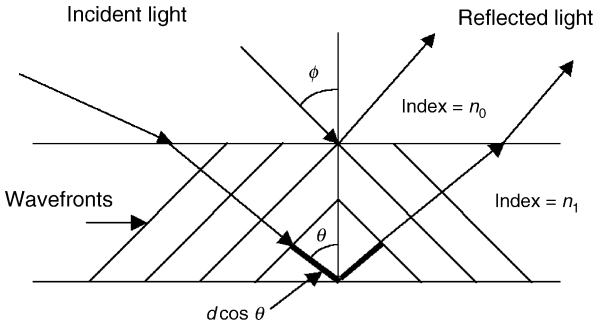

Figure 22 Diagram showing the principle of optical shift with viewing angle. Courtesy of Flex Products, Inc.

filter and d is the distance between the surface of the filter and the reflector. The angle θ and the angle ϕ are related by Snell's law: $n_0 \sin \phi = n_1 \sin \theta$.

Light interference occurs where the wavefronts superimpose on one another. The fractional number of wavelengths that can fit into this path length difference is given by $\Psi = 2n_1 d \cos(\theta)/\lambda$, where λ is the wavelength of light. Waves reflected from these two surfaces will interfere constructively when Ψ is an integral number of wavelengths and interfere destructively when Ψ is at multiples of half wavelengths. As the viewing angle (ϕ) increases, the angle θ also increases. Thus, constructive interference translates into a reflectance peak that moves toward shorter wavelengths as the angle of viewing is increased due to its cosine dependence.

The Fabry–Perot filter can use any transparent dielectric (colored or clear), a reflective metal, although optical metals are preferable since they have the highest reflectance (e.g., Ag, Al, Ni, Cu), and an absorber that is partially transmissive and partially reflective. Thin metals, absorbing dielectrics, and metal nitrides are typical materials used as an absorbing layer.

Light Interference Inks

Inks based on interference pigments have been developed over the last thirty years, starting with pigments based on high-index thin film coated micas (typically TiO_2 coated micas) and culminating with

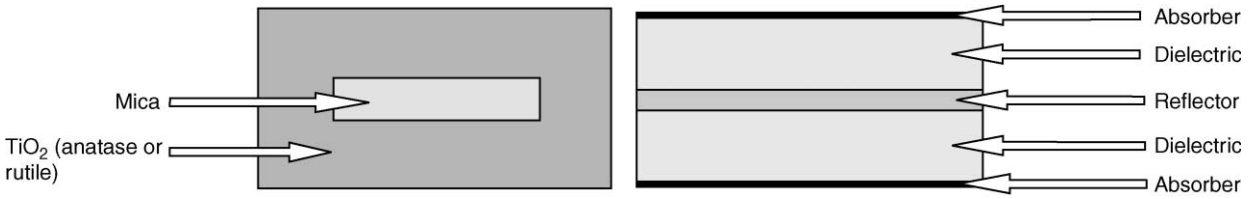

Figure 23 Left image – cross-section of interference mica; right image – cross-section of optically variable pigment (OVP®). Courtesy of Flex Products, Inc.

OVP® pigments based on the Fabry–Perot structure (Figure 23).

Inks created from micas are known as pastel or pearlescent inks, whereas inks formulated from OVP® are known as optically variable inks (OVI®). The latter inks are used as a primary defense against counterfeiting, defeating color copying and color printing from computer images. The difficulty with using interference micas for security features is that they can be readily purchased in the commercial world. In contrast, OVP® is a tightly controlled material and cannot be purchased by the general public.

OVI® security ink has been formulated into intaglio, silkscreen, flexographic and gravure applications. Its use on security documents encompasses over 75 banknotes worldwide, including the newly issued Euro notes, post-1996 $10, $20, $50, and $100 US banknotes, and banknotes for China. With the use of such inks, postage stamps, tax stamps, identification cards, and other security documents have also been effectively protected against counterfeiting. Color control for OVI® is assured because OVP® can be blended according to additive color theory to produce a desired color and color shift. Two examples of OVI® – the 100 Pula Botswana note and the new 100 Euro note – can be seen respectively in Figures 24 and 25.

OVI® inks have been extremely successful for banknote protection and might even be a *de facto* standard, because they meet the seven characteristics of an effective anticounterfeit solution as described earlier.

Figure 24 100 Pula Botswana note showing green-to-blue color shift OVI® with latent images. Reproduced with permission from SICPA.

Figure 25 100 Euro note showing magenta-to-green OVI®. Courtesy of Flex Products, Inc.

Devices Based on Light Polarization

The use of light polarization as an anticounterfeit feature has taken several avenues, one as coatings or pigments, the other as invisible images that are detected with a linear polarizer. With the exception of the zero-order diffraction device described earlier, polarization devices are based on cholesteric liquid crystals, using either nematic (planar oriented) layers or helical twisted layers.

Liquid crystal pigments are constructed from cholesteric polysilozanes that have been oriented and cross-linked in place with photopolymerization. With this cross-linking, pigments are relatively stable to temperature changes. These materials can form helical structures in either right or left twist orientation. Such materials reflect 50% of a band of wavelengths, centered at wavelength, λ_0, of the incoming light as circularly polarized light and 50% of the band centered at λ_0 as transmitted, circular polarized light, but with the opposite twist. The remaining wavelengths pass through the structure with no interaction. The amount and type of the

chiral phase (components that inherently orient into a helical structure) in the polymer determine the pitch of the helical structure. This, in turn, determines the wavelength of reflection, i.e. $\lambda_0 = nP$ where n is the average refractive index and P is the pitch length of the material (pitch length determined by 360° rotation of the helix). At tilted viewing angles, the color changes according to the formula $\lambda = \lambda_0 \cos\theta$ where θ is the viewing angle relative to the vertical, and λ_0 is the reflected wavelength seen perpendicular to the surface. By the judicious combination of left- and right-handed helical based layers, or by inserting a half-wave retarder layer between two layers having the same helical structure, the resulting pigments reflect nearly 100% at λ_0.

When these materials are properly processed and ground (particles 2–50 microns thick, with an aspect ratio of 3:1 in lateral/thickness dimensions), particles with the helical structure perpendicular to the planar surfaces can be realized. Such pigments, or liquid crystal polymeric coatings, when printed, have color-shifting properties with viewing angles that defeat color copiers and the like, since toners have no color-shifting properties (Figure 26). These pigments also have an additional security feature, namely, that when viewed through a circular polarizer having the opposite twist, the color-shifting pigments appear black.

Figure 26 Anticounterfeit label showing liquid crystal coating viewed straight-on and at tilt angles. Courtesy of Flex Products Inc.

A special technology known as linear photo-polymerization (LPP) is a process to produce photo-patterned liquid crystal polymer (LCP) $\lambda/4$ phase retarders, which, when combined with a series of layers involving a reflector, and a linear polarizer, shows positive and negative images. Without the diagnostic linear polarizer, however, the image is invisible (Figure 27).

Adding a nematic liquid crystal layer, which exhibits a helical twist configuration, extends this technology. The latter technology can produce colored images when viewed with a linear polarizer. Such devices can be coated or hot-stamped onto a substrate containing viewable information.

Combination Devices

Beginning in 2000, combinations of holographic structures with liquid crystal or interference thin films were developed, which could make counterfeiting even more difficult. Such structures emerge as a hologram floating on a color shifting background. Magnetic layers, integrated into part of the optical interference stack, allow spatial orientation and 3D effects during printing.

Decorative Coatings

Coatings Based on Diffractive Pigments

When pigments based on diffractive effects are created, individual flakes have surface contours of groove-like structures of 2000–3500 lines mm^{-1}. In spray-out coatings using such pigments, diverse interplay of subtle rainbow colors results (Figure 28). The effect is particularly striking in full sunlight as, for example, on curved surfaces found on cars and motorcycles. Some manufacturers have successfully used finely shredded diffraction gratings

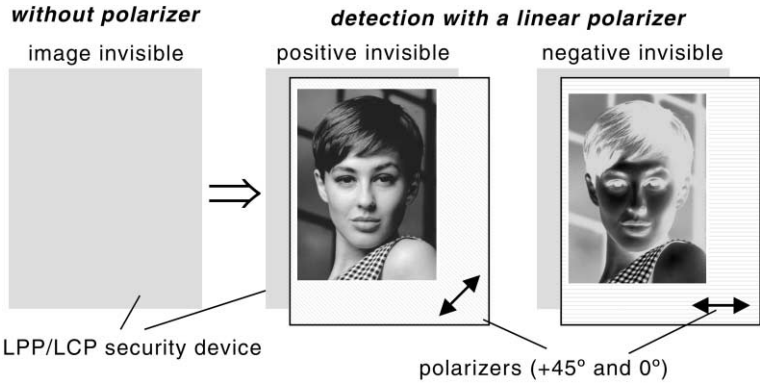

Figure 27 Reflective optical LPP/LCP security device showing a complex LPP/LCP retarder image visualized with one polarizer; rotation of the polarizer changes the image from positive to negative. Reproduced with permission from Rolic Research, Ltd.

Figure 28 Motorcycle painted with diffraction-based pigments. Courtesy of Flex Products, Inc.

(ca. 25 microns thick) as flakes mixed in paints for decorative purposes. The use of such thick flakes seriously limits the applicability and uniformity of the coating.

Coatings Based on Interference Pigments

Pigment-based interference effects are widely known and have been used for decades in the paint, plastics, and cosmetic industries. These structures are based on TiO_2 coated mica, where the mica thickness is between 300 and 600 nm with planar diameters ranging from 1 to 200 microns, depending on the application.

Depending on the thickness of the TiO_2, different reflective colors of silver, gold, red, blue, and green are achievable. For maximum color reflection, a black substrate or viewing at a particular angle is required so as to prevent dilution of the reflected color from light reflected from the substrate surface. Colored mica pigments are platelets of mica coated with colored oxides. Metallic-like colors are also formed from iron oxide coated micas. In the first instance, two colors may be seen: the platelet color (due to absorption) and the interference color at one angle. Only the interference color may be seen at another viewing angle. If the substrate is colored, the color switches from the interference color to the substrate color as the viewing angle changes. More recently, laminar pigments with an all-dielectric optical stack have been produced with a low-index central core, encapsulated with high-index layers that cause interference.

Interference pigments based on absorber/dielectric/metal/dielectric/absorber have also been introduced into the decorative marketplace. These structures are based on aluminum as the central layer, a dielectric spacer layer, and either a wavelength selective absorber layer such as iron oxide (Fe_2O_3) or a nonwavelength selective absorber such as chromium (Cr). In Fe_2O_3 based pigments, the face-on colors are mainly found in the yellows and reds whereas for the Cr-based pigments, a full color gamut is possible.

Diffractive Foils

These foils are based on diffractive and grating surfaces where the contours are generally less than 2000 lines mm^{-1}. These materials show a glittering effect, i.e., multiple points of color, as the viewing angle is changed.

Interference Polymeric Films

These films are made from multilayer extrusions of pairs of polymers of 50 or more layers. Each pair is composed of two different polymers with a slightly different refractive index. Each layer is approximately one-quarter wave in thickness. Due to the small refractive index differences between layers, the resultant film is approximately 25 microns thick. Uniform color at a given viewing angle is generally not possible due to the lack of thickness control. Hence, they tend to look like oil slicks, with each color changing as the viewing angle changes (Figure 29). Interference polymeric films have found use as decorative gift wrapping material.

Holographic Foils

As indicated earlier, holograms designed for non-security markets may range from simple 2D holograms to more complex ones that function for either decorative or brand protection purposes. Another application of holographic foils is in holographic fabrics, whereby small holograms approximating several millimeters in diameter are affixed in a pattern to the cloth (Figure 30).

Aluminum Flake Based Inks and Coatings

These inks are composed of leafing or nonleafing aluminum powders and a polymeric vehicle. The use of leafing pigments produces images and coatings of high brilliance, whereas nonleafing pigments produce a matte or satin-like finish.

Summary and Challenges for the Future

Optical scientists have shown tremendous creativity in discovering and employing clever technical devices in the fight against counterfeiting of valuable documents. Optical solutions have been created that meet the functional as well as the economic needs of the document security industry. A cadre of research institutions and manufacturing companies has accepted the challenge of protecting the instruments of our economic and physical security.

This vigilance will have to continue in the future. Nearly as fast as new defenses are developed, criminals are illicitly using new tools to defeat the protection schemes. Financing for sophisticated counterfeiting efforts is likely to increase, whether sourced by international terrorists or drug dealers. Likewise, the more we move toward an information society, the more we depend on machines to count, sort, and verify documents and money. This machine-driven trend will mandate new features, especially in banknotes and cards.

Figure 30 Fabrics showing holographic effects. Reproduced with permission from Amagic Holographics, Inc./K-Laser Technology, Inc.

It is likely that the future of optical anticounterfeiting technology will be strongly influenced by:

- Active, rather than passive, devices. That is, devices that can be applied to a document and later stimulated or interrogated by a machine to elicit a specific effect or signal.
- Schemes that may be merged with new biometric technologies, especially for individualized documents, such as passports and identification cards. In such applications, it will be necessary to confirm that a document is genuine, and that it is in the possession of its rightful owner.
- The need to clearly differentiate security applications from decorative or aesthetic uses. Effective security products must always be carefully controlled and their availability limited.
- The willingness of the public to accept regular changes in the appearance of value documents. Currency will have to undergo redesign on a three-to-six year cycle, rather than the long cycles typical in the past.

This chapter was intended only as a survey of the issues involved in anticounterfeiting protection. To learn more about the optical methods discussed here, or to learn more about the science of anticounterfeiting, please consult the "Further Reading" section and the Internet sites listed in Table 2.

Diamond Optical Devices and Coatings

What do a human, a plant, the photoresist used in microfabrication, and a polymer have in common? Why has carbon become a crucial part of all known living systems? The answer to these questions may be embedded in carbon's hybrid bonding structure (sp, sp^2, and sp^3 C–C bonds). Carbon has 4 electrons in its outermost shell (the valence shell), which is the second shell. At first sight, one would expect that these 4 electrons are distributed among its one 2s and three 2p orbitals. However, it is well known that, in the diamond lattice, each carbon atom bonds with its four neighbors. Are the electrons in 2s and 2p orbitals

responsible for the four bonds? One possible answer is that the 2s, $2p_x$, $2p_y$, and $2p_z$ orbitals of the carbon atom form bonds with their neighbors. There are two problems with this answer. First, these bonds will have different strengths (s and p orbitals), which is in contradiction with the experimental fact indicating an equal strength for all the four C–C bonds in the diamond. Second, the computed strength of such bonds will be lower than that found experimentally. What is then the nature of C–C bonds found in organic compounds?

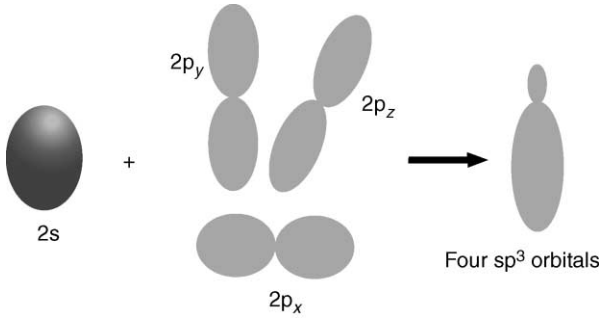

Figure 1 Hybridization of s and p orbitals in carbon to form sp^3 orbitals, which form the so-called sigma bonds responsible for the strong diamond lattice.

The answer to this difficult question was provided in 1931 by Linus Pauling (1901–1994), the winner of two Nobel prizes. With the help of quantum mechanical calculations, Pauling showed how one s orbital and three p orbitals can mix, or hybridize, to form four equivalent atomic orbitals with tetrahedral orientation. The resulting hybrid orbitals are called sp^3 orbitals as shown in Figure 1. The sp^2 or sp^1 orbital results if two or one p orbital combine with the s orbital, respectively, to form the hybrid. While sp^3 C–C bonds lead to a diamond lattice, the sp^2 C–C bonds lead to graphite, and a material which contains both sp^2 and sp^3 C–C bonds is called diamond-like carbon (DLC). The optical properties, such as the bandgap, of DLC depend on the sp^3/sp^2 ratio. If a sheet consisting of a monolayer of graphite, which consists of sp^2 bonds, is wrapped into a pipe, the resulting structure is called a single-wall nanotube (SWNT), as shown in Figure 2a. A multiwall nanotube (MWNT) has many such layers (Figure 2b–c). Other elements such as oxygen (in H_2O) and nitrogen (in NH_3) also form sp^3 orbitals but carbon seems to be only one which is capable of forming sp, sp^2, or sp^3 bonds, depending upon the bonding environment (Figure 3). This may explain why nature has selected carbon

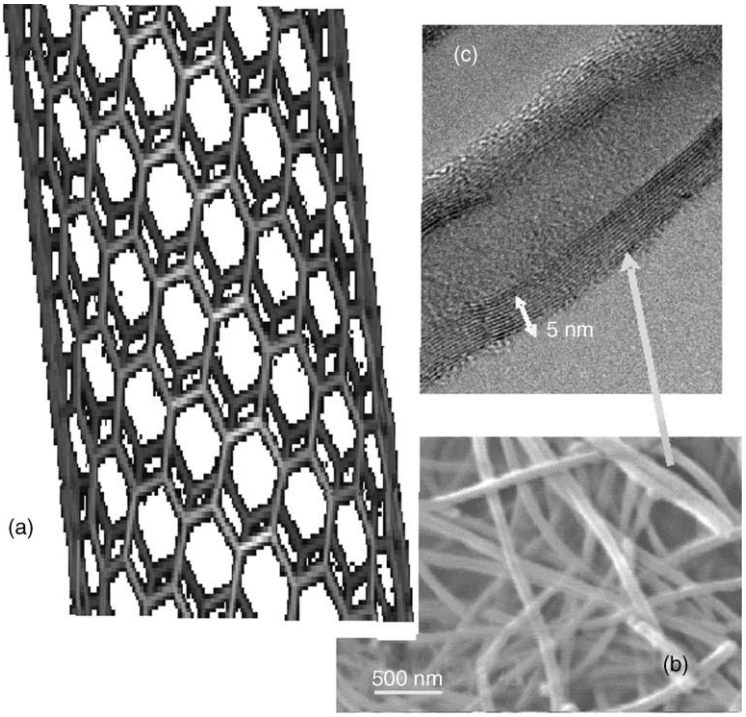

Figure 2 CNT: (a) drawing of a single wall CNT showing sp^2 bonded layer; (b) a mat of multi-wall CNTs; and (c) a TEM of MWNT showing 13 sp^2 bonded layers.

[a]Diamond may convert to graphite well below 4000 °C depending upon the ambient and it oxidizes at 650 °C to form CO_2/CO in O_2.

(perhaps due to its bonding flexibility, to form long C–C chains and rings) as the material of choice for building living systems.

The sp^3 bonding in a diamond lattice makes it a very unique material with a combination of properties not matched by any other known materials (Table 1). In fact, the C–C sp^3 bond in diamond is responsible for its remarkable properties leading to current and potential applications as shown in Figure 4. Although diamond (for centuries) and its bonding structure (for over 70 years) has been known for a long time, the growth of diamond films using chemical vapor deposition (CVD) took a long time to mature. Again, this delay relates to the difficulty with which the diamond lattice with sp^3 C–C bonds is fabricated.

Diamond Growth by CVD

First evidence of diamond growth by CVD, by Eversole in 1952–1953, led to the use of H_2 and CH_4 in the hot filament CVD (HFCVD) to grow diamond on diamond substrates (homoepitaxial growth) by Angus in 1971. The inexpensive CVD polycrystalline diamond (poly-C) was grown on non-diamond substrates by Deryagin in 1976, Spitsyn in 1981, and by Matsumoto *et al*. in 1983. Currently,

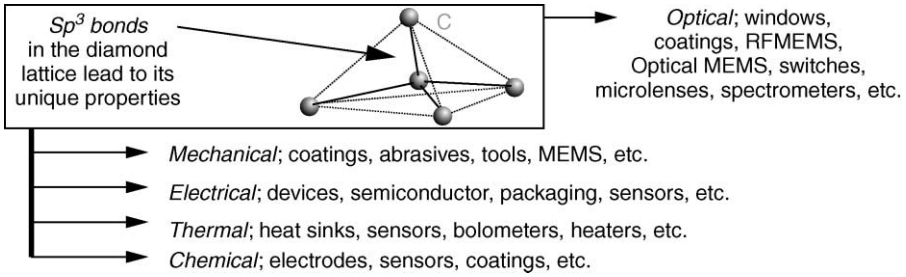

Figure 4 Sp^3 bonds in diamond make it a unique material.

Table 2 Different diamond deposition methods

Disadvantages	Contamination, fragile filament	Rate	Contamination, small area	Small area	Expensive

HFCVD, hot filament CVD.

it is believed that, during the CVD of diamond, the CH_3 is responsible for deposition of C as diamond and non-diamond phases. The atomic hydrogen, present in the growth environment, removes the non-diamond phases leaving behind the diamond phase. Near the end of the 1990s, basic science of CVD diamond was well understood, and today diverse plasma and thermal techniques have been developed to produce poly-C films several mm thick and over 12 inches in diameter. Optically smooth 300-micrometer thick undoped poly-C wafers are available on the market. Although there are some reports of n-type poly-C and crystalline diamond growth, the well-established techniques exist only for *in situ* doping of p-type diamond.

A number of diamond growth techniques are currently available for the growth of diamond and carbon nanotubes. Microwave plasma CVD (MPCVD) can be used for the growth of both diamond and carbon nanotubes. As shown in Table 2, the deposition rate of diamond shows a large variation (0.1–3600 micrometers/hour) depending on the growth technique. For applications of diamond in optical coatings, optoelectronic devices and optical systems, the study of transmission, reflection and absorption of light for diamond is very important. These properties of diamond are responsible for its beauty and glamor. For applications in optoelectronic materials, devices and systems, the micro-fabrication and -machining technologies are crucial, particularly in the case of inexpensive poly-C films.

Absorption, Reflection, and Transmission in Diamond

The optical properties, which have been studied for hundreds of years, of naturally occurring single crystal diamond have led to the gem commerce. The fundamental concept involved in the tremendous historical fame of diamond is its high refractive index, n_d (in the range of 2.38–2.64 depending upon the wavelength of light). The refractive index of a material is a measure of decrease of velocity of light (which is also true for all electromagnetic waves) when the wave enters the material. Mathematically, n_d is defined by

$$n_d = V_{vac}/V_d \qquad [1]$$

where V_{vac} and V_d are velocities of light in vacuum and diamond, respectively.

When a beam of light of intensity I_0 in air is incident normally on the surface of diamond, the reflected part of the beam, characterized by the reflection coefficient R, depends on n_d, and R is given by

$$R = \left(\frac{n_a - n_d}{n_a + n_d}\right)^2 \qquad [2]$$

where n_a is refractive index of air and n_d is given by Sellmeier dispersion equation:

$$n_d = \sqrt{1 + \frac{4.3\lambda^2}{\lambda^2 - 0.0121} + \frac{0.33\lambda^2}{\lambda^2 - 0.031}} \quad [3]$$

where λ is the wavelength of light expressed in micrometers. When the beam enters diamond, part of it is absorbed in diamond. The absorption, characterized by the absorption coefficient α, is caused by: (i) impurities (such as nitrogen, boron, hydrogen, etc.); and/or (ii) intrinsic defects (such as dangling bonds, sp^2 bonds, and sp bonds). However, if the energy of light is close to or above the bandgap of diamond (5.5 eV), the absorption can be caused by electronic transitions from valence to conduction bands. The intensity $I(x)$ at a distance x below the diamond surface is given by

$$I(x) = I_0(1 - R)\exp(-\alpha x) \quad [4]$$

The fundamental expressions for α are different for indirect and direct type semiconductors. However, the modeling of α, for energies close to the bandgap of diamond, can be accomplished empirically using Urbach's rule according to the following equation:

$$\alpha = \alpha_0 \exp\left[\frac{\sigma(T)(E - E_0)}{kT}\right] \quad [5]$$

where α_0 and σ are Ubach tail parameters, and E_0 (6.5 eV) is direct gap energy of diamond. K is Boltzmann constant and T is the temperature. As at $T = 300$ K, $\alpha_0 = 4.23 \times 10^{11}$ cm^{-1} and $\sigma = 0.585$, eqn [5] can be simplified:

$$\alpha = 4.23 \times 10^{11}\, e^{22.6(E-6.5)} \quad [6]$$

where the units for α and E are in cm^{-1} and eV, respectively. Using the expression $E = 1.24/\lambda$, where E is in eV and λ is in micrometers, eqn [6] can be written as

$$\alpha = 4.23 \times 10^{11}\, e^{27.9(1/\lambda - 5.24)} \quad [7]$$

where λ is in micrometers. The variations of α and n_d with wavelength and energy of light are shown in Figure 5, which are plotted using eqns [3] and [7]. Impurities and intrinsic defects in diamond strongly affect α, n_d, and its other properties.

Impurities in Diamond

A pure diamond with perfect lattice structure is transparent to ultraviolet (UV), visible, infrared (IR), millimeter and microwave regions of the electromagnetic spectrum. However, even an impurity-free diamond has some absorption in the infrared due to phonon excitations and an ultraviolet cutoff due to band-to-band absorption. The defects, impurity-related and intrinsic, in single crystal diamond have been extensively studied because they strongly affect its properties. In fact, diamonds are classified according to the type of defects that are dominant.

Impurities in diamond give rise to additional energy levels in its bandgap. If the density of these impurities is sufficiently high, they can cause absorption of electromagnetic radiation (including light) on one hand and break the lattice symmetry on the other. The breaking of the lattice symmetry can lead to one-phonon IR absorption, which is forbidden in pure diamond. The fact that impurities affect the optical properties of diamond led to its classification into types Ia, Ib, IIa, and IIb which correspond to pale yellow, golden yellow, no color, and blue, respectively. The transmission properties of these various types of diamond are depicted in Figure 6. The dominant impurities are nitrogen

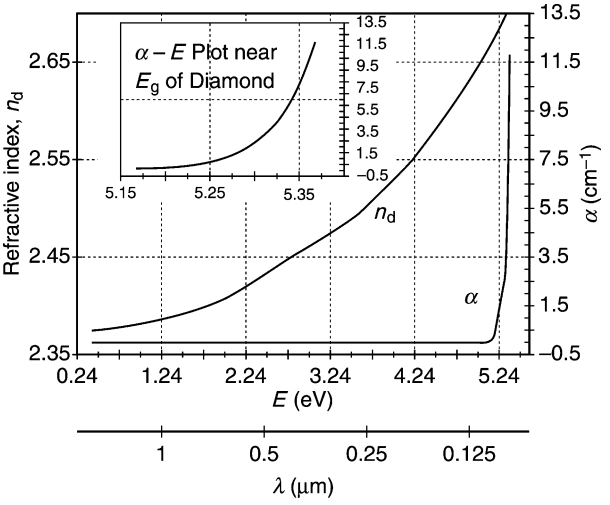

Figure 5 Wavelength and energy dependence of absorption coefficient and refractive index of diamond.

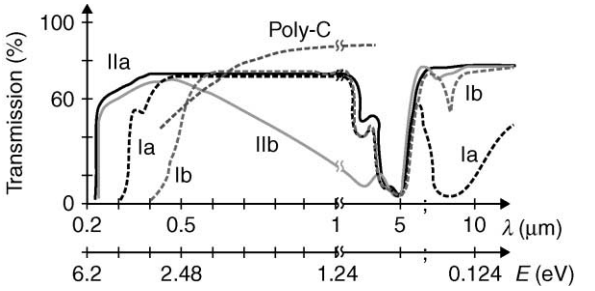

Figure 6 Transmission spectra of natural diamond and CVD polycrystalline diamond (poly-C).

(5–2500 ppm atomic) in type I and boron (10 ppm atomic) in type II. It may be pointed out that boron-doped diamond is a semiconductor with p-type conductivity measured at room temperature. Nitrogen-doped diamond does not show n-type conductivity at room temperature as the donor levels are too deep to be ionized.

Polycrystalline CVD Diamond

Due to the lack of a reliable hetero-epitaxial diamond growth technique, the crystalline diamond films are very expensive (require single crystal diamond substrates for their growth) and, consequently, their widespread commercial use is severely limited. Polycrystalline diamond (poly-C) grown by CVD, which can be as inexpensive as any other material if mass produced, is very attractive for optical and other applications (Figure 2). The properties of high-quality (with high density of sp^3 C–C bonds) poly-C films are comparable to those of crystalline films.

As shown in Figure 6, the transmission properties of poly-C are comparable to or better than those of type I and II diamonds for part of the energy range. Free-standing commercial poly-C films are typically polished and have thicknesses in the range of 50–300 micrometers (the least expensive are 300 μm thick). White poly-C films transparent to visible light are also available. Such films, with optically smooth surface, can be considered free of scattering effects. These films can be considered as a transparent plate in air and, for normal incidence of light with energy less than the bandgap, the transmission coefficient is given by

$$T = \frac{(1 - r_1^2)(1 - r_2^2)}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos(2\delta)} \qquad [8]$$

where the Fresnel coefficients are given by

$$r_1 = \frac{n_a - n_d}{n_a + n_d}, \qquad r_2 = \frac{n_d - n_a}{n_d + n_a} \qquad [9]$$

where n_a and n_d are refractive indexes of air and poly-C, respectively, and δ is phase change for a poly-C film with a thickness of t:

$$\delta = \frac{2\pi}{\lambda} n_d t \qquad [10]$$

Using $n_a = 1.0003$, $n_d = 2.4$, and $t = 100$ μm, eqn [8] can be written as

$$T = \frac{1}{1.49 - 0.493 \cos\left(\frac{3015}{\lambda}\right)} \qquad [11]$$

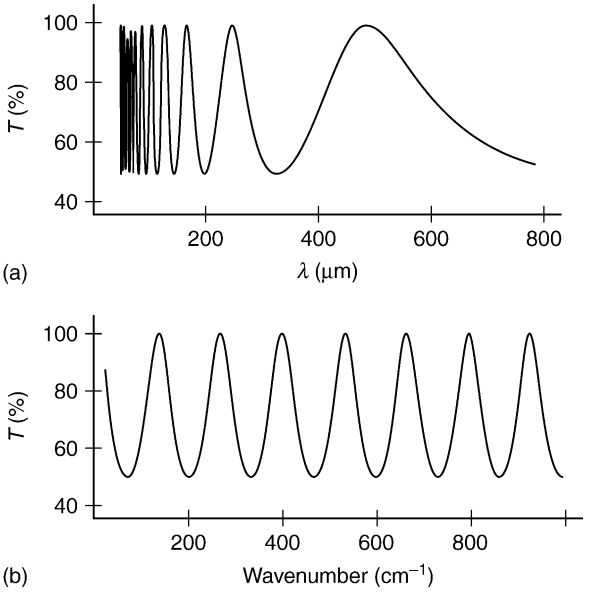

Figure 7 Transmission coefficient of a polished poly-C film with a thickness of 100 μm as a function of (a) wavelength and (b) wavenumber.

or

$$T = \frac{1}{1.49 - 0.493 \cos(0.048\, k)} \qquad [12]$$

where λ is in μm and k, the wavenumber, is in cm^{-1}. Variation of T as a function of λ and k, is shown in Figure 7. A similar behavior is observed for non-polished poly-C films if the wavelength is larger than the surface roughness of the films. For a sample with a very rough surface, scattering effects need to be included in eqn [8].

Electroluminescence in Poly-C

In a luminescence process, the electron must first be excited to higher energy, which can be accomplished by light (photoluminescence), electron beam (cathodoluminescence) or electrical energy (electroluminescence). A subsequent electron transition to lower energies leads to emission of light. A common example of electroluminescence is a forward biased p–n junction made out of direct bandgap type semiconductor such as GaAlAs. The light emitting diodes (LED) and LASERS are based on electroluminescence. Red, green, and blue LEDs are made from GaAlAs, GaP, and SiC/GaN, respectively. Indirect bandgap type semiconductors, such as diamond, typically do not exhibit electroluminescence. The fact that electroluminescence has experimentally been observed in crystalline diamond and poly-C seems to be, at first sight, a contradiction of its

indirect bandgap. In fact, defects in diamond are believed to be responsible for their luminescence properties. All types of diamond are found to have a number of defects related to vacancies and impurities. Due to a unique combination of properties of diamond (Table 1), its electroluminescence properties offer a very unique application potential in optical microelectromechanical systems (MEMS), displays and communication devices in IR, visible and UV regions.

Electroluminescence (EL) in optoelectronic devices is produced by excitation of electrons by electronic current. Yellow-green EL has been observed in Schottky diodes made of boron-doped poly-C. Blue-green and blue-violet EL has been observed in free-standing poly-C films, with thicknesses in the range of 15–400 micrometers, when the samples were subjected to applied fields in the range of 2 V/μm. The EL peaks are observed at energies in the range of 3–3.85 eV, with the main peak occurring at 3 eV.

Recently, a very interesting type of EL has been observed in poly-C and carbon nanotubes, which seems to have an application potential in displays and optical MEMS. Under applied electric fields in the range of 20–40 V/μm, electrons are known to tunnel out of a poly-C film into vacuum and the process is called field emission. EL has been observed during the field emission process, and this new effect is called field emission EL (FEEL). A typical FEEL spectra is shown in Figure 8. It is believed that FEEL results from direct type defects in poly-C, which are populated during the field emission process. The electrons in these defects, instead of being field emitted, make transitions to lower energy levels leading to light emission. The main FEEL peak is observed at 2.6 eV which is in the visible range.

Poly-C Applications

The current applications of diamond, which include optical windows, temperature sensors, heat sinks, cutting tools, surgical instruments, and optical coatings, are based on natural, synthetic, and CVD diamond. The cost of producing diamond has always been prohibitive in widespread diamond applications. Fortunately, over the past 20 years, the development of CVD diamond technologies has eradicated the fears of diamond being too expensive for its widespread applications. As the CVD poly-C can be as inexpensive as any other electronic material, widespread applications of diamond are expected for poly-C. In the area of micro- and nanostructures, the poly-C can provide a unique opportunity for both polycrystalline and crystalline microdevices. Using the present fabrication techniques, the grain size in poly-C can be varied in the range from a few tens of nanometers (nanocrystalline diamond) to hundreds of micrometers (commercial free-standing poly-C films). This leads to a whole range of device structures ranging from inter- to intra-grain devices. An intra-grain device made in poly-C will be an inexpensive single crystal device with properties better that those found in natural/synthetic diamonds, because an intra-grain poly-C device will have a higher degree of purity (because it is grown by CVD).

The applications of poly-C in microsystems (current, in-progress, and future) include optical MEMS, biological/protective/hard coatings, sensors,

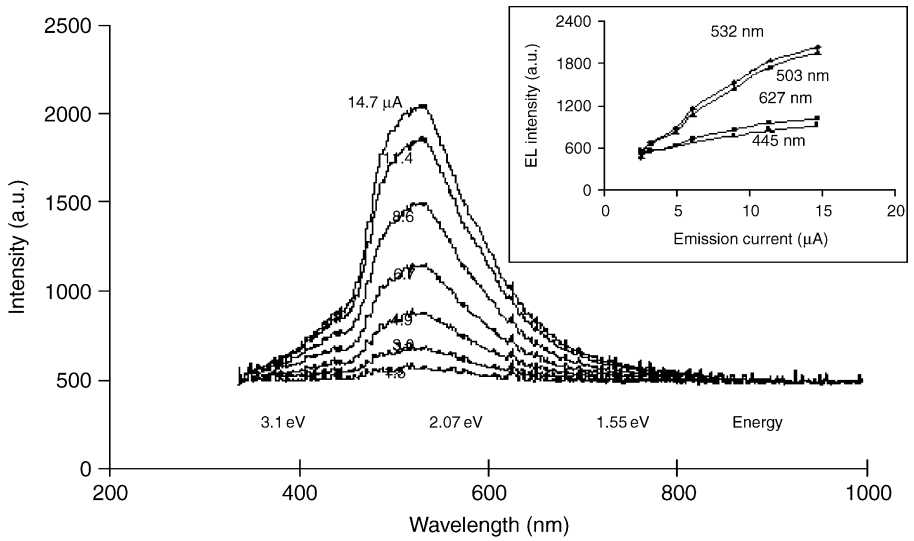

Figure 8 FEEL spectra in poly-C as function of wavelength and emission current (inset).

field emission displays, and WIMS (wireless integrated microsystems). Intra-grain microlenses, RFMEMS, heat pipes, sensors, microabrasives, and spectrometers may lead the way for unique poly-C applications.

Optical MEMS

A basic MEMS structure, with electrostatic actuation mechanism, is shown in Figure 9. Currently, most of the Optical MEMS and RFMEMS (radio frequency MEMS) devices are made from poly-Si (polycrystalline Si) using surface or bulk micro-machining fabrication techniques. The ability to integrate micro-optical elements with movable structures and micro-actuators has opened up many new opportunities for optical and optoelectronics systems, as MEMS allow a more effective manipulation of optical structures than the conventional methods. Optical MEMS have applications in displays, sensing, data storage, and communication systems. Some of the examples are optical switches, optical cross-connects, wavelength division add/drop mixers, tunable filters/lasers/detectors, dispersion components, polarization dispersion components, and spectrometers.

Material-related limitations put some constraints on the current optical MEMS technologies and applications. Diamond is an excellent material for optical MEMS and can extend the application range and reliability. The use of poly-C in optical MEMS can also remove the traditional cost constraints associated with the use of single crystal diamond. Although the poly-C optical MEMS are in their infancy, recent developments are very exciting. Figure 10 shows a poly-C resonator structure fabricated using a poly-C fabrication technology compatible with Si processing techniques. Such structures, if used as filters and switches, can lead to a superior performance as compared to any other currently used material. Poly-C on-chip spectrometers are also expected to operate in a large wavelength range.

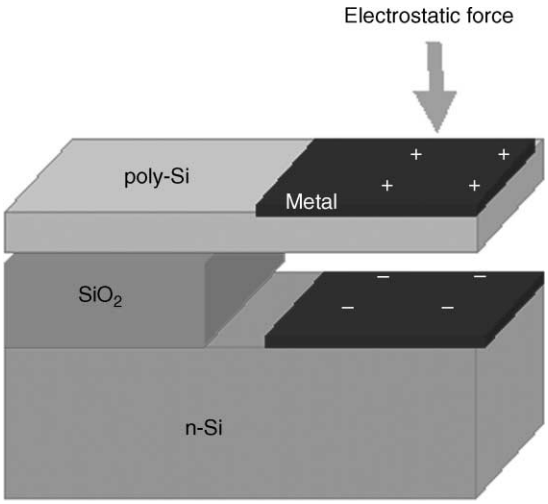

Figure 9 A simple MEMS structure with electrostatic moving of the cantilever beam.

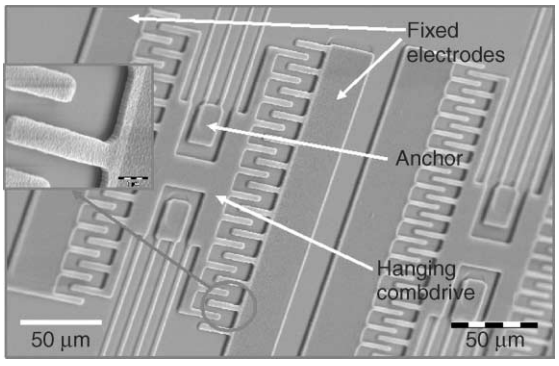

Figure 10 A poly-C MEMS combdrive for high-quality factor resonators, inertial sensors, optical MEMS, etc. Poly-C is superior to poly-Si as its Young's modulus is 4 times higher than that of poly-Si.

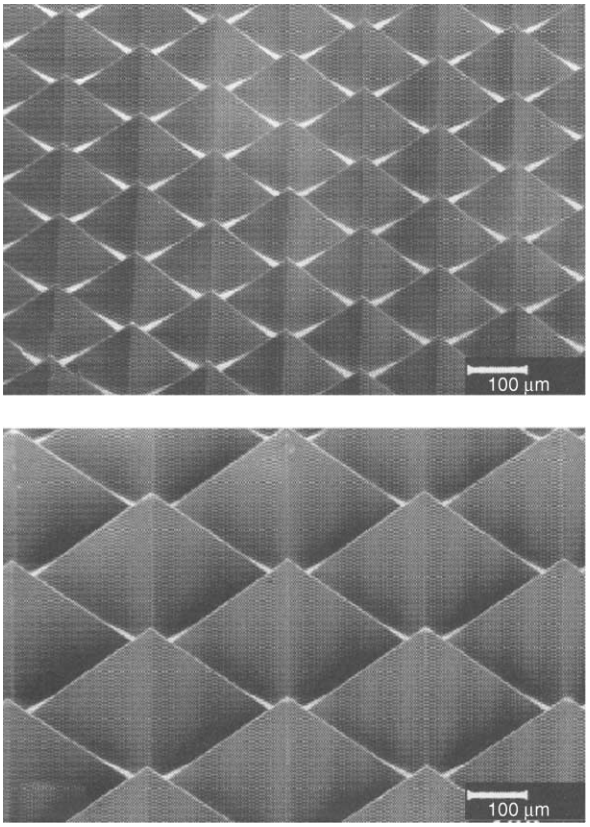

Figure 11 Poly-C microabrasive structures two different densities of pyramids. (Courtesy of Dr. H. Bjorkman of Upsala University.)

Microabrasives

Poly-C is also a very promising material for microabrasives. Micromachined poly-C MEMS structures have recently been fabricated for possible use for microabrasives. Figure 11 shows micromachined MEMS structures which are expected to enhance the life of a tool. Such abrasives by design are inherently cost-effective because they are batch fabricated.

Introduction

Since the very beginning of laser technology, Laser-induced Damage Thresholds (LIDT) of optical components were always an obstacle for the development of laser systems operating at high power levels. In such systems, the surface or the bulk of the optical components can be damaged by laser radiation of sufficiently high power or energy density resulting in an uneconomical standstill of the laser and its application. In the early days of high power laser development, mainly inclusions in laser rod materials were discussed as a major complication for an augmentation of the output power in solid state laser systems. Nowadays, in the course of the development of optical materials with excellent quality and power handling capability, the problem of laser-induced damage has shifted from the bulk to the surface of the optical component. The optical surface is subjected to various production steps and environmental influences, which modify its structure and composition. Especially, the thin film coating, which is deposited on the optical surface to adapt its reflectance and transmittance to the application, contributes predominantly to the reduction of the LIDT values. As a consequence, the measurement and optimization of the power handling capability of thin films is considered as one of the primary research areas in modern optics technology and is supported by an extensive scientific community.

In the following, a brief review will be given on selected fundamental damage mechanisms in thin films, considering also the scaling of LIDT values for different operation conditions. Also, current standards for the measurement of LIDT will be described, and examples illustrating some practical aspects of high power optical coatings will be presented. Finally, a summary of the present state of the art will be given and recent trends in laser technology will be discussed in respect to research in laser-induced damage.

Fundamental Damage Mechanisms in Thin Films

During thirty years of intense research in laser damage of thin films, a broad spectrum of different damage and degradation mechanisms had been discovered and studied for a variety of laser operation conditions and wavelengths. For prominent high-power laser systems often applied in industrial production fields or fundamental research, specific models for laser-induced breakdown have been developed, which are also of practical relevance. In many experiments, damage sites with the morphology illustrated in Figure 1 are observed. The coating is delaminated from the surface of the optical component in the center of the laser beam area. Obviously, mechanical stress has built up in the coating by heating, which is induced by the absorbed laser power. At a certain stress level, exceeding the adhesion strength of the coating to substrate surface, the thin film cracks and may even delaminate from the component. In other cases of this absorption-induced damage effect, the film reaches its melting point prior to the mechanical threshold and

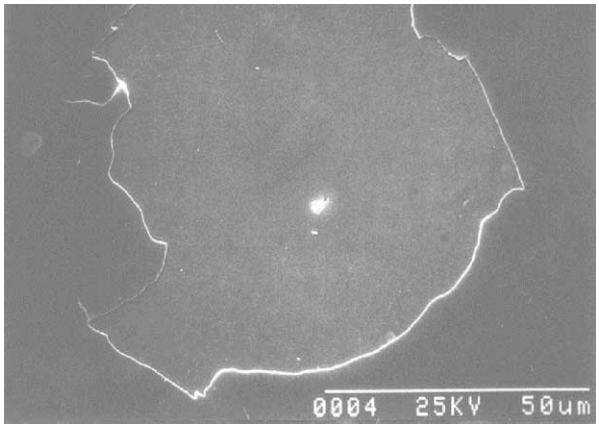

Figure 1 SEM-picture of a damage site on an alternating coating of SiO_2/HfO_2. The system was irradiated by a Nd:YAG-laser with an energy density of 45 J/cm^2. As a dominant damage mechanism, a delamination of the coating by extreme mechanical stress is suggested. Figure 2 Nomarski micrograph (magnification 250×) of a damage site on an antireflecting coating of SiO_2/Ta_2O_5. The system was irradiated with an energy density of 51 J/cm^2 at a wavelength of 1.064 μm. A delamination of the coating in the center of the beam is surrounded by a recrystallization zone.

evaporates or changes its crystalline structure. The morphology of such damage sites exhibits a discoloring or an increased surface roughness in the center of the laser beam (see Figure 2). Absorption-induced damage is dominated by the instantaneous heating of the coating material in the area of interaction with the laser beam and can be described on the basis of the heat diffusion equation. In this approach, the source term in the heat diffusion equation is given by the heat coupled into the system by the absorbed laser power, and the boundary conditions are determined by the geometry and the structure of the layer system as well as the spatial laser beam profile. Apparently, absorption-induced damage has to be considered only for components with significant absorptance at their operation wavelength. Typical examples for coating materials and wavelength regimes, where absorption-induced damage is frequently observed, are the wavelength 10.6 μm of the CO_2-laser with ZnSe, ZnS, and fluorides as coating materials, or the DUV/VUV-wavelengths dominated by excimer lasers and fluoride coating materials. The effect of absorption-induced damage in optical materials is also of practical relevance for cw- and long-pulse operation conditions of the laser system corresponding to long thermal diffusion lengths. For cw-irradiation, the temperature rise in the component can be calculated by numerical methods involving finite elements or differences. For boundary conditions with circular symmetry and a Gaussian beam profile (beam diameter w, power P), an analytical expression can be derived for the temperature rise ΔT in the center of an irradiated circular component

$$\Delta T = \frac{2\beta_s P}{\pi^{3/2} k w} \tan^{-1}\left(\frac{16\kappa t_I}{w^2}\right)^{1/2} \qquad [1]$$

In this model the temperature rise is dependent on the thermal properties (k: thermal conductivity, κ: thermal diffusivity), on the surface absorption of the component (β_S), and on the beam diameter. For irradiation times t_I, long compared to the typical heat diffusion time w^2/κ, eqn [1] reduces to the asymptotic dependence

$$\Delta T \to \frac{\beta_s P}{\pi^{1/2} k w} \qquad t_I \to \infty \qquad [2]$$

Obviously, the temperature rise ΔT scales with the P/w for these long-time irradiation conditions compared to the short pulse regime, where the scaling of the temperature rise is proportional to P/w^2. For the application of optical components in high power cw- and long-pulse lasers, this P/w scaling law has to be considered carefully, because the power handling capability depends critically on the size of the irradiated area. Also, the onset of damage may be delayed in respect to the start of irradiation by time constants in the range of several 10 seconds.

In the course of the development of improved coating processes, optical absorptance could be reduced to very low levels in the near infrared and visible spectral region. For example, high reflecting mirrors for the wavelength of the Nd:YAG-laser with total losses below 1 ppm can be produced with

advanced ion beam sputtering processes nowadays. Therefore, another principal damage mechanism, which is based on inclusions or defects in the coatings, is often found in the near infrared spectral range. A detail of a damage site representing inclusion dominated damage induced by a pulsed Nd:YAG-laser in a coating of HfO_2/SiO_2 is shown in Figure 3. In the laser beam area numerous craters are located, which extend from circular voids with different diameters in a range below 1 μm. At the high magnification of the employed electron microscope, the multilayer structure of the coating system can be resolved indicating an origin of damage approximately in the same depth of the layer structure at the substrate surface. The underlying damage mechanism is initiated by inclusions or other defects with an absorption, which is significantly higher than for the surrounding thin film material. As a consequence, the inclusion is rapidly heated during the interaction with the laser beam and explodes removing the covering layer structure. This inclusion breakdown can be modeled by calculating the temperature behavior $T(r)$ at the radial position r of a sphere (radius g, thermal conductivity k_E, diffusivity κ_E) which is embedded in a medium with defined properties (see eqn [3]). The interaction of the sphere, which has a size in the range of the wavelength λ and a refractive index n', with the laser irradiation, is described by the Mie absorption coefficient Q. For the instant of damage, a critical temperature at the outer surface of the sphere ($r = g$) is assumed, which is often related to the melting point of the layer material

$$T(r) = \frac{3QI}{4\pi k_E g}\left[\frac{k_E}{3k} + \frac{1}{6}\left(1 - \frac{r^2}{g^2}\right) - \frac{2gb}{r\pi}\int_0^\infty \mathrm{d}y \exp\left(-\frac{y^2 t_p}{\tau_1}\right) \times \frac{(\sin y - y\cos y)(\sin ry/g)}{y^2\left[(c\sin y - y\cos y)^2 + b^2 y^2 \sin^2 y\right]}\right] \quad [3]$$

$$Q = \pi g^2\left[1 + \frac{2\exp(-8\pi n' g/\lambda)}{8\pi n' g/\lambda} + \frac{\exp(-8\pi n' g/\lambda) - 1}{(8\pi n' g/\lambda)^2}\right]$$

$$\tau_1 = \frac{g^2}{\kappa_E} \quad b = \frac{k}{k_E}\left(\frac{\sqrt{\kappa_E}}{\sqrt{\kappa}}\right) \quad c = 1 - \frac{k}{k_E}$$

Besides the thermal properties of the host material (thermal conductivity k, diffusivity κ), the properties and the statistic distribution of the inclusions have to be known for a quantitative description of inclusion breakdown.

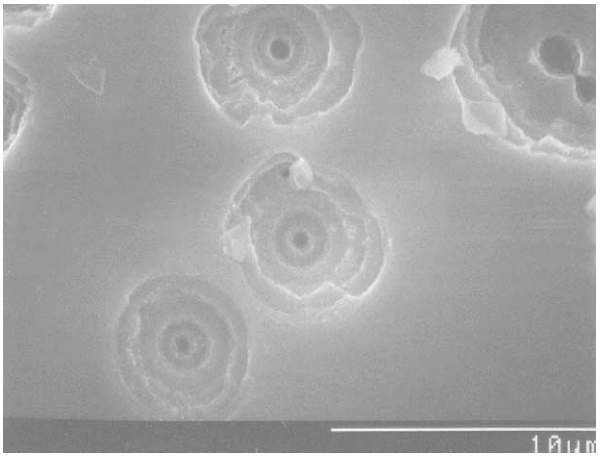

Figure 3 SEM-picture of damage site on a high reflecting coating of SiO_2/HfO_2. This inclusion-dominated breakdown mechanism was initiated at an energy density of approximately 130 J/cm^2 with a Nd:YAG-laser.

In contrast to the nearly deterministic behavior of absorption induced damage, defect dominated damage mechanisms often exhibit a statistical nature. Since the inclusions are not homogeneously distributed in the layer structure, a variation of the threshold value is observed for different damage sites on a single sample. The assessment of the inclusion parameters is extremely difficult in practice. Therefore, the inclusion model is mainly employed for the prediction of tendencies for the LIDT as a function of the beam parameters and the properties of the layer materials.

Different aspects related to the substrate polishing, cleaning, and deposition process have to be considered for an investigation in the various origins of inclusions or defects in a layer structure. Besides contamination of the substrate surface prior to the deposition process, particles may be generated during the deposition process by mechanical abrasion of material from moving parts in the plant or by delamination of material coated on the inner walls. Also, the deposition source may contribute to the formation of defects by sputtering of particles or droplets from the melt or the target. Especially in low energetic thermal deposition processes, defects are often the origin for the formation of nodules. These conical faults in the layer structure reduce the LIDT because they are less resistant against intensive laser radiation than the bulk of the coating system.

Besides models, which are based on the transformation of laser radiation into heat, direct electronic excitation has to be considered as a breakdown mechanism for short-pulse lasers. In these intrinsic breakdown models for dielectric materials, the

generation of a high electron density in the conduction band is assumed. This carrier generation can be explained by high field ionization of electrons in the valence band of the dielectric material. Many theoretical concepts introduce the avalanche effect as an important mechanism contributing to the generation of free electrons. Electrons excited by strong field ionization can interact with the electric field and accumulate excitation energy. By collisions with the lattice, this energy can be also transferred to the electrons in the valence band. Thus, when the energy of the free electrons exceed a critical value, other electrons can be excited to the conduction band, and a carrier generation like an avalanche arises. Another theoretical approach is the multiphoton model which is formulated on the basis of multiphoton absorption for the generation of free electrons. In most intrinsic models it is assumed, that laser-induced damage breakdown occurs when the electron density in the conduction band reaches a critical value of approximately 10^{21} 1/cm^3. At this high electron density, a plasma state is reached and the impinging radiation is coupled efficiently into the layer structure resulting in its destruction.

Intrinsic damage is often characterized by a deterministic damage behavior with a well defined threshold value which is also characteristic for damage in bulk materials. As a prominent example, damage induced by ultra-short pulses with a duration below 1 ps can be often attributed to intrinsic mechanisms, because the diffusion length of thermal effects can be neglected in comparison to the intensive interaction of the laser radiation with the electrons of the coating materials. In this case, the generation rate dn/dt of electrons in the conduction band can be described on the basis of the impact ionization rate and multiphoton excitation

$$\frac{dn}{dt} = \alpha n(t) q I(t) + \beta_m \left[q I(t) \right]^m \qquad [4]$$

In this model $I(t)$ is the power density of the laser radiation, and q is a correction factor representing interference effects in the coatings, which may result in a local power exceeding the power density of the radiation impinging on to the layer system. The electron excitation mechanisms are described by the impact ionization coefficient α and the m-photon absorption coefficient β_m. The relative contributions of both excitation mechanisms to laser-induced breakdown are depending on the pulse duration and the bandgap energy of the layer material.

In a rough approximation, the damage threshold increases with the bandgap energy of the materials as a consequence of the photon absorption coefficient β_m decreasing with its order m. For short pulse durations below a few 10 fs, multiphoton processes contribute significantly in the range of some 10% to the free-carrier generation. In most materials, avalanche ionization develops to the dominant generation mechanism for pulse durations above 100 fs. These tendencies could be demonstrated for single layers of selected oxide material deposited by ion beam sputtering on quartz substrates, which were tested in a pulse duration regime from 20 fs to 1 ps. According to the theoretical model, the expected increase of the damage also influencing values with the pulse duration was observed in the damage experiments.

In practice, the power handling capability of optical components is also often limited by imperfections like scratches, digs, and areas with high roughness on the optical surface. In most deposition techniques applied in optical technology, the layer system tends to replicate or even enhance surface imperfections of the substrate. In the application, additional weak points may be introduced by improper handling or contamination of the optical surfaces. If the contaminants are not removed by the impinging high-power laser radiation, they increase the surface absorption and act as initiation points for laser-induced damage. Voids, grooves, pores, or scratches reduce the power capability of the optical element, because they act as concentrators for the electric field.

Units and Scaling of Laser-Induced Damage Threshold

According to the theoretical models of laser-induced damage, the appropriate units of measurement for LIDT values are mainly given by the dominant damage mechanism and the irradiation time. For pulsed laser radiation and dielectric breakdown effects, the laser-induced damage threshold is usually reported in W/cm^2. In the case of absorption-induced damage or inclusion dominated breakdown and a pulse duration short compared to the thermal diffusion time in the layer structure, LIDT values are often scaled in J/cm^2. The unit of linear power density (W/cm) is indicated for the LIDT of long-pulse, cw-lasers or other sources, which induce a temperature increase in the optical component with rise times in the regime of seconds.

Laser-induced damage thresholds of optical thin films are critically dependent on the operation conditions of the applied laser system and on the design of the layer structure. For example, even the damage mechanism can change if the wavelength or the pulse duration is varied. Therefore, LIDT

values should be scaled with the irradiation parameters only for small intervals, in cases where the fundamental damage mechanism is clarified. In all other situations, the extrapolation of threshold values is extremely difficult and may lead to inaccurate results. Especially, an overestimation of the LIDT value holds severe dangers in practical applications, where the replacement of a damaged component and the repair of other parts impaired by the damage event causes high expenses. If the damaged components consist of toxic materials (e.g., ZnSe, GaAs, CdTe, ThF_4, chalcogenides, Be, Cr, etc.) severe health hazards may occur, and an expensive decontamination of the environment may be necessary. Therefore, the determination of the laser-induced damage threshold using the actual laser parameters under controlled environmental conditions is always recommended for unclear cases.

In the present state of research in laser-induced damage mechanisms, only few tendencies are generally accepted as confident for scaling of LIDT values. As a function of the pulse duration, laser-induced damage thresholds increase for longer pulses. For inclusion and absorption dominated breakdown, a $t_p^{1/2}$-law is often used in the pulse duration regime between 10^{-10} to 10^{-8}s. This dependency can be extended to other pulse regimes up to pulse lengths in the ms-range, if the exponent is replaced by a value between 0.5 to 2. In respect to the laser wavelength, a decrease of the LIDT value with decreasing wavelength is observed for most materials and operational conditions. Investigations in the influence of the beam diameter have been performed by many research groups, indicating a decrease of the LIDT values for increasing beam diameters. Especially for inclusion dominated breakdown, the event of damage for a certain laser irradiated site will be dependent on the distribution of inclusions at that position. If the beam size is small, the probability for interrogating a defect vulnerable to damage is low. By increasing the spot diameter, this probability will asymptotically reach unity, because at a certain beam diameter, at least one defect will always be covered by the beam. Therefore, the onset of laser-induced damage is not dependent on the beam diameter for inclusion-dominated breakdown, which is often encountered in conventional optical coating systems. Another special case is the scaling of the cw-damage threshold with the beam diameter. Since the cw-LIDT is expressed in linear power density, the power handling capability increases more slowly with the beam diameter for the cw-lasers than expected from the normal pulsed operation. For example, extrapolating the LIDT value of 100 W at a beam diameter of 1 mm for a laser mirror to a beam diameter of 10 mm, results in a maximum power load for the component of 1 kW according to the correct P/w-law. The threshold power would be extremely overestimated to approximately 3.2 kW, if the general P/w^2-dependence is applied.

Measurement of Laser-Induced Damage Thresholds

As a consequence of the complicated relation between the laser damage mechanism and a broad spectrum of thin film properties and laser parameters, laser-induced damage threshold measurements have to be performed under well-defined conditions. To investigate the comparability of LIDT measurements, an extended international round-robin experiment has been conducted on coated optics for the wavelength of 1.064 μm at the beginning of the 1980s. This experiment indicated the need for a clearly specified LIDT-measurement procedure, and conceptual work was initiated to develop a corresponding ISO-Standard series. During recent years, an International Standard (ISO 11254) has been adopted covering testing conditions relevant for most typical laser applications. In the first part of ISO 11254 1 on 1-testing of optical surfaces, in respect to laser damage, is described. The fundamental approach of the standard measurement procedure is illustrated in Figure 4. A laser source operating in transversal and longitudinal single mode is employed for the irradiation of the sample surface. The beam

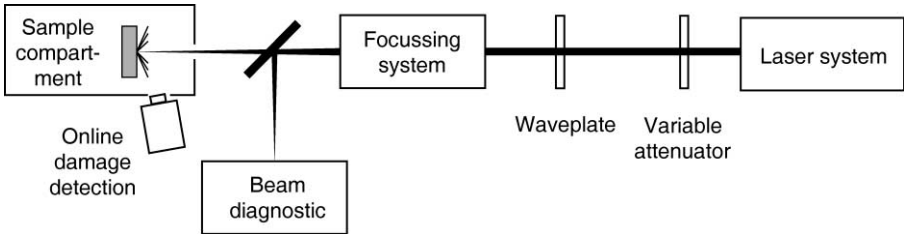

Figure 4 Fundamental setup for the measurement of laser-induced damage thresholds.

parameters of the laser are assessed by a beam diagnostic system which monitors the spatial and temporal profile as well as the energy of the laser radiation in the target plane. In order to achieve the high energy density levels necessary to destroy the surface of the specimen, a well characterized focusing system is installed. For adjustment of the laser energy in the target plane, an attenuating system is employed. In the 1 on 1 measurement protocol, each site on the sample surface is subjected to a single laser pulse once only. In a test sequence, the test surface is examined by pulses of different energies, covering low values without damage and high values causing damage. After the test, the specimen will be inspected with a Nomarski interference contrast or a darkfield microscope at a magnification of 150× or higher to identify the damaged sites. For the evaluation of the damage test, the damage probability method is recommended. In this evaluation scheme, the ratio of the number of damaged sites to the total number of sites objected to a certain energy or power level is interpreted as the damage probability. The plot of these damage probability values as a function of energy or power, which is called the survival curve of the optical component, provides an insight into the damage mechanisms involved. The damage threshold is given by the highest quantity of laser radiation for which the extrapolated probability of damage is zero. A typical example for a 1 on 1 damage test at the wavelength 1.064 μm and the extrapolated LIDT value is depicted in Figure 5.

In most catalogs of optics manufacturers, the 1 on 1 LIDT values are used to illustrate the power handling

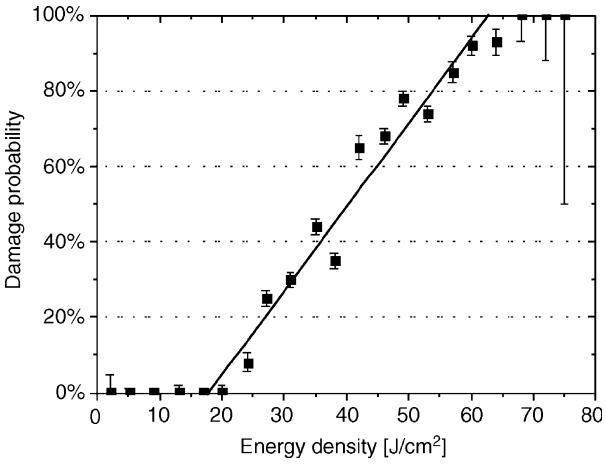

Figure 5 Survival curve of an anti-reflective layer system (two layer V-coating, SiO_2/Ta_2O_5) on fused silica substrate for the Nd:YAG-laser wavelength. The measurement was performed at a wavelength of 1.064 μm, a beam diameter of 420 μm, and a pulse duration of approximately 15 ns, respectively.

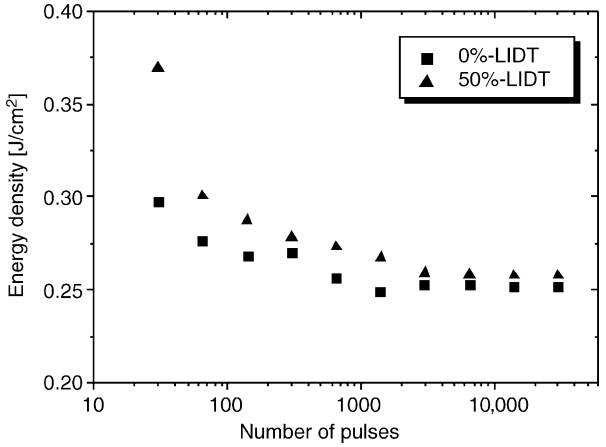

Figure 6 Characteristic damage curve of a high reflecting mirror of SiO_2/TiO_2 for fs-laser systems. The layer structure was tested with a high repetition (1 kHz repetition rate) fs laser system operating at a pulse duration of 150 fs.

capability of their products, even though 1 on 1 data are of limited importance for practical applications, where an optical component is always subjected more than one time to a laser beam. This customary situation is covered by Part 2 of the ISO-LIDT-Standard which describes a damage test procedure for a series of pulses (S on 1-tests). For an assessment of the reliability, the concept of the characteristic damage curve is introduced by this standard. This curve is deduced directly from the S on 1 test data by plotting the energy density for a selected damage probability as a function of the number of pulses (see Figure 6). By an extrapolation of the characteristic damage curve to high pulse numbers in the order of 10^9 to 10^{12} shots, the lifetime of the optical component can be roughly estimated. For a certification of optical components in respect to their power handling capability, a third part of ISO 11254 is under development, which is concentrated on different testing protocols of a defined surface fraction at power levels expected in the application. The fundamental approach of these tests is a simulation of conditions at the upper limits of operation parameters encountered in practice.

Optical Coatings for High Power Lasers

For the development and application of coating systems with high LIDT values, several major aspects have to be considered. In the first approach, appropriate materials and processes have to be selected which deliver coatings with sufficient power resistance. In many studies, a correlation of the LIDT values of the constituent single layers to the power

handling capability of a layer system was observed. Therefore, single layers of potential deposition materials were investigated at the wavelengths of prominent laser systems from the VUV- to the FIR-spectral region. For specific deposition processes, often a clear ranking of the coating materials in respect to their power handling capability could be demonstrated. An example for a Nd:YAG-laser with a pulse duration of 15 ns is illustrated by Table 1. With the exception of the ZrO_2-layer, which exhibited severe inhomogeneity and a high inclusion density, a correlation can be assumed between the LIDT value and the melting point of the bulk materials under these operation conditions. This dependency can be attributed to absorption-induced damage as well as to the inclusion model, and therefore, the damage morphology has to be studied in each case to identify the dominating damage mechanism. In the fs-regime or the UV/VUV-spectral range, often a dependence of the power handling capability on the bandgap of the materials is found. According to the relationships of the avalanche and other dielectric breakdown models, materials with highest bandgaps are frequently encountered at the top of an LIDT ranking.

For the influence of the coating process on the laser-induced breakdown of optical coatings, no clear tendencies can be detected. For example, Ion Beam Sputtering (IBS), which is considered as the deposition process for coatings with extremely low losses and contamination, cannot always surpass conventional thermal deposition processes in laser stability. In general, ion or plasma assisted deposition techniques produce coatings with lower LIDT values than conventional coating processes for most operation conditions. Sol-gel processes, which were developed for the deposition of removable coatings on large optics in laser fusion, can reach superior power handling capabilities. In general, as a consequence of the complicated relation between the production parameters and laser-induced breakdown, production processes for optical coatings have to be optimized separately for different wavelength regimes and irradiation conditions.

Table 1 Laser induced damage thresholds of selected single-layer coatings in relation to the melting points of the corresponding bulk materials. In the last column, LIDT values of anti-reflective coatings (AR-Coating) composed of the high index material and SiO_2 are compiled to illustrate the correlation between single LIDT values and the damage threshold of layer systems

Material	*Melting point (°C)*	*LIDT value (J/cm²) single layer*	*LIDT value (J/cm²) AR-coating*
TiO_2	1775	13 ± 1	14 ± 1
Ta_2O_5	1918	28 ± 2	32 ± 5
HfO_2	2758	41 ± 3	46 ± 6
ZrO_2	2700	34 ± 4	28 ± 1
Al_2O_3	2072	39 ± 1	
SiO_2	1723	34 ± 7	

Besides the fundamental production parameters, the design of the coating system is of similar importance for the achievement of high LIDT values, because damage is directly driven by the electric field strength in the layer structure. A standing wave field pattern is depicted in Figure 7 for a high reflecting stack of Ta_2O_5 and SiO_2. The design consisting of layers with an optical thickness of 1 QWOT is typical for most standard laser mirrors. The power density reaches extreme values always at the interfaces between the layers and even exceeds the incoming irradiation power density (100%). Interfaces between the layers can be considered as weak points in a coating system, because additional contamination may occur during the switching of the material in the production process. Also, the adhesion between the adjacent layers may be reduced, and mechanical stress may be built up by the different materials. To improve damage thresholds of laser mirrors, the thickness of the first few layer pairs can be adjusted to shift the points of maximum field strength into the bulk of the layer with higher damage resistivity (see Figure 8). Also, a thick layer can be attached to the system in order to stabilize the outer layer pair in respect to thermal or mechanical stress. Another technique, which can be applied to enhance the stability of the interface is the codeposition of materials, resulting in a gradual interface with a mixing zone of materials between the layers. This region of codeposited material exhibits a higher resistance against mechanical stress resulting in an improvement of LIDT values of up to 20%.

The effect of the internal electric field strength distribution on the power handling capability of a layer system should be most apparent for intrinsic damage mechanisms, which are dominant in the ultra short pulse regime below 1 ps. According to the fundamental model (see eqn [4]), a direct relationship of the damage threshold to the maximum field strength value within the layer system is expected. As an example, an investigation in the threshold behavior of ion beam sputtered coating systems with different field strength values is illustrated in Figure 9. In this experiment, the maximum field strength in the last low index layer of SiO_2 has been adjusted to factors between 0.4 and 1.6 of the impinging field strength (see upper diagram in Figure 9) by depositing different designs on a basic 1-QWOT layer stack of TiO_2/SiO_2. In the lower part of Figure 9, the S on 1 LIDT values, measured with a fs-laser, are depicted for selected pulse numbers N. For all layer systems,

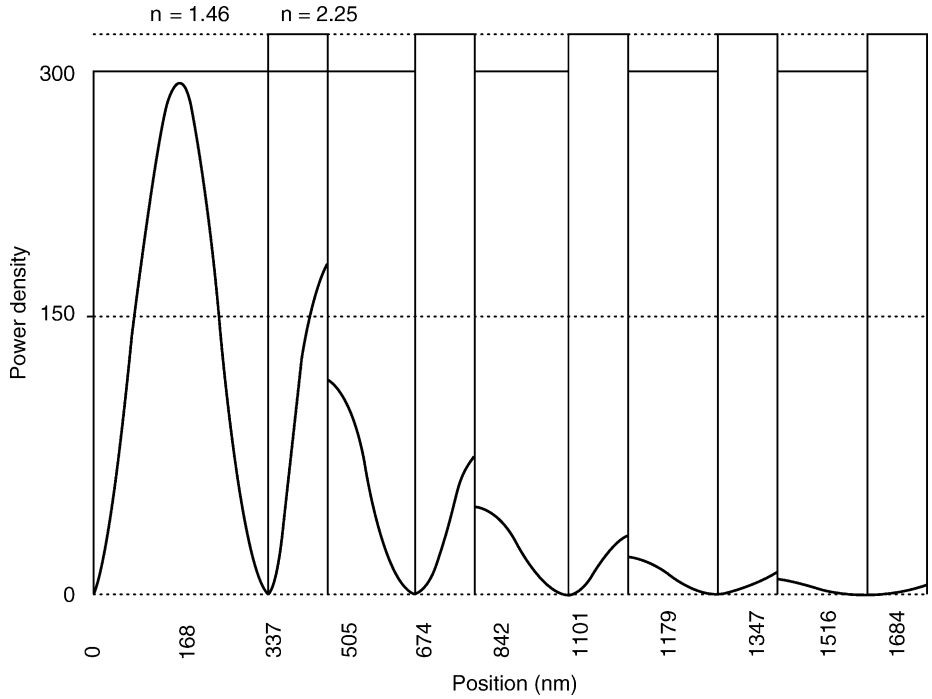

Figure 7 Distribution of the power density in a high reflecting layer stack of SiO_2/Ta_2O_5. The first nine layers of the system and a final thick stabilizing layer of SiO_2 next to the air interface are depicted. The incoming energy density is calibrated to 100%. Figure 8 Distribution of power density in a high reflecting layer stack of SiO_2/Ta_2O_5. The first nine layers of the system, which is designed for reduced power density at the interface in the first layer pair are depicted. Reproduced with permission from Ristan D, Ebert J and Welling H (1989) Optische Beschichtungen für Hochleistungslaser. *Laser und Optoelektronik* 21(4): S.53.

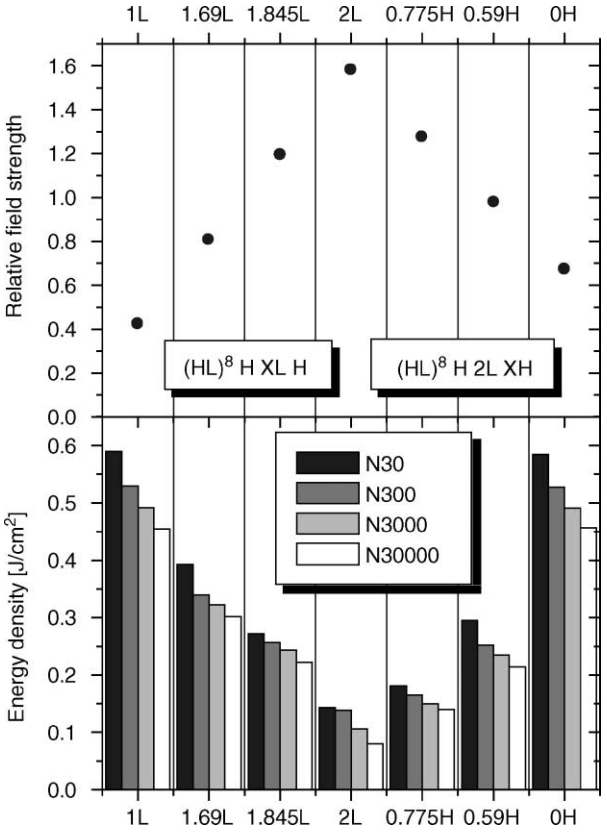

Figure 9 Damage thresholds (lower diagram) and internal field strength relative to the field strength of the impinging wave (upper diagram). The damage thresholds were measured with an ultrashort pulse laser operating at a repetition rate of 1 kHz, a pulse duration of 150 fs, and a beam diameter of 100 μm on the sample surface. Damage thresholds for selected numbers between $N = 30$ to $N = 30\,000$ of pulses are indicated by columns. The plotted maximum field strength in the last SiO_2-layer is adjusted on the basis of design variation.

which were deposited in separate deposition runs, a strong correlation between the maximum field strength and the laser threshold is observed. This experiment clearly demonstrates the role of the electric field strength distribution in high-power coatings and the potential of advanced thin film design strategies.

Besides the properties of the coatings, the quality of the substrate has to be considered in respect to surface imperfections and to the polishing procedure. For example, substrates for the production of high-quality optics with enhanced power handling capability in the VIS/NIR-spectral range should be polished to a surface roughness of less than 1 nm_{rms} with a surface imperfection value $5/1 \times 0,010$ according to ISO 10110. For an illustration of the effect of the polishing grade on the LIDT values, selected results are compiled in Table 2 for substrates of BK7-glass and high reflecting mirrors.

Table 2 Laser-induced damage threshold values of samples polished using compounds of different grain size. Besides the LIDT values of the uncoated surfaces, also data for anti-reflective coatings of selected materials on these surfaces are summarized

Coating type	*LIDT value (J/cm^2) polishing type I*	*LIDT value (J/cm^2) polishing type II*
Bare surface	76 ± 1	68 ± 12
Ta_2O_5/SiO_2	44 ± 2	38 ± 1
HfO_2/SiO_2	47 ± 16	35 ± 5
Nd_2O_3/MgF_2	34 ± 6	24 ± 8

Substrates with the polishing Type I and Type II were processed with powder of different grain diameter (2 μm and 3 μm) in conventional pitch polishing. For the LIDT values of the bare substrate and the coatings, a clear relation to the surface roughness can be observed. Especially for optical coatings with significant transmittance, subsurface damage in the substrate has to be taken into account. As a consequence of the chemical and mechanical interaction of the surface with the polishing compounds, impurities and dislocation are introduced in the surface structure resulting in a reduction of the damage threshold.

Summary

In the course of the rapid development of laser technology, a large background in high power optical coatings had been built up during the last three decades. Nowadays, the corresponding experience in the production of high power coatings is mainly located at industrial companies and a few research institutes, which are also involved in the characterization of optical coatings. For an illustration of the present state in thin film technology, damage threshold values of advanced optical components are summarized in Table 3 for laser systems and operation conditions often applied in industrial production environments.

Besides the spectacular experiments in laser fusion, isotope separation, and fundamental physics, industrial applications of lasers in material processing, medicine, information technology, and semiconductor lithography are considered as major pacemakers for the progress of high power optics. Therefore, trends in these technology fields will dominantly govern the future development of thin film technology. For example, in semiconductor lithography at a wavelength of 157 nm, which would open the way to feature sizes well below 100 nm, optical coatings with extended lifetimes are still on rank 6 of the list of challenges to achieve an effective lithographic production facility. In next generation lithography, optics

10,6 μm, CO_2-Laser	AR/th	>20 J/cm^2 (100 ns, 1,4 mm) >2 kJ/cm^2 (1,2 ms, 250 μm) >3 kW/mm (cw, 100 μm)
	HR/th	>25 J/cm^2 (100 ns, 1,4 mm) >2 kJ/cm^2 (1,2 ms, 250 μm)

of even smaller wavelengths, around 13 nm, have to be optimized to achieve the 60 nm node. Ultra-short pulse lasers gain importance as innovative tools for material processing, laser medicine, and biology, as well as the analysis and control of chemical reactions. For the development of fs lasers needed in these applications, special high-power broadband coating systems are required. In addition to high LIDT values, these coatings have to fulfil demands with respect to their group delay dispersion for the compensation of dispersion effects in the laser systems. Other challenges have to be expected from applications, where a combination of the high-power handling capability with additional properties has to be achieved. As a typical example, high-power laser coatings with improved mechanical or chemical stability for applications in laser medicine can be considered.

List of Units and Nomenclature

dn/dt	generation rate of electrons in the conduction band
g	radius of a spherical inclusion; (cm)
$I(t)$	power density of laser radiation,
k	thermal conductivity; (W/(cm °C))
k_E	thermal conductivity of a spherical inclusion; (W/(cm °C))
LIDT	laser induced damage threshold (J/cm^2; W/cm^2; W/cm)
n'	refractive index of a spherical inclusion; (1)
P	output power of a laser; (W)
q	correction factor representing interference effects in coatings
Q	Mie absorption coefficient of a spherical inclusion;
QWOT	quarter wave optical thickness: unit for the thickness of the layer
t_I	irradiation time for a cw-laser; (s)
$T(r)$	temperature in a spherical inclusion at the radial position r; (°C)
w	diameter of a laser beam with Gaussian profile; (cm)
α	impact ionization coefficient; (1)
β_m	m-photon absorption coefficient; (1)
β_S	surface absorption of an optical component; (1)
ΔT	temperature rise in the center of an irradiated circular spot; (°C)
κ	thermal diffusivity; (cm^2/s)
κ_E	thermal diffusivity of a spherical inclusion; (cm^2/s)
λ	wavelength of a laser; (cm)

Introduction

Black surfaces play an important role in many, if not most, optical systems. Optical instruments and systems of all types often rely on black surfaces to help minimize the effect that stray or off-axis light can have in degrading optical system performance. The strategic selection and placement of appropriate black surfaces can often limit significant detrimental stray light effects in an optical systems, thereby dramatically improving system performance. The high emissivity of black surfaces also gives them an important role in the design and construction of black bodies, calibration surfaces, and radiator surfaces.

The characterization and selection of black surfaces is an important field of optics and optical system design. However, the selection of black surfaces is a specialized undertaking requiring careful study to ensure the proper selection of particular surfaces for each optical system. A black surface that works well in one application may not be at all appropriate for a different application, where different systems performance goals are desired. The wavelength of operation of the system is an important consideration since a surface which has low reflectance at one wavelength band may have different reflective properties at another wavelength or range of wavelengths. Specialized measuring devices called goniophotometers are often used to characterize the reflectance and scatter of black surfaces for a given wavelength or set of wavelengths. Goniophotometric measurements can be used to create a specialized functional description of reflectance and scatter off a surface, called the Bidirectional Reflectance Distribution Function (BRDF) or Bidirectional Scatter Distribution Function (BSDF). In practice, having the BRDF or BSDF of a surface is extremely valuable for surface selection and is more useful than other reflectance and scatter measurement measurements or descriptions. Comparing the measured BRDF or BSDF of several surfaces helps to distinguish the general optical properties of these surfaces and allows a direct comparison of the value of these different surfaces in an optical system as they contribute to overall system performance.

The BRDF distinguishes, at a particular wavelength, how a surface specularly reflects or how it scatters light in different directions when incident light from a particular direction relative to the surface (at a given angle of incidence) interacts with the surface. By understanding the BRDF of a surface, the optical designer can understand how the surface behaves in a given system location when illuminated from a specific direction. The BRDF of a black surface is also important because it can be used as a mathematical function in stray light analysis programs to predict system performance. The BRDF and other properties of surfaces can be input into stray light codes so that the propagation of light from black surfaces can be modeled through Monte Carlo-based propagation models. Using these models, the stray light can be directed through the placement of black surfaces into directions less likely to degrade system performance. Thus a measure of stray light control can be gained through absorption by black surfaces or by redirection of the stray light into less critical directions.

Black surfaces may be considered a subset of a class of surfaces known as spectrally selective surfaces. The term ‘spectrally selective surface’ indicates that the spectral properties of many surfaces are different when examined in various spectral regions. For applications such as the design of blackbodies, space radiators, and baffles, surfaces with unique spectral emissive and reflection properties are needed. Large databases of spectrally selective surfaces are available to allow the optical designer flexibility in choosing surfaces for applications where specific optical reflectance and optical scatter properties

are desired. Spectrally selective surfaces are important for applications that range from solar energy to telescope design. In some applications, it is desirable for a surface to be highly absorbing at one wavelength and more reflective at another, rather than to be highly absorbing of light over a wide range of wavelengths. An analysis of the spectral properties of a large number of surfaces allows the optical designer to choose surfaces optimized for a particular application.

Black surfaces come in many types, but may be generally characterized as being more shiny (specular) or more diffuse (Lambertian) in their reflective and scattering properties, depending on the form of their BRDF curve. Surfaces are often described in computer models as a combination of their respective specular and Lambertian properties for a given wavelength. Many black surfaces have significant reflectivity at some region of the electromagnetic spectrum, even if they are highly absorbing at one wavelength. Some black surfaces are constructed to be remarkably nonreflecting over a range of wavelengths; these surfaces are often used as baffle surfaces for telescopes and instruments that must operate over a wide range of wavelengths. No black surface can work well in all optical systems. Optical designers must understand the specific optical properties of a black surface to determine if the surface can work in their particular system. To characterize a surface, it is helpful to know at least the BRDF of the surface at the wavelength of interest as well as basic materials properties of the surface. The specific BRDF at the most appropriate wavelength for the system can be used with the optical system stray light model to determine if the surface can fulfill the designer's, expectations of it for the system performance. The placement and choice of black surfaces in an optical system are often critical decisions with highly significant effects on overall system performance.

For this reason, optical designers rely greatly on databases of the reflection and scatter properties of black surfaces in order to make the right choice of surface. These databases have been created to provide the optical engineer with the information needed to understand a wide variety of candidate surfaces and select the most appropriate ones. These databases not only describe the optical properties of surfaces but also elucidate material properties so that the selection process can examine the heat resistance, outgassing rates, fade resistance, durability, and a myriad of other surface or material properties that may be relevant.

The reflectance and scatter data on black surfaces are often taken using a variety of reflectance-measuring instruments and the data format often varies greatly. When published and unpublished data sets are compiled, they are often confusing and sometimes even contradictory. This has made the comparison of surfaces a difficult proposition. In recent years, there have been successful attempts to gather existing large amounts of existing data so that comparisons among black surfaces can be made in a data-rich environment so that anomalous data can be ignored. A significant amount of reflectance data on black surfaces has been created by private or governmental organizations such as NASA and NIST – the US National Institute for Standards and Technology. These data now appear in databases of BRDF and reflectance measurements. Designers are relying increasingly on databases of BRDF surfaces rather than the individual measurements that can be found in the optical physics and applied optics published literature.

Uses of Black Surfaces

Table 1 lists some of the major areas in which black surfaces or black coatings may be used in instruments and optical systems. The optical properties of desirable surfaces may be different for the specific categories in the table. Plausible surfaces for these different applications can be found in materials databases such as the SOLEXIS™ database which contains a useful compilation of data from private

Table 1 Possible uses for black surfaces and black coatings in optical systems

Apertures	Baffles	Barrels	Calibration screens	Choppers

Enclosures and curtains for rooms and instruments	Integrating sphere enclosures	Lens edges	Light traps	Mounts
Radiators	Radiometers	Solar collector absorbers and concentrators	Standards and references of reflectance	Targets

and governmental data compilations from the US, Canada, and the former Soviet Union.

Selection of Optical Black Surfaces

The selection of appropriate black surfaces for a given application becomes progressively harder as the number of optical requirements (e.g., reflectivity, scatter, emissivity, etc.) and materials requirements (e.g., stiffness, coefficient of thermal expansion, etc.) increase. Because of this, the selection process for specialized surfaces for space applications can be quite involved, since there are a large number of criteria, each of which may be regarded as an essential requirement.

The optical system designer must consider at least the following aspects of the system in selecting a surface:

- the wavelength(s) and waveband(s) of interest;
- the position of the surface in optical system;
- the general robustness required of the surface;
- the environment of the optical system;
- the cost including inspection, handling, and assembly; and
- the production and delivery schedule, including spares.

The selection process must carefully address the system needs as well. Poor decisions are often made when only a cursory study of potential black surfaces is made or when databases and the literature on the subject are neglected. Therefore, an important part of the selection process is the management of the timing of the selection, in order to give the designer time to access available information and to influence the system design in a timely manner.

If black surfaces are used for stray light control, then the use of these surfaces must be planned at the beginning of the optical system design process. If the placement of black surfaces and the array of potential surface treatments are examined early in the program, the optimal choices can often be determined in a careful manner that enhances the system performance. If the selection is saved until the very end of the program, the choice of surfaces will be more limited and improvements in system performance may be minimal, even with the most excellent black surfaces. This is because the location of the surfaces in the system often proves to be as critical as the choice of surface. If the surface is in the wrong location, the best optical black may not be able to improve the stray light performance. For best results, the layout of the system and the placement of baffles must be considered first, before the baffle surfaces are selected.

An optimal flowchart of good system design for black surface selection is given in Figure 1. Figure 2 describes a work flowchart where black surface selection is neglected until the end of the program, often with dire consequences for system performance, cost, and schedule.

For space-based systems, the effect of atomic oxygen in a low-earth orbit environment is an important consideration. For space systems, the designer must also examine how black surfaces may be affected by or contribute to contamination and outgassing. Other considerations are the generation of particles during launch, the effect of solar

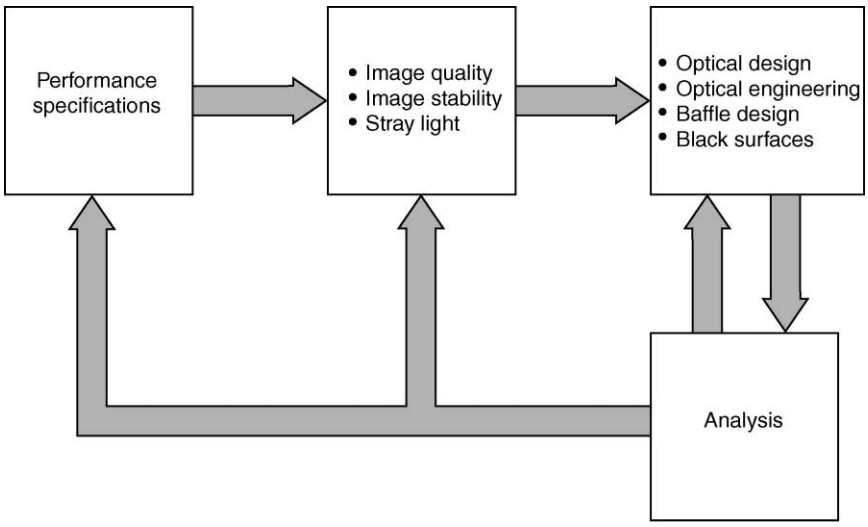

Figure 1 Diagram of the system design process which treats black surface selection as an important part of basic system design, to be done early in the design process. This gives the designer an opportunity to conduct system tradeoffs to optimize system performance.

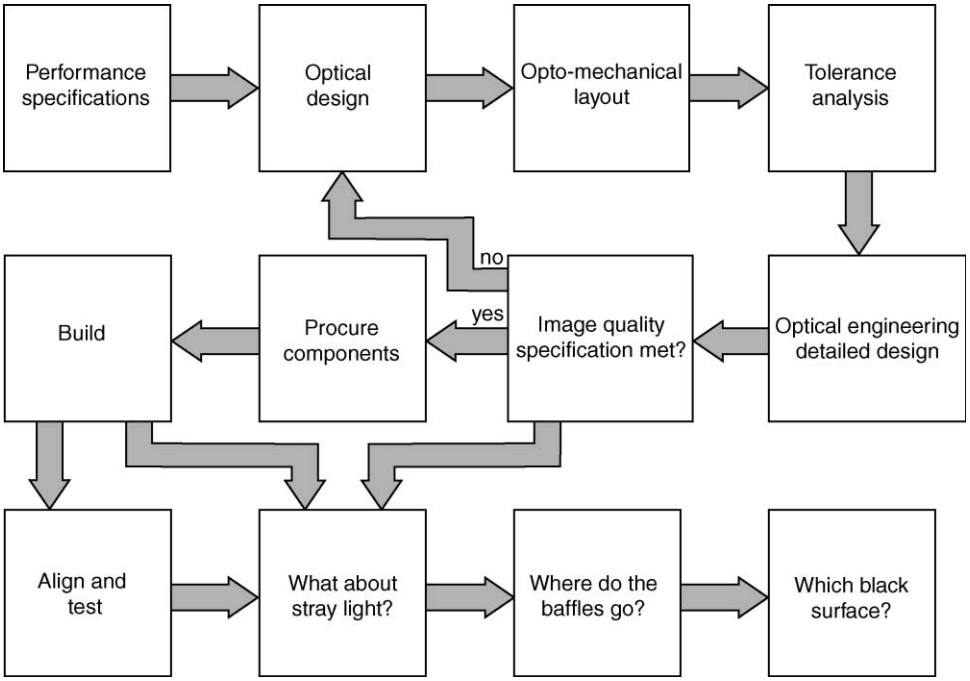

Figure 2 Diagram of a poor system design process. This process addresses the selection of black surfaces late in the system design process, where selection is significantly more difficult, expensive, and risky. Even with a late selection, there may be severe impacts on schedule.

ultraviolet radiation on black surfaces, and how spacecraft charging may affect conductive, dielectric, or insulating black surfaces. Since black surfaces may have a large surface area in an optical system, the designer must ensure that the black surfaces do not contribute significantly to the risk of system failure through some degradation process that may contaminate other optical surfaces. For space-based systems, data on surface outgassing and the past performance of a surface in a specific space environment is essential.

There are a variety of resources available to assist in the selection of black surfaces. The best databases allow the user to create 2-dimensional and 3-dimensional BRDF plots for extensive lists of potential black surfaces. For most surfaces, with no preferred directionality in the structure of the surface, a 2-dimensional BRDF plot is adequate. Most of these databases provide information on a wide variety of spectrally selective materials including black, white, and reflective surfaces for thermo-optical applications for ground and space-based instrumentation. The BRDF plots can be examined by the user or fed into existing, commercially available optical design and analysis software packages. The results of these models indicate whether the chosen surfaces give adequate performance or whether more specialized coatings are necessary to achieve the desired level of performance.

A significant problem for many designers is that the formulations of many paints and other surface treatments often change. Sometimes the name of the coating remains the same even as the optical properties change, due to a change in the compounds or methods used to prepare the coating. Sometimes the name changes with or without a change in the formulation. These often unpublished changes increase the risk of using older plots from the published literature as definitive optical modeling data. Experts in the optical blacks area continuously investigate these changes and their implications and can advise optical designers of the implications of recent changes in the paint and coating arena. These experts are often aware of situations where coating failures have occurred or where mission performance was degraded by unanticipated changes in coatings, even if reports of this incidents were never published.

In summary, the selection process, by its very nature, must be a deliberate and careful effort to examine the best surface options. Some of the better surfaces which were considered laboratory standards (e.g., 3M Black) are no longer easily available and replacements must be found. For the most systematic decision-making process, access is needed to the best optical black surface databases, often commercial databases with hundreds to thousands of BRDF curves on several hundred materials. The use of

these optical surface databases can substantially reduce the costs, time, and scope of a measurement program, as well as streamline the selection process. Additionally it allows the designer to consider materials used successfully in other programs which may not be familiar to the designer. Finally, the designer may avoid using materials that have been rendered unreliable through changes in the manufacturing process or in the coating chemistry.

Characterization of Black and Spectrally Selective Surfaces

Optical Characterization

An understanding of black surfaces relies heavily upon an understanding of the meaning and use of the BRDF. While the optical properties of surfaces can be characterized through specular and diffuse reflectance measurements, the use of BRDF measurements has become extremely important. BRDF measurements are equally adept at characterizing highly specular and highly diffuse surfaces and the myriad of surfaces with both characteristics. The BRDF is often used in general to describe the angle-dependent optical scatter from these surfaces. This is important as the angular distribution of scatter can be used to calculate if the scatter from a black surface will be a limiting factor in the resolution or noise level of the system. BRDF measurements can even be used in computer graphics visualization programs that illustrate what a surface may look like under various illumination conditions. For example, the BRDF is used in computer graphics models to render a certain color for an automobile or a countertop in a kitchen. For some black surfaces, the angular distribution of scatter can be used to calculate a variety of surface parameters such as the surface roughness, given certain assumptions about the surface. For opaque black surfaces, BRDF measurements have proved to be one of the best overall descriptors of the optical properties of the surface.

BRDF is defined as the ratio of scattered radiance (watts/(cm^2 sr)) to surface irradiance (watts/cm^2); its units are inverse steradians. Radiance is used in the definition, in order to make the BRDF independent of the parameters of the measuring instrument, such as the detector aperture and distance to the detector. BRDF measurements are made by a variety of instruments for a number of wavelengths. For example, BRDF measurements of surfaces have been made in wavelengths ranging from the vacuum ultraviolet to the far infrared. The most common BRDF measurements made on black surfaces are made at laser wavelengths of 0.6328 and 10.6 micrometers. However, these measurements may be of limited value if the system is operating at substantially different wavelengths, where the surface's BRDF is significantly different.

To make a BRDF measurement requires a light source, a sample mounted and illuminated by that source, a receiver (detector) to measure the scatter from the sample, and the computer/electronics package to accurately record the detection of the scattered light. Additionally the sample and/or light source must be able to be moved so that the sample can be illuminated from nearly every angle, and scattered light from the surface can be detected in a hemisphere around the sample. The geometry of the BRDF measurement is illustrated in Figure 3.

To make a BRDF measurement on black surfaces, appropriate sources, detectors, and low-scatter optics must be used. This becomes more difficult for wavelengths less than about 0.25 micrometers. At longer, infrared wavelengths, diffraction effects become important. Despite the instrumental difficulties, it is often better to measure the amount of scatter at a specific wavelength λ and angle θ_s, rather than try to predict it from theoretical models. This is because the extrapolation to new angles or wavelengths using scaling theories is not always accurate or even possible. Methods for wavelength scaling (extrapolating from BRDF data for one wavelength to data for any other wavelength) or angle scaling (where data taken at particular incident and scatter angles are extrapolated to other angles) will not be discussed as BRDF curves are now widely available for many surfaces at a variety of wavelengths and angles.

The definitions of BRDF are given in Table 2.

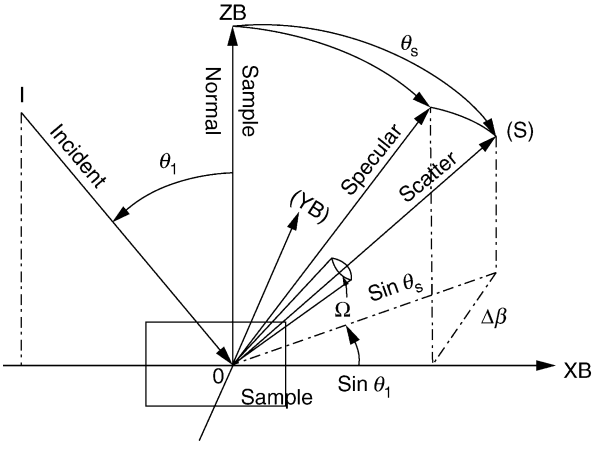

Figure 3 Geometry of BRDF measurement and the angle conventions accepted by the American Society for Testing Materials (ASTM). The plane of incidence is the I-0-ZB plane and the scatter plane is the S-0-ZB plane.

Table 2 BRDF term definitions

Bidirectional reflectance distribution function BRDF	The sample radiance divided by the sample irradiance. The procedures given in this practice are correct only if the field of view (FOV) determined by the receiver field stop is sufficiently large to include the entire illuminated area
Scatter	The radiant flux that has been redirected (by interaction with the sample) over a range of angles
Sample coordinate system	A coordinate system is fixed to the sample and used to a specify position on the sample surface for the measurements. The sample coordinate system may be application and sample specific. A Cartesian coordinate system is recommended for flat samples, with the origin at the geometric center of the sample face with the Z axis normal to the sample
Plane of incidence, PLIN	The plane defined as containing the central ray of the incident flux and the sample normal
Beam coordinate system, XB, YB, ZB	A Cartesian coordinate system defined with the origin on the central ray of the incident flux at the sample surface, the XB axis in the plane of incidence (PLIN) and the ZB axis normal to the surface. The angle of incidence, scatter angle, and incident and scatter azimuth angles are defined with respect to the beam coordinate system
Incident direction	The central ray of the incident flux specified by θ_i and φi in the beam coordinate system
Angle of incidence, θ_i	Angle between the central ray of the incident flux and the ZB axis
Incident azimuth angle, φ_i	The fixed 180° angle from the XB axis to the projection of the incident direction onto the XB–YB plane. It is convenient to use a beam coordinate system in which $\varphi_i = 180°$ since this makes φ_s the correct angle to use directly in the familiar form of the grating equation. Conversion to a sample coordinate system is straight forward, provided the sample location and rotation are known
Scatter direction	The central ray of the scattered flux specified by θ_s and φ_s in the beam coordinate system
Scatter angle, θ_s	Angle between the central ray of the scattered flux and the ZB axis
Scatter azimuth angle, φ_s	Angle from XB axis to the projection of the scatter direction onto the XB–YB plane
Specular direction	The central ray of the reflected flux that lies in the PLIN with $\theta_i = \theta_s$ and $\varphi_s = 0$
Delta theta, $\Delta\theta$	The angle between the specular direction and the scatter direction
Delta beta, $\Delta\beta$	The projection of $\Delta\theta$ onto the XB–YB plane, that is, the $\Delta\theta$ angle measured in direction cosine space. For scatter in the PLIN, $\Delta\beta = \sin\theta_s - \sin\theta_i$. For scatter out of the PLIN, the calculation of $\Delta\beta$ becomes more complicated
Receiver solid angle, Ω	The solid angle subtended by the receiver aperture stop from the sample origin
Sample radiance, L_e	A differential quantity that is the reflected radiant flux per unit projected receiver solid angle Ω per unit sample area. L_e is often an average calculated from scattered power, P_s collected by the projected receiver solid angle $\Omega\cos\theta_s$, from the illuminated area, A. The receiver aperture and distance from the sample determines Ω and the angular resolution of the instrument
Sample irradiance, E_e	The radiant flux incident on the sample surface per unit area. In practice, E_e is an average calculated from the incident power, P_i, divided by the illuminated area, A. The incident flux should arrive from a single direction; however, the acceptable degree of collimation or amount of divergence is application specific and should be reported

Table adapted from ASTM E1392-90 "Standard Practice for Angle Resolved Optical Scatter Measurements on Specular or Diffuse Surfaces," American Society for Testing Materials, 1990.

Given these definitions, BRDF, is mathematically described by

$$\text{BRDF} = \frac{L_e}{E_e} = \frac{(P_s/\Omega A\cos\theta_s)}{(P_i/A)} = \frac{P_s}{P_i\Omega\cos_s}\ [\text{sr}^{-1}]$$

The BRDF is a function of many measurable quantities. It depends on the angle of incidence of the incident flux and the wavelength of this radiation. It also depends on the direction in which the scattered light is measured as well as the wavelength and polarization of the incident and scattered flux. The BRDF can be calculated for a given angular configuration of incident source and detector from the average radiance divided by the average irradiance. The BRDF is therefore referenced by the incident power. The $\cos\theta_s$ term in the formula accounts for the foreshortening of A as the angle θ_s increases, so that true radiance is being used in the calculation. Because of this, the BRDF is constant for a surface with Lambertian (uniformly diffuse) properties. The detector must have a field of view so that all of A can be viewed and such that P_i includes the entire beam. In practice, P_i is measured by removing the sample from the measurement position. Then the detector is moved into the straight-through position. Often a reference detector is used to monitor the incident beam power so that any changes after the initial V_i, measurement can be recorded.

For BRDF measurements to be meaningful, the instrument signature must be examined and understood. This is particularly important in the measurement of low-scatter surfaces. The instrument signature is the BRDF when the sample is removed and there is no sample scatter. In this case the stray light and scatter signature of the device will be apparent. Angular positioning errors and electronic noise can also be important. For example, as θ_s approaches 90° the accuracy of measuring θ_s becomes critical due to the 1/cos θ_s term in the BRDF equation. Ideally the instrument signature is a small fraction of the BRDF being recorded. An understanding of the instrument signature provides the needed information to decide where the BRDF data loses its meaning.

The BRDF is most often displayed in a plot, where the BRDF value (vertical axis) and the angle of scatter (horizontal axis) are plotted on logarithmic scales. In these 'log–log' plots it is easy to examine the scatter distribution close to the specular direction which, for shiny surfaces, represents the bulk of the scattered light. For surfaces that are diffuse in nature, a log–log plot of the BRDF generally yields a straight line. The slope of this plot is characteristic of the surface of the process which is used to produce the surface. This straight-line plot is useful in comparing samples made with the same process. Deviations from the slope of the line or the value of the points on the line indicate that there may be problems with a sample. Thus the simplest scattering instrument can be used for quality control of black samples. For a fixed angle of incidence and a fixed detection angle, variations in the BRDF value may indicate changes in the materials or the processes which created their surfaces. The quality control process can be performed by looking for variations in the BRDF among the different samples.

The BRDF can be used as a measure of surface roughness – an important attribute for a diffuse black surface. As random surface roughness features increase on a surface, the scatter from the surface also increases. Because of this, the BRDF can be used to characterize surface roughness parameters. If the surface roughness is all in the form of small, micro-rough surface features, the BRDF value then is very much proportional to the surface power spectral density function (PSD), which is a measure of the power plotted against spatial frequency. The characterization of surface roughness by BRDF scatter measurements only works if the scattered energy is due to surface micro-roughness. If the scatter is from larger surface features or from surface contamination, then it will be difficult to accurately characterize the surface roughness. Thus only smooth, mirror-like black surfaces can be used for this simple leap from BRDF values to surface roughness parameters. Some sample BRDFs of black surfaces are found in Figures 4–7.

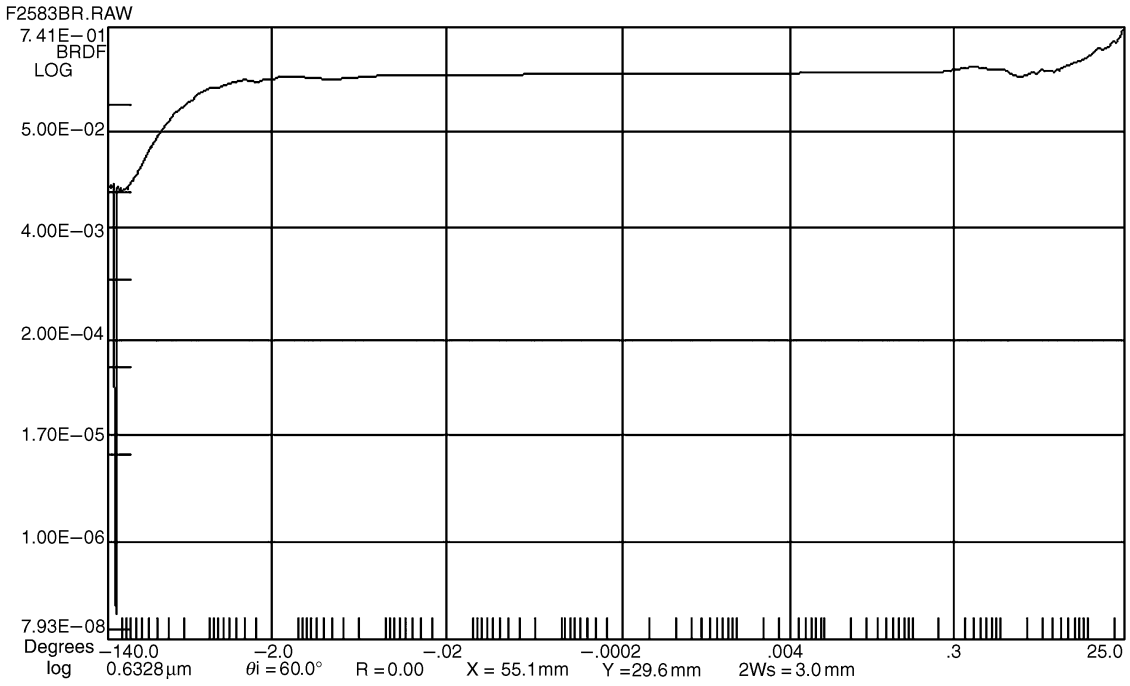

Figure 4 BRDF at wavelength of 0.633 micrometers and 60° incidence angle of black anodize sample. Plot generated by SOLEXIS using CASI software from Schmitt Measurement Systems, Portland, OR, USA.

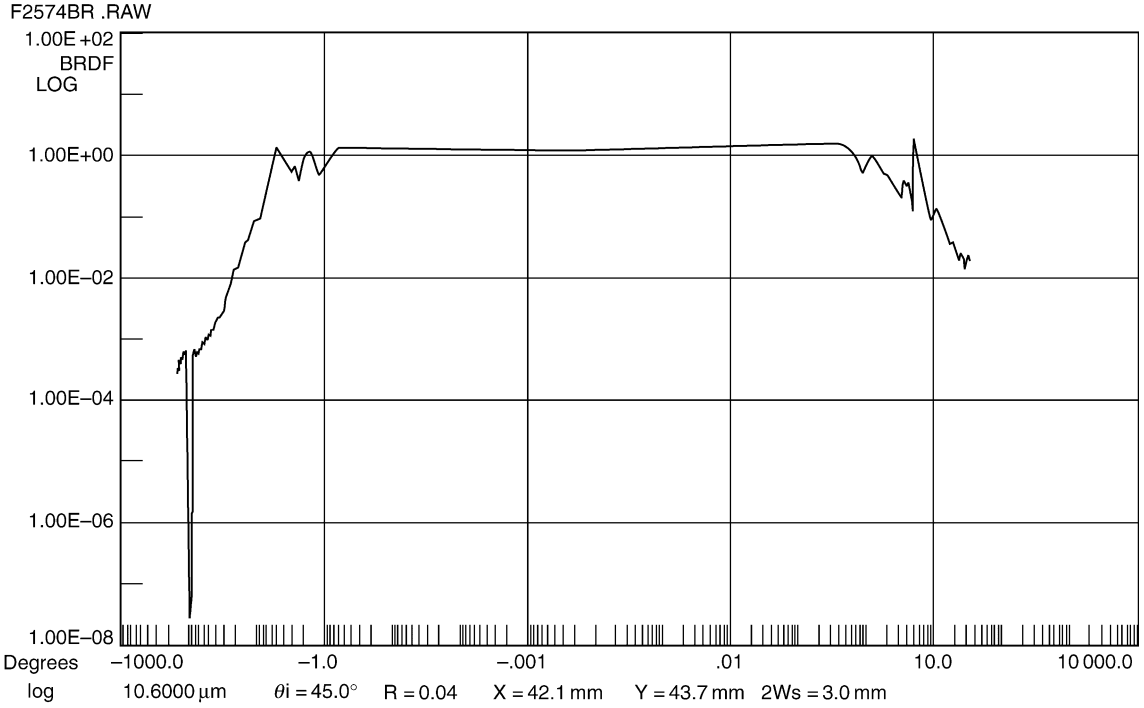

Figure 5 BRDF at wavelength of 10.6 micrometers of black anodize at 45° incidence. Plot generated by SOLEXIS using CASI software from Schmitt Measurement Systems, Portland, OR, USA.

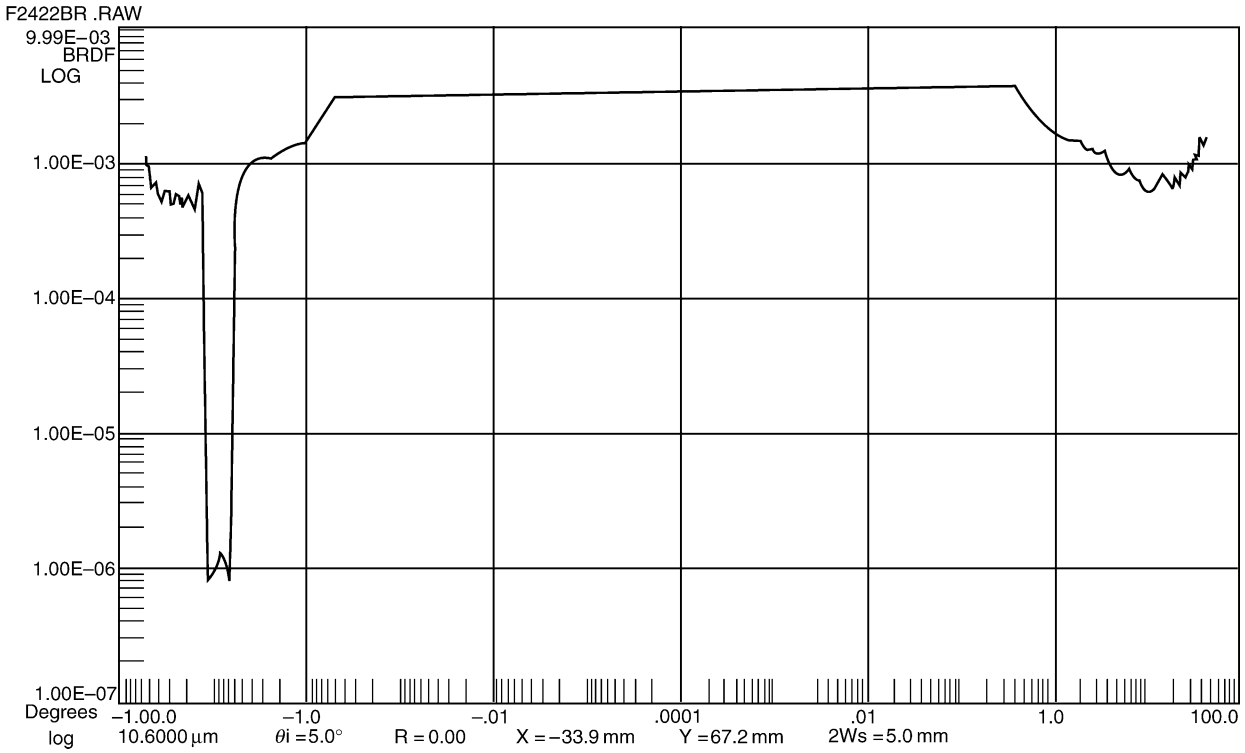

Figure 6 BRDF at a wavelength of 10.6 micrometer of Martin Optical Black at 45° incidence. Plot generated by SOLEXIS using CASI software from Schmitt Measurement Systems, Portland, OR, USA.

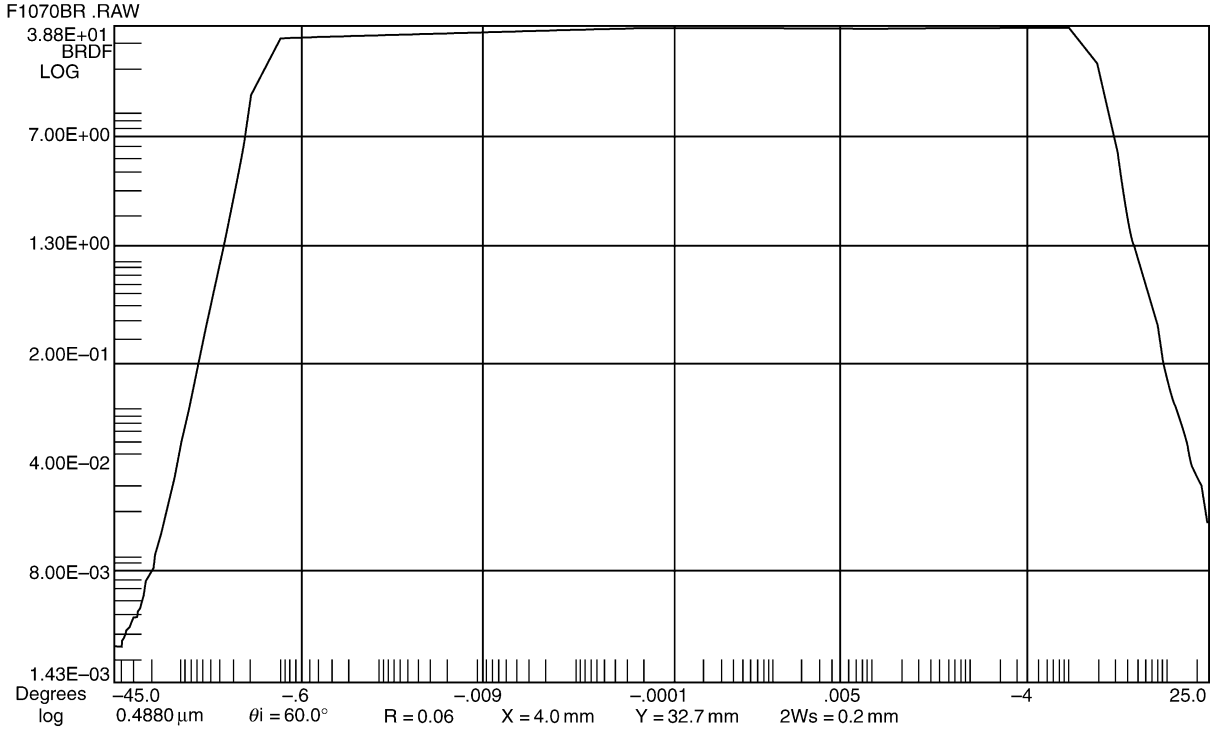

Figure 7 BRDF at a wavelength of 0.488 micrometers of a glossy black surface at 60° incidence. Plot generated by SOLEXIS using CASI software from Schmitt Measurement Systems, Portland, OR, USA.

Examples of Black Surfaces

Black surfaces appear in many forms. They may be either diffuse or specular in nature, or both. Black surfaces may be created by painting a surface, by altering a surface (such as through an anodization process), or by any number of other surface treatment effects. For example, absorbing compounds may be added to paint or to a surface to decrease reflection. Adding large (compared to the wavelength) craters or holes to a surface may result in multiple reflections within the surface leading to decreased reflection. Surfaces may be modified to increase their light-scattering ability, with the hope that reflection in a specific direction will be reduced. Sometimes surfaces may be created in such a way as to enhance thin-film interference effects, leading to reduced reflection. These and other techniques may be combined together in an attempt to reduce reflection and make the material appear blacker in a particular wavelength range of interest or in a particular direction.

Some sample black surfaces are given in Table 3, although databases are much more current on current names and manufacturers.

Many black surfaces use surface texture to enhance their light-absorbing ability. Scanning electron micrographs of surfaces reveal the surface morphology and how multiple reflections can be used for light trapping. Surface chemistry, changes in the index of refraction, and the use of particles of different sizes are also used to create better absorbers. A variety of other proprietary methods are used as well (Figures 8–11).

Future Developments

There are many new kinds of black surfaces being developed for specialized applications. Black surfaces can be created using a variety of new techniques and materials. For example, new surfaces can be created using laser ablation or chemical microetching of surfaces. Surfaces can also be created using new materials such as carbon nanotubes or by using the technology used to create flocked materials. These new kinds of surfaces generally have good absorption at a variety of wavelengths. Even with the creation of these new surfaces, the greatest gain in an optical system will probably be attained through a concerted effort to choose the appropriate black surfaces early in the program and to place them properly in the optical system. An early selection of surfaces and an analysis of their performance will lead to a higher level of system performance than a search for an exotic, ultrablack surface at a late stage

in the program. Although better black surfaces are constantly being developed, the most important future development in the area of black surfaces may be a wider realization of the importance of an early and comprehensive surface selection process. The value of starting the selection process early using black surface databases has been confirmed repeatedly by optical designers.

Thin Film Optical Coatings

D Ristau, Laser Zentrum Hannover e.V., Hannover, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

Thin-film optical coatings are employed to adapt the properties of an optical surface to its specific application. Commonly, optical coatings comprise a sequence of single layers of different transparent materials with a thickness in the range of the operation wavelength. Depending on this coating design, the spectral characteristics of an optical surface can be tuned to nearly any required transfer function including a suppression of reflection for a broad spectral range by an antireflective coating or even the achievement of highest reflectance values up to 99.999% using a high reflecting layer stack. Besides these basic functions, optical coatings can be employed to realize a variety of transfer spectra specified for multiple wavelengths or wavelength ranges to manipulate radiation according to even extremely sophisticated demands in optical systems for laser technology, communication, or fundamental research. Moreover, the desired optical properties can be combined with additional specifications, for example, concerning the mechanical or chemical stability of an optical surface by selecting adapted coating materials. As a consequence of this enormous versatility, thin-film optical coatings can be found in nearly every product and development of modern optical technology today. Aside from the large market of consumer optics including ophthalmology, camera objectives, binoculars, and optical systems for data storage, progress in optical coating technology is predominantly driven by demanding applications in many future technology fields. As one prominent pace-setter, semiconductor lithography imposes new demands on optical coatings extending the operation wavelength of stepper systems in chip production to the extreme ultraviolet (EUV)-spectral range. Other examples can be found in communication technology, where thin-film filters with a bandwidth below

0.5 nm are required, or also in laser material processing, where coatings with high power handling capability and lifetime are indispensable for the development of cost-efficient laser tools.

In this article a concentrated review will be given on the design, production, and on specific properties of optical coatings. After an introduction to the fundamental principles of operation of coating systems, basic expressions for the optical transfer function of a single layer will be derived and extended to layer structures on the basis of the matrix method. Selected conventional and ion processes for the production of coatings will be discussed with respect to the achievable optical and structural properties of the coatings. Also, the thickness control of the coatings during production will be considered introducing the crystal monitoring technique as well as optical measurement strategies at a single wavelength or in a broad spectral range. The article will conclude with a review of the present state of optical coatings and an analysis of future trends.

Design of Optical Coatings

The colorful appearance of optical coatings and microstructures, which can be observed on some butterflies and other insects, was present in nature long before mankind invented them. The beginning of the technical evolution of optical surfaces may be dated back to Greek culture, where polished metal surfaces were used as mirrors. Considering the application of transparent coatings, the investigations of Joseph Fraunhofer in the reflectivity of aged glass surfaces during the year 1819 should be mentioned as a first approach towards an antireflective coating. On the basis of controlled etching, this technique was further developed for different glass materials by Dennis Taylor in 1891 to realize the first antireflective coatings on lenses for applications in optical devices. In 1899, the Fabry–Perot theory was developed as a milestone in the theoretical description of multilayer structures. This theory describes the interference of partial waves reflected from two parallel optical surfaces, which can be considered as the fundamental arrangement of a multilayer structure (see Figure 1). In an optical thin-film system, layers of different transparent materials are composed on a stack deposited on the surface of the optical component (substrate refractive index n_T). In general, to adjust the spectral characteristics of the layer system to the demanded specifications, at least two layer materials with a high refractive index n_H and a low index n_L have to be selected. The choice of the thin-film materials is dependent on the application wavelength and the desired stability of the coating system as well as on their optical properties essential for the specific design and the targeted optical quality. Similar to the Fabry–Perot principle, the optical function of the layer structure is based on the interference of partial waves reflected and transmitted at the interfaces between the layers. The trace of the incoming wave and the induced partial waves are depicted in Figure 2 for a single layer, which can be considered as the basic unit for coating systems even with highest complexity. For a theoretical description of the transfer function of this single layer, the contributions of the individual partial waves have to be calculated and accumulated to form the total transmitted and reflected wave. In this classic approach, the incoming wave can be described by the function of a plane wave with amplitude E_0, wavenumber $k = 2\pi/\lambda$ incorporating the wavelength λ, and frequency ω:

$$E(x,t) = E_0 \exp[-\mathrm{i}(kx - \omega t)] \qquad [1]$$

At the first interface, a part of this plane wave is directly reflected with an amplitude of $A_0 = E_0 r_1$

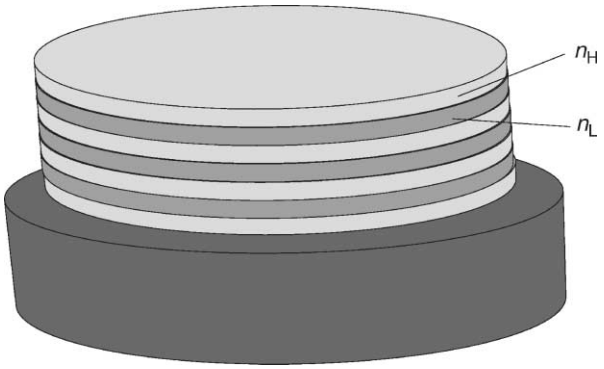

Figure 1 Basic structure of a thin-film system. Transparent layers of at least two different materials (n_H, n_L) are deposited on a substrate with refractive index n_T.

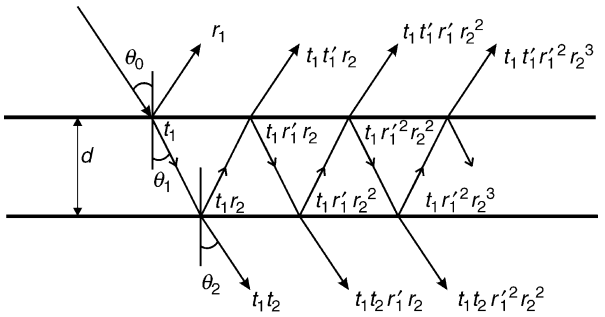

Figure 2 Schematic path of a plane wave incident onto a single layer with refractive index n_1. The reflection and transmission coefficients for the amplitudes at the interfaces $m = 1, 2$ are denoted by t_m and r_m, respectively. A prime added to the coefficients indicates a transfer of the wave opposite to the direction of incidence.

(order zero), which can be calculated using the reflection coefficient r_1 given by the Fresnel formulas. After passing the first interface, a reflection and transmission of the incoming wave at the second interface has to be considered. Also a phase shift has to be taken into account, which is introduced by the path of the wave from the front to the rear interface of the single layer. This phase shift δ_i is dependent on the thickness d_i of the layer and the refractive index n_i:

$$\delta_i = \frac{2\pi n_i d_i \cos\theta_i}{\lambda} \qquad [2]$$

For oblique incidence also the angle of incidence θ_i in the layer, which has to be calculated by Snell's law, has to be taken into account. The index i has been chosen in this consideration for convenience to account for the layer number in coating systems, which will be discussed later. Following the wave reflected the first time inside the layer, a further phase shift for the path from the rear side to the front side has to be taken into account. This partial wave is then transmitted by the front surface resulting in an amplitude A_1 of the first-order wave leaving the layer:

$$A_1 = t_1 t'_1 r_2 E_0 \exp(-i2\delta) \qquad [3]$$

where t'_1 is the transmission coefficient for the amplitude of the wave passing the layer at the interface to the ambient. By following the wave further through the layer, the amplitudes A_k of each partial wave of order k can be determined:

$$A_k = t_1 t'_1 r_2 E_0 \exp(-i2\delta) * (r'_1 r_2 \exp(-i2\delta))^{k-1} \qquad [4]$$

Obviously the contributions of the partial waves follow the rule of a geometric expansion, and therefore the total amplitude of the wave reflected by the layer, which is the sum of the amplitudes of the partial waves, can be expressed in closed form:

$$A_{\text{tot}} = \left[r_1 + \frac{t_1 t'_1 r_2 \exp(-i2\delta)}{1 - r'_1 r_2 \exp(-i2\delta)} \right] E_0 \qquad [5]$$

The reflection coefficient r_S of the single layer is given by the ratio between the total amplitude of the reflected wave and the amplitude of the incoming wave:

$$r_S = \frac{r_1 + r_2 \exp(-i2\delta)}{1 + r_1 r_2 \exp(-i2\delta)} \qquad [6]$$

In this equation, the coefficients r'_1 and t'_1 have been replaced by using the relations

$$t_1 t'_1 = (1 - r'_1)(1 - r_1) = (1 - r_1)(1 + r_1) = 1 - r_1^2 \qquad [7]$$

In principle, this method of compiling the contributions of the partial waves reflected at the layer interfaces can be extended also to the calculation of systems with more than one layer. But, considering the enormously increasing number of partial beams, the resulting equations become extremely complicated for multilayer structures. Therefore, the matrix formalism, which can be deduced from the boundary conditions of the electric and magnetic field at the interfaces, is usually employed for the calculation of thin-film systems. The major advantage of this approach, which was developed in the 1940s, is the representation of each layer by a single matrix M_i containing all specific parameters of the film. The matrix M_i of a thin film at position i within the layer system relates the electric (E_{i-1}) and magnetic (H_{i-1}) field strength at the front face to the field strength values (E_i and H_i) at the rear face of the layer:

$$\begin{pmatrix} E_{i-1} \\ H_{i-1} \end{pmatrix} = \mathbf{M}_i \begin{pmatrix} E_i \\ H_i \end{pmatrix} = \begin{pmatrix} \cos\delta_i & \frac{i}{n_i}\sin\delta_i \\ i n_i \sin\delta_i & \cos\delta_i \end{pmatrix} \begin{pmatrix} E_i \\ H_i \end{pmatrix} \qquad [8]$$

By considering the boundary conditions for the field strengths at the interfaces, the matrix components given in eqn [8] can be determined. On the basis of the matrix formalism, the transfer function of a layer system can be simply accomplished by multiplication of the matrices M_i representing the constituent single layers. Thus, the transfer matrix M_S of a stack, which is formed by a number K of single layers with layer 1 located at the first interface with respect to the incoming wave, is given by

$$\mathbf{M}_S = \mathbf{M}_1 \mathbf{M}_2 \mathbf{M}_3 \ldots \mathbf{M}_i \mathbf{M}_{i+1} \ldots \mathbf{M}_K \qquad [9]$$

For calculating the reflection coefficient r_{SK} of the entire arrangement including the substrate (index of refraction n_T) and the ambient medium (index of refraction n_0), again the ratios of the amplitudes have to considered:

$$r_{SK} = \frac{n_0 \mathbf{M}_{11} + i n_0 n_T \mathbf{M}_{12} - i\mathbf{M}_{21} - n_T \mathbf{M}_{22}}{n_0 \mathbf{M}_{11} + i n_0 n_T \mathbf{M}_{12} + i\mathbf{M}_{21} + n_T \mathbf{M}_{22}} \qquad [10]$$

As a consequence of its perceptible structure, the matrix method can be readily transferred into computer codes, which cover the calculation of all important properties of even extremely complicated layer systems. In particular, considering the fundamental relations of the matrix method, also the field strength distribution within the layer structure can be determined. In software packages, which are commercially available as standard tools for optical thin-film technology, often the film thickness D_i of the layers is expressed in the units of QWOT (quarter wave optical

thickness) at the design wavelength λ_Z:

$$D_i = \frac{4n_i d_i}{\lambda_Z} \qquad [11]$$

In the case of normal incidence, the matrices M_i reduce to simple expressions for layers of integer QWOT values, because the corresponding phase shift terms are multiples of $\pi/2$. Clearly, an integer QWOT value of optical thickness also represents an extreme value in the spectral behavior at the design wavelength. This fact is often exploited for a precise thickness control by optically monitoring the reflectance or transmittance of the growing layer at the design wavelength λ_Z: by recording the transfer behavior as a function of time during production, extreme values and accordingly thickness values of multiple QWOT can be accurately determined. Thus, if a layer structure is composed only of multiple QWOT layers, switching between the layer materials can always be precisely performed at a minimum or maximum read-out of the optical monitor tuned to the design wavelength. In respect of this advantage in production, most coating designs are based on QWOT layers indicating the practical importance of the unit QWOT. For an efficient description of the designs, often a notation in capital letters is used, which indicate a 1 QWOT layer of a certain coating material. For example an alternating QWOT-stack with 11 layers of a high-index material (H, refractive index n_H) and a low-index material (L, refractive index n_L) is described by the sequence HLHLHLHLHLH or even more condensed by $(HL)^5H$. The QWOT stack is the fundamental design for dielectric high reflecting mirrors and represents the basis for a variety of functional coatings in optical thin-film technology. By applying the matrix method, an approximate expression for the reflectance R_S at the design wavelength can be derived for such a stack:

$$R_S \approx 1 - 4n_0 n_T \frac{n_L^{2N}}{n_H^{2(N+1)}} \qquad [12]$$

This expression is only valid for a large number N of QWOT layers and underlines the role of the materials for the practical production of optical coatings. Highest reflectivity with lowest number of layers can be achieved only by selecting materials with a high contrast of their refractive indices. This contrast also influences the spectral broadness of the high-reflecting region of the stack (Figure 3).

Besides highly reflecting mirrors, antireflective coatings are another important class of functional coatings for modern optics and laser technology. Antireflective coatings often involve non-QWOT layer structures of more than two materials in order to accomplish the demands of lowest residual reflectivity for a broad spectral range. Eye glasses with antireflective coatings covering the entire visible spectral range can be considered as a prominent example for consumer optics, which impose requirements on the coatings also in respect to their stability against cleaning and other environmental influences during normal use. In this context, the introduction of optical plastic materials is an additional challenge in consumer optics and ophthalmology, which has to be mastered by adapted designs and production processes. In contrast to the typical demands of consumer optics, antireflective coatings on laser windows are

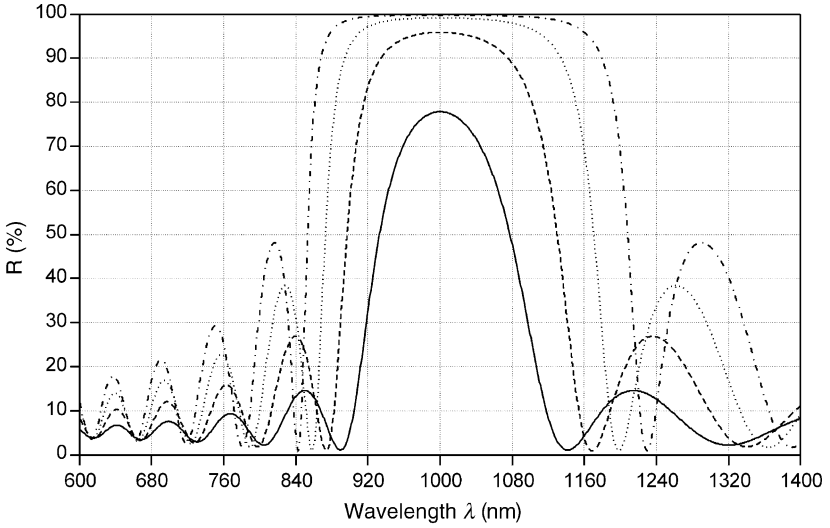

Figure 3 Spectra calculated for high-reflecting QWOT stacks (15 layers, substrate index $n_T = 1.52$) composed of a low-index material ($n_L = 1.46$) and different materials with high indices of refraction varying between $n_H = 1.7$ (solid), 1.9 (dashed), 2.1 (dotted) and 2.3 (dash-dotted). The spectral broadness and the reflectivity increase with the ratio n_H/n_L.

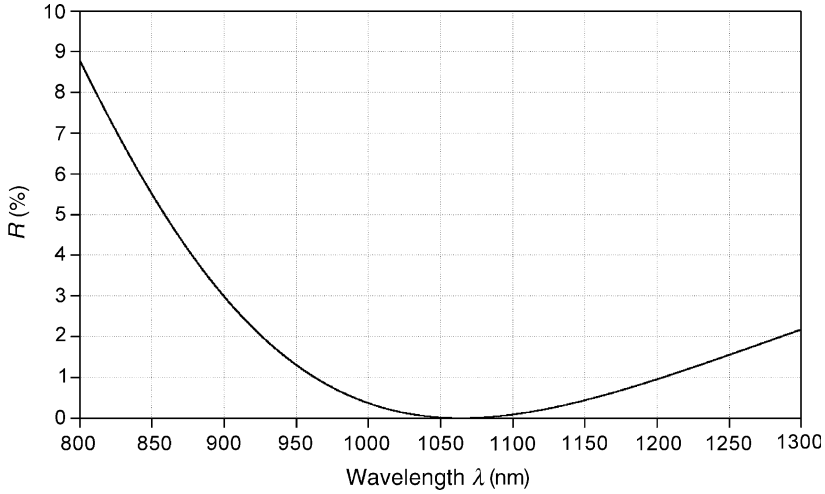

Figure 4 Spectrum of an antireflective coating for the wavelength 1.064 μm, which is designed as a V-coating with two layers of Ta_2O_5 ($n_H = 2.03$; $d_H = 0.383$ QWOT) and SiO_2 ($n_L = 1.46$; $d_L = 1.308$ QWOT) for a quartz substrate (substrate index $n_T = 1.46$).

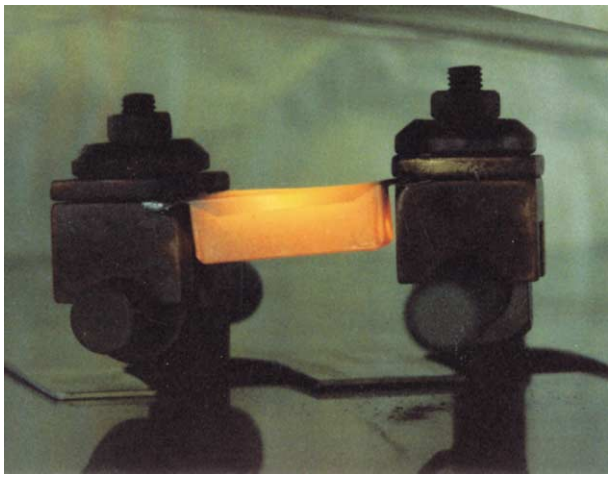

Figure 5 Boat evaporation source in operation. The deposition material is put into the boat which is made of a metal with high melting point. A high electric current is conducted through the boat for heating to temperatures up to 2000 °C.

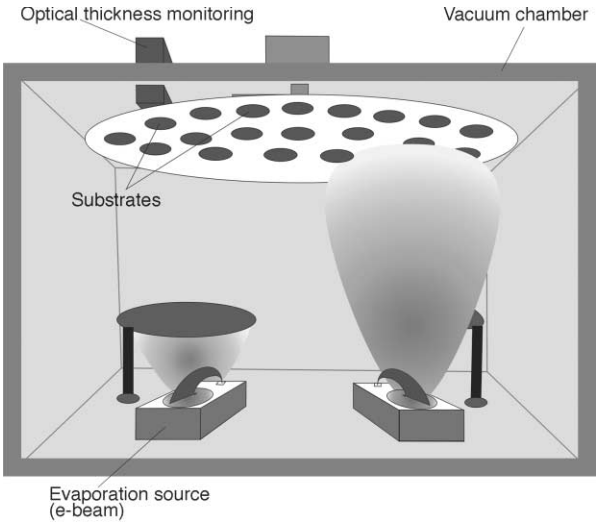

Figure 6 Outline of a modern box coater used for the production of optical coatings with e-beam deposition processes.

often restricted to one wavelength, but have to fulfill extreme requirements with respect to optical losses and power handling capability. Therefore, most antireflective coatings in laser technology are composed only of two thin layers to minimize the total thickness, which is often a direct measure of the expected losses of the layer system. With such a coating, which is often called V-coating according to its spectral characteristic (Figure 4), the reflectivity of the window surface can be suppressed ideally for one wavelength.

Production of Optical Coatings

The industrial production of optical coatings started in the 1940s on the basis of glass bell jar systems equipped with diffusion pumps and boat evaporators for the deposition of single layers of metals for mirrors and fluoride materials for antireflective coatings. Metal containers are used as boat evaporation sources. These containers are filled with the deposition material and heated by electric currents up to several 100 A (Figure 5). In the course of the rapid improvement of vacuum systems and especially the development of the electron beam evaporator over the next three decades, new materials with improved optical and mechanical quality could be combined to form more complicated dielectric coating systems. The layout of an e-beam deposition plant of these times, which can still be considered as fundamental for the advanced deposition systems of today, is illustrated in Figure 6. In such a box coater, the

substrates are installed in a calotte which is rotated to achieve a uniform distribution of the layer thickness. The deposition materials are put in water-cooled crucibles and are subjected to an electron beam operated at currents in the range between 0.1 A to more than 10 A and voltage levels of several kilovolts. As a consequence of the interaction with the energetic electrons, the deposition material can be heated to high temperatures above 5000 K allowing the evaporation of most of the desired deposition materials. These achievable high temperatures in conjunction with the good controllability are the major advantages of e-beam sources (Figure 7) in comparison with the classical boat evaporation process. In particular, e-beam evaporation opened the way for the deposition of oxide materials and other optical materials with high evaporation temperatures, which exhibit optical properties as well as a high mechanical and chemical stability superior to the material classes accessible with boat evaporation. However, the cost efficient boat evaporation technique is still applied today for the deposition of metals or temperature-sensitive materials for coating systems in the vacuum ultraviolet (VUV)/UV and mid-infrared (MIR) spectral ranges. If the shutter above the deposition source is opened, the evaporated material reaches the substrates and forms the layer by condensation. This condensation process is sensitively dependent on the environmental conditions of the substrates and the deposition sources. Sufficient microstructural properties of the growing layer can generally be achieved only under fine vacuum below 100 Pa and heating of the substrates to temperatures in the range of some 100 °C. Even under well-optimized conditions, the typical microstructure of such thermally evaporated coatings exhibits specific deficiencies (Figure 8) which influence the optical and mechanical properties of the layer systems. Often, microcrystallites with diameters in the range of a few nm are observed, which are arranged in columns of a typical size growing from the substrate interface to the outer surface of the layer. For a simulation of the growing mechanisms for this low energetic deposition process, uncomplicated models with a few input parameters already lead to satisfactory results. Assuming a kinetic energy of 0.1–0.3 eV, which is typical for thermal evaporation according to the Boltzmann distribution, the impinging atoms can move only a small distance or even adhere directly at their position of incidence on the growing layer. As a consequence of this small mobility, the atoms are not able to reach their energetically optimum positions in the layer, and they even obstruct the path of the following atoms by shadowing. On the basis of these assumptions, computer simulations of the growing process result in structures which are comparable to the columnar growth observed in practice. The packing density of such a columnar structure is significantly below the bulk values of the corresponding deposition materials, and it contains also a high number of defects and voids, which reduce the optical quality of the coating. In particular, the coating tends to

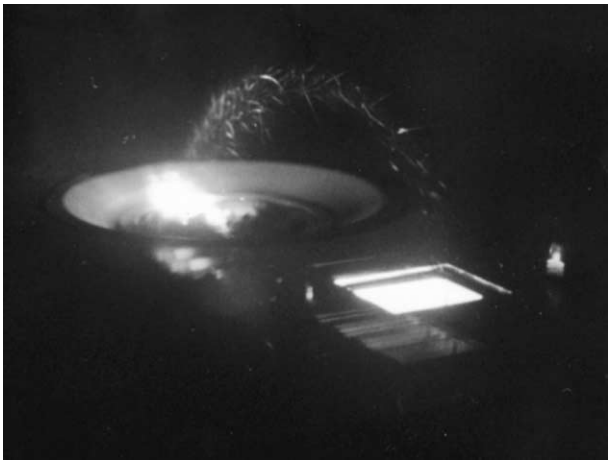

Figure 7 Electron beam source in operation. The deposition material is put in a water-cooled crucible and subjected to an e-beam. Since the zone heated by the e-beam is entirely embedded in the surrounding deposition material, very low contamination levels and temperatures above 5000 °C can be achieved. For the generation of the e-beam an arrangement similar to the system of a cathode ray tube is employed: the electrons emitted by a hot filament are focused by an aperture and accelerated by a high voltage.

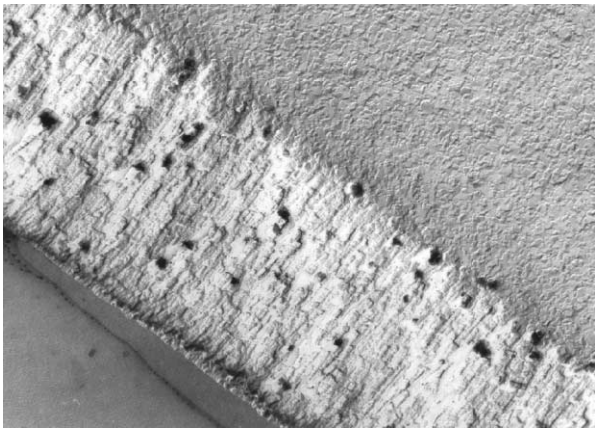

Figure 8 Microstructure of a MgF_2 single layer (geometric thickness approximately 780 nm) deposited by conventional boat evaporation. For the preparation of the TEM picture, the coating has been fractured and replicated.

adsorb water from the normal atmospheric environment into its internal structure leading to a shift of the spectral characteristics as a function of the ambient conditions. Besides this loss of spectral stability, the adsorbed water also induces an increased optical absorption of the coatings in the VUV and the MIR spectral ranges.

The increasing demand in laser technology and other optical applications for coatings far exceeds the quality level of conventionally deposited coatings and this was the driving force for the development of advanced concepts for the production of optical coatings during the last three decades. Considering the fundamental growth mechanism of conventional optical coatings, two basic approaches for an improvement of the microstructure are available. On one hand, the mobility of the atoms on the surface of the growing layer can be increased by the insertion of additional energy from other sources. This concept leads to the development of ion-assisted deposition processes, where the additional energy is transferred to the adatoms by collisions with ions generated directly in the plant by an ion source at energy levels of approximately 30–300 eV (Figure 9). Especially, by the deposition of oxide materials, which can be assisted directly with oxygen ions for balancing their stoichiometry, coating systems with high environmental stability and low optical losses can be achieved for the VIS up to the MIR spectral range. On the other hand, the energy of the adatoms can be directly increased in sputter processes which deliver deposition energies orders of magnitude higher than the thermal energy range. Besides adapted activated reactive magnetron sputter processes, particularly ion beam sputtering (IBS) was developed for a coating process delivering high-end coatings mainly for laser technology with an unsurpassed optical quality (Figure 10). For example, mirrors with total losses below one ppm can be produced for the Nd:YAG laser (wavelength 1.064 μm) with adapted IBS processes.

In addition to stable deposition processes, precise control of the layer thickness with an accuracy below 1 nm is a further important step towards the realization of complex optical coatings. Most deposition plants are equipped with quartz crystal monitors, which measure the optical thickness on the basis of the resonance frequency shift of an oscillating quartz crystal induced by the increase in mass of the deposited coating. The relative accuracy of these monitors ranges from 2% to 10% and is well suited for the regulation of the deposition rate. In order to achieve the required precision for high-quality coatings, optical monitors are often employed, which record the transmittance of the growing layer system at a single wavelength or even in a broad spectral range. Since these systems account directly for the optical properties of the deposited layer system, an efficient and accurate control of the film thickness is possible allowing the production of extremely sensitive filters with bandwidths below 1 nm for telecommunications or mirrors with defined group delay dispersion for fs-laser systems (Figure 11).

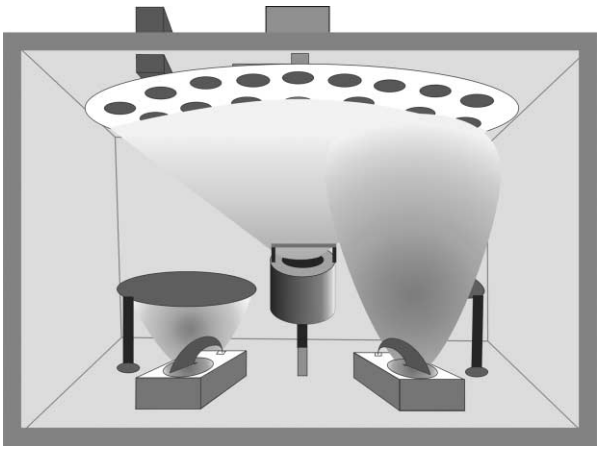

Figure 9 Ion assisted deposition. An additional ion source is installed, which delivers inert or reactive ions impinging on the growing layer. The energy transfer from the ions to the adatoms results in improved microstructure of the produced coatings with higher packing density.

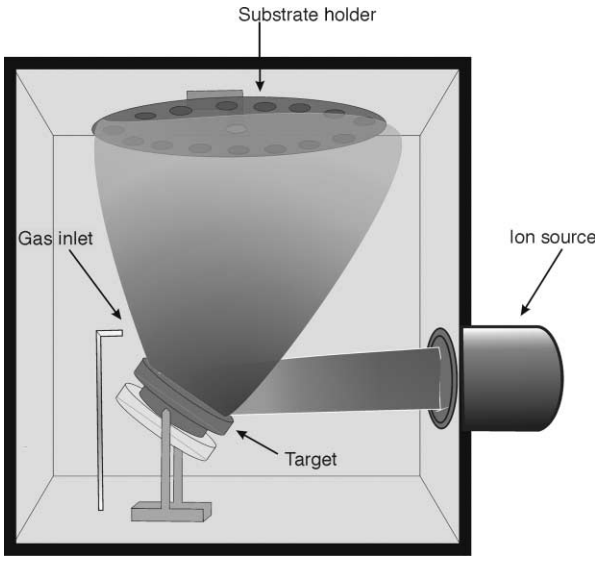

Figure 10 Principle of the ion beam sputtering (IBS) process. Inert ions with an energy in the range 1–2 KeV are generated in an ion source and directed onto the target which consists of the desired deposition material. Material is sputtered from the target and reaches the substrates. As a consequence of the high energy of the adatoms (5–30 eV) the formed layer exhibits a superior microstructure.

Quality Parameters of Optical Coatings

Besides the spectral characteristics, a variety of specific parameters has to be considered for each application of optical coating systems (Table 1). For laser systems the laser-induced damage threshold and the optical losses have to be evaluated in the context of technical and also economic requirements. Absorption is a loss channel, which transforms a fraction of the impinging radiation energy into heat, inducing a temperature increase in the coating. This generated temperature profile influences the imaging properties of the optical component via thermal expansion and temperature-induced alterations of the refractive indices of the coating as well as the substrate materials. Despite numerous technical problems, absorption always implies the loss of laser energy which is produced with high economic expense. Absorption losses are related to defects and impurities, which are introduced during the production process into the layer by a variety of contamination mechanisms. Furthermore, an unbalanced stoichiometry with a higher metal content is often observed as a cause for increased absorption in dielectric optical coatings, which are mainly composed of binary metal compounds. Absorptance values of optical components are determined by laser calorimetric techniques described in ISO 11551. In this measurement scheme, the temperature increase in the sample is monitored during irradiation with a well-characterized laser beam. After this heating phase, the laser beam is blocked and the temperature curve during the cool-down cycle is also recorded. On the basis of the measured temperature development, the absorptance can be calculated taking into account the laser power and the heat capacity of the specimen.

All mechanisms, which deflect radiation from its specular direction, contribute to optical scattering representing the second major loss channel in optical coatings. Since scatter losses are mainly attributed to microstructural imperfections and the surface roughness of the layers, a scaling with wavelength can be deduced from the corresponding theoretical models. Especially in the VUV/UV spectral range, high scatter values are apparent and may dominate the losses of the optical components. For longer wavelengths, the contribution of scattering is decreased to a point in the MIR spectral range where it can be neglected in comparison to the absorption losses. Scatter effects

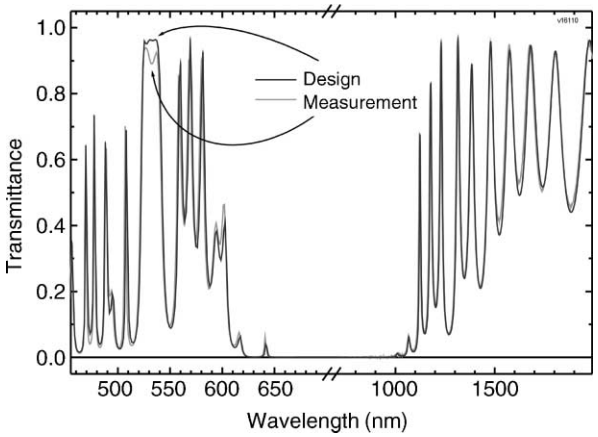

Figure 11 Example of a complicated layer system deposited under the control of an advanced optical broadband monitoring device: double chirped mirror (56 non-QWOT layers of SiO_2/TiO_2). Only small deviations between the calculated spectrum and the spectrum of the produced coating can be observed.

Table 1 Selected quality parameters of optical coatings and surfaces in conjunction with corresponding ISO standards and measurement principles

Specification	*Parameter/Unit*		*Standard/Measurement principle*
Laser induced damage threshold (LIDT)	cw-LIDT	W/cm	ISO 11254-1: cw-laser irradiation
	1 on 1-LIDT	J/cm^2	ISO 11254-1: irradiation with single pulses
	S on 1-LIDT	J/cm^2	ISO 11254-2: repetitive irradiation with pulses
	Assurance	J/cm^2	DIS 11254-3: irradiation sequence
Optical losses	Absorptance	ppm	ISO 11551: laser calorimetry
	Total scattering	ppm	ISO 13696: integration of scattered radiation
Transfer function	Reflectance	%	CD 13697: precise laser ratiometric method

Surface quality	Scratch/Digs		ISO 10110: 13 parts containing different types of imperfections
	Roughness		
Stability	Abrasion		ISO 9211: different test methods
	Environmental Stability		ISO 9022: 21 parts containing a variety of conditioning methods

may impair the imaging properties or the resolution, and they reduce the efficiency of an optical system. Besides the economic aspect of each loss effect, scattering can also be considered as relevant for safety in high-power laser systems, where some 100 ppm of scattered radiation carry enough power to injure or blind the operator. In the ISO 13696 standard, measurement procedures based on the collection or integration of the total radiation scattered by the sample are described.

Depending on their application, coatings have to withstand also manifold mechanical, chemical, and environmental influences. Severe mechanical and chemical requirements are imposed onto coatings for ophthalmology or consumer optics, which are often cleaned with abrasive and aggressive cleaning solvents and tissues. To qualify coatings for these applications, various testing procedures have been developed and are routinely employed in industrial quality management. Coatings for laser systems and precision optics are predominantly certified according to conditioning methods described in the ISO standard series 9211. Test procedures with respect to environmental influences are extensively outlined in the more than 20 parts of ISO 9022, which is dedicated to a variety of climatic, mechanical, and chemical conditioning cycles.

Summary and Outlook

Optical coatings are the major tool for engineering the properties of functional optical surfaces for an extensive spectrum of applications. On the basis of the matrix algorithm, a comprehensive theoretical model for the spectral transfer characteristics of optical coatings is available, which has been transferred to commercial computer programs. Now, most design problems can be solved with these computer codes, whereas the reproducible and precise production of optical coatings with high quality could only be partially achieved until today (Table 2). Besides conventional thermal processes, new ion-assisted deposition processes and sputtering concepts are gaining importance in optical thin-film technology. For the quality management of optical coatings, a variety of often standardized testing procedures has been developed during the last two decades including the determination of the power handling capability, the measurement of the optical losses and a broad spectrum of conditioning methods for optical coatings.

Demanding future challenges will be imposed on optical coatings by the development of semiconductor lithography in the EUV spectral range to achieve nodes well below 100 nm in chip production. Another important trend is directed by new laser applications in material processing, medicine and communication technology, operating at extremely high repetition rates and power levels, or with ultrashort pulses in the fs-regime. Other requirements will be defined by the rapid development of optical technology towards a broad range of special products with short innovation cycles obligating significant progresses in thin-film technology in the direction towards flexible and reproducible process concepts

Table 2 Selected quality parameters of optical coating systems for laser applications

Laser, wavelength	*Type*	*Absorption ISO 11551*	*Total scattering ISO 13696*	*Laser induced damage threshold, ISO 11254*
157 nm, F_2 excimer	HR/th		1–4%	
193 nm, ArF excimer	AR/th	0.7–2.5%	0.2–0.5%	1–2 J/cm^2 (1on1, 20 ns)
	HR/th	0.4–2.0%	0.2–2.5%	2–4 J/cm^2 (1on1, 20 ns)
248 nm, KrF excimer	AR/th		<0.025%	10 J/cm^2 (1on1, 30 ns)
	HR/th	<500 ppm	<0.2%	>20 J/cm^2 (1on1, 30 ns)
	HR/IB		<0.1%	>3 J/cm^2 (1on1, 30 ns)

	HR/th	<0.10%	–	>25 J/cm^2 (100 ns, 1.4 mm) >2 kJ/cm^2 (1.2 ms, 250 μm)

Types: HR: highly reflecting mirror; AR: antireflective coating; th: thermal evaporation; IB: ion beam sputtering.

for coatings with increasing complexity. In all fields of modern optics, optical thin films will represent an enabling technology which will play a key role for many future applications and products.

List of Units and Nomenclature

A_0	amplitude of partial wave of order zero
A_1	amplitude of first-order partial wave
A_k	amplitude of the partial wave of order k
d_i	thickness of layer number i
D_i	film thickness expressed in units of QWOT
E_0	amplitude of a plane wave
E_i, H_i	electric field strength and magnetic field strength at the rear front of layer number i
IAD	ion-assisted deposition
IBS	ion beam sputtering
k	wavenumber of a plane wave $k = 2\pi/\lambda$
M_i	matrix of layer number i
M_S	composite matrix of a layer stack of K single layers
n_0	index of refraction of the ambient medium
n_H	refractive index of a high-index material
n_i	refractive index of layer number i
n_L	refractive index of a low-index material
n_T	refractive index of the substrate
QWOT	quarter wave optical thickness: unit for the thickness of the layer
r_1, r_1'	reflection coefficients of the ambient–layer interface
r_2	reflection coefficient at the layer–substrate interface
r_S	reflection coefficient of a single layer
r_{SK}	reflection coefficient of a layer stack of K single layers
R_S	reflectance of a QWOT stack
t_1, t_1'	transmission coefficients of the ambient–layer interface
δ_i	phase shift of a plane wave in layer number i
λ	wavelength of a plane wave
λ_Z	design wavelength
θ_i	angle of incidence in layer number i
ω	frequency of a plane wave

X-Ray Coatings

P Dhez, Université Paris Sud, Orsay, France

© 2005, Elsevier Ltd. All Rights Reserved.

In all spectral ranges, there exist two principal options for coating an optical element. This may be a simple layer, as for example a metallic layer is frequently used in the visible spectral region. The second option is to use a multilayer coating, making use of the optical properties of two or more materials to achieve enhanced reflectivity over a limited spectral range. In both cases, a knowledge of the refractive

index of the materials (real or complex) is required, and of course one must choose materials that can be coated in a practical deposition process. A frequent side-advantage of coating is to make it possible to choose the material of the substrate for its mechanical or cooling properties without regard to the optical properties of the coatings.

Originally (at the beginning of the twentieth century) the progress of X-ray optics was hampered by a poor understanding of the nature of these rays, and in particular by the observation that they are very weakly reflected and refracted. After the electromagnetic nature of these rays had been confirmed, the problem of producing polished surfaces that were sufficiently smooth on an atomic scale to reflect X-rays still remained. Optical coatings gave little hope of improvement due to the growth of roughness during the coating process. Thus early attempts to make X-ray mirrors produced poor results and little progress was made until the 1960s. However, in the past 30 years, much technical progress has been made, and now many optical principles used in the visible spectral region have been extended to very short wavelengths. Even refractive and diffractive focusing lenses (not treated here) have been implemented in the X-ray region.

In the first section we outline the history of the discovery of the properties of X-rays, which were achieved mainly in experiments using crystals. This allows us to understand how their electromagnetic nature was discovered, and how they interact with materials. We then describe the phenomenon of the 'total reflection' of X-rays, which occurs only at very high angles of incidence ('grazing incidence') and its main applications in X-ray optics. Finally, we outline the principles of mirrors based on interference, their applications in the X-ray region, their advantages and their limitations.

X-rays Compared to the Other Electromagnetic Spectral Regions

Infrared radiation was discovered by W. Herschel in 1800, and ultraviolet rays by J. Ritter in 1801. These were the only 'invisible rays' known before Maxwell's contribution to the understanding of the electromagnetic spectra through the development of his equations in 1869. The discovery of radio waves by H. Hertz in 1887 confirmed that our eyes are blind to most of the electromagnetic spectrum.

In 1895, W. Roentgen discovered some previously unknown 'rays' that had the surprising property of being able to penetrate low-density material opaque to visible light. This discovery was a side-effect of his studies of low-pressure electrical discharges, fashionable at the time. The nature of these unknown or 'X'-rays as Roentgen named them, remained unknown for 12 years or so. Were they electromagnetic waves or particles? Roentgen used lenses, prisms and mirrors to try to detect a reflective, refractive or focusing effect, with inconclusive results. Although the electromagnetic nature of the X-rays was favored, the magnitude of the frequency or the refractive index was unknown. We note that natural radioactivity and gamma rays were discovered a year after X-rays, and the same questions concerning their nature were raised. However, in neither case did the ignorance of the nature of the radiation impede their use in medical radiography or in cancer therapy.

In 1906, the experiments of C. Barkla provided the first evidence of the electromagnetic nature of X-rays. In scattering X-rays from blocks of a light element (in this case, carbon), he was able to show that the scattered radiation was polarized, and therefore had the nature of a transverse wave. This kind of experiment had been performed almost a century previously to demonstrate the transverse wave nature of visible light. In 1916, following a suggestion by M. von Laue that X-rays might be diffracted from a grating of period comparable to their wavelength, Friedrich and Knipping succeeded in diffracting X-rays from the atomic planes of a natural crystal. This experiment established definitively the electromagnetic nature of X-rays and also the scale of their wavelength.

In 1915 W. L. Bragg summarized the diffraction rules for crystals through his equation [1], now known as the simplified Bragg law:

$$2d_i \sin\theta_i = N\lambda_i \qquad [1]$$

This equation relates the diffracted X-rays wavelength λ_i to a set of parallel atomic planes separated by a distance d_i and to the incidence angle θ_i. N is an integer indicating the order of diffraction, as in the grating equation. In using this equation, care is needed because of two peculiarities compared to the usual mirror or grating equations in the visible range. In the Bragg equation, the angle of incidence θ is measured from a given atomic plane to the incident rays. However, inside a crystal several different atomic planes exists, not only the planes parallel to the surface as indicated in **Figure 1**. In addition, θ is not measured from the normal as is usual in optics; hence the angle θ is referred to as the glancing or grazing angle of incidence.

We note that the Bragg equation is not restricted to X-rays, but is a coherent scattering phenomenon which is common to all cases where waves, such as

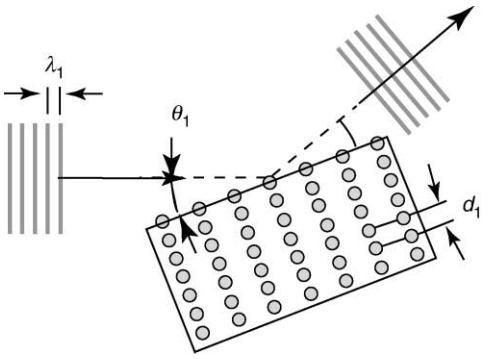

Figure 1 The geometry for the conditions leading to selective reflection on a periodic medium.

sound waves or ripples on water, are diffracted by regular arrays of scattering centers.

In order to visualize the phenomena, we refer to Figure 1 which is a schematic representation of a plane wave incident upon a two-dimensional array of scattering centers (electrons around nucleus, in the case of X-rays), shown here as dots. As the sine function has a maximum value of 1, the maximum wavelength λ that can be reflected from a spacing d is given by $\lambda = 2d_{max}$. As the largest value of $2d$ that can be found in natural crystals is about 2 nm (in natural muscovite mica, for example), X-rays of 2 nm, with an equivalent energy of about 620 eV, are the 'softest' (least energetic) that can be reflected in this manner.

The model shown in Figure 1, similar to that proposed by M. von Laue, does not take into account the detailed interaction of the atoms with the X-rays, and therefore ignores effects such as absorption and refraction, and discrete atomic transitions. A.H. Compton attempted the first treatment of the interaction of matter with X-rays from an atomic viewpoint. In 1917, he developed a classical theory in which the electrons bound to the nucleus are treated as harmonic oscillators. In this way, he was able to derive an expression for the atomic scattering coefficients and to describe resonance effects at frequencies corresponding to specific atomic transitions. A few years later, he was able to establish a link between these 'atomic scattering factors' and the macroscopic concept of refractive index. This new formulation allowed the use of the Fresnel equations, widely used in other spectral regions, to calculate the intensity of X-rays reflected from smooth, polished surfaces. These surfaces may be amorphous as well as crystalline.

The refractive index can be written in several ways; since it is close to unity over the X-ray range, the most common form is complex:

$$n = 1 - \delta - i\beta \qquad [2]$$

where δ is the refractive index decrement, and the imaginary part β the absorption index. For photon energies corresponding to X-rays, both have small negative values, typically 10^{-3}–10^{-6}, and are correcting factors to the vacuum index 1. As in other photon energy ranges, the absorption and the refraction coefficient variations are linked through the Kramers–Krönig relations. In the visible range the index values are usually larger than 1, being below 1 only around specific optical thresholds. In the UV region, the index values become smaller than unity at energies above about 30 eV, which corresponds to the energy range for which atoms can be ionized.

At an early stage, Roentgen demonstrated X-ray absorption by sheets of materials. The demonstration of refraction took much longer and was more difficult. The first direct X-ray refraction index measurement was achieved in 1924, using a prism and an X-ray tube. Figure 2 is the scheme of the experiment, which is easy to perform in the visible range to measure the refraction of a transparent material. The footprint of the direct beam on the photographic plate is made before inserting the prism. In the visible range for which $n > 1$, the beam is refracted at larger angle than the glancing incidence angle, and so below the direct beam direction as shown in Figure 2a. At the contrary, as indicated in Figure 2b, the X-ray beam is refracted toward the prism surface and such an experiment effectively demonstrated that the index was slightly inferior to unity, as suggested by A.H. Compton. We will return

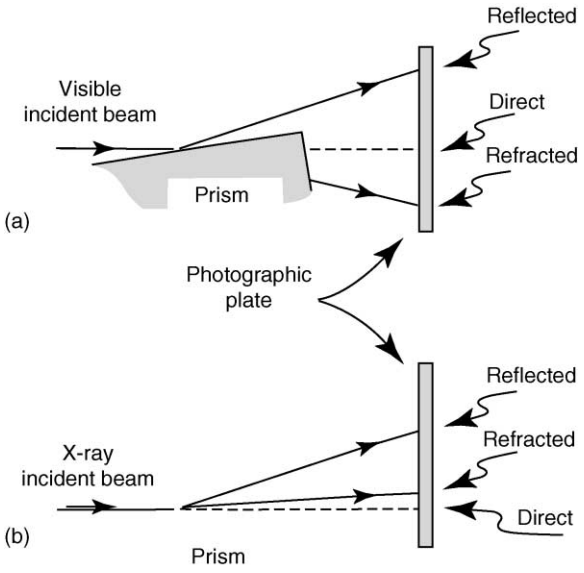

Figure 2 The geometry of the experiment used to evaluate the magnitude and the sign of the refractive index in the X-ray and the visible ranges.

to this peculiarity in the following section, when the total reflection phenomenon is described.

More details about the successive steps in our understanding and the pioneering works on X-rays can be found in standard textbooks.

Total Reflection X-Ray Mirrors

Using Fresnel's equations and tabulated values of the refractive index one can verify that, on any material, grazing incidence is necessary to reflect X-rays. Reflectivity calculations over the range from EUV to X-rays (30 eV to 10 keV), with approximations to allow calculations for rough surfaces, can be carried out using the web site of the Center for X-ray Optics of Lawrence Berkeley Laboratory http://www-cxro.lbl.gov, and curves similar to those presented below can be reproduced.

In the case of normal incidence, Fresnel's equation indicates that for any material the X-ray reflectivity $R^2 = |(n-1)/(n+1)|^2$ is very low, typically below 10^{-4}. This is a direct consequence of the X-ray index values, which are close to unity, as mentioned above.

In the visible range, normal incidence reflectivity from the surface of a transparent medium is low but can be increased just by going to glancing incidence. This is also the case in the X-ray region but in addition as the real part of the X-ray refractive index is lower than that of the vacuum, we have an 'external' total reflection phenomenon. From Figure 2 one can see how, for a sufficiently small incidence angle, the refracted wave becomes parallel to the interface. This is well known in the visible range (in which case it is the 'internal' reflection) and the phenomenon is used, for example, in fiber optics.

Figure 3 shows examples of calculated reflectivity variations versus grazing incidence angles, for perfectly smooth glass (SiO_2), nickel, and platinum surfaces. Curves are drawn for the 8 keV energy photons, corresponding to the Cu Kα line produced by conventional X-ray tubes. One observes that for this energy the reflectivity is low beyond a grazing angle around 1°, then rises quickly at low angles. This is typical of the total reflection phenomenon. The grazing angle corresponding to a 50% reflectivity is called the critical angle Θ_c, its value being roughly proportional to the refractive index decrement at the relevant photon energy. Notice that weaker absorption materials, lower Z, lead to more abrupt reflectivity variation but with smaller critical angles.

Such reflectivity variations at grazing incidence were systematically studied with X-ray tubes as early as the 1930s. The penetration depth of X-rays at grazing incidence was also studied. The evanescent wave inside the material, under total reflection conditions, is confined to a surface layer of a few tens of wavelengths. Hence, in the total reflection of X-rays, a coating having a thickness of a few tenths of a micron, on any substrate, is all that is required.

Figure 4 shows examples of the variation in nickel reflectivity calculated over the energy range 0.3–10 keV, for several grazing incidence angles. Nickel is one of the coatings commonly used for X-ray mirrors. The abrupt reflectivity variations and the dips correspond to the energies of the nickel atomic thresholds L (0.85 keV) and K (7.5 keV) for which the index tables predict a rapid change in absorption and refraction coefficients. Choosing an incidence angle provides a practical way of limiting the reflected spectral range. The energy cut-off of the

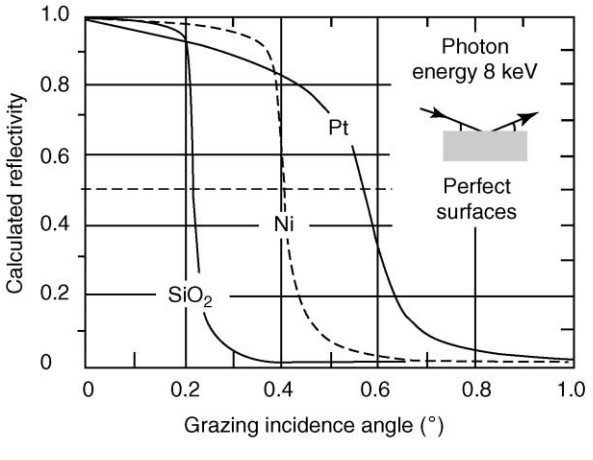

Figure 3 Examples of calculated reflectivity variations versus the incidence angle in the case of 8 keV X-rays on perfect platinum, nickel and glass surfaces.

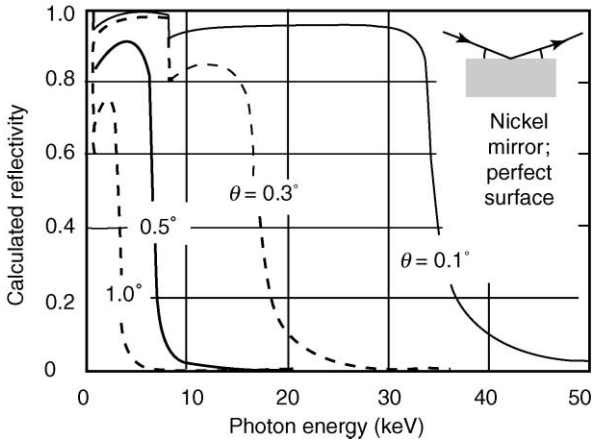

Figure 4 Calculated reflectivity variations versus photon energy, on a perfect nickel surface, for different incidence angles.

X-ray mirror acts as a filter for the higher-energy photons. That is effectively the method of suppressing the short wavelengths from an incident spectrum if they are not desired in an experiment.

When using highly divergent sources such as X-ray tubes, the restriction to operation at grazing incidence leads to a strong limitation of the collected solid angle, and thus of the beam size and angular aperture. These constraints are less stringent on highly collimated beams emitted by synchrotron sources. Thus, most synchrotron beam lines use total reflection optics in the form of curved mirrors, to refocus the beams and remove the undesired high X-ray energies. Recently, X-ray imaging optics, consisting of a series of parabolic and hyperbolic nested grazing incidence mirrors to increase the collected aperture, have been launched on satellites.

The reflectivity curves in Figures 3 and 4 are calculated for perfect surfaces. Real surfaces, even polished surfaces, have roughness created by defects over a large and continuous range of spatial frequencies, ranging from several centimeters down to the atomic scale. Coating a surface replicates the large period defects. Eventually new defects are added at near-atomic scale by nucleation of the coating material. Interferometric methods have been developed to study the range of defects from centimeter to micron spatial periods, whereas the atomic force microscope (AFM) is able to measure roughness from the micron down to the 0.1 nm scale. As waves are scattered most efficiently by asperities of a size comparable to their wavelength, scattering measurements are used in the X-ray region to probe defects of atomic scale. The prevalence of scattering explains why mirrors that reflect well in the visible range were disappointing when used in early X-ray experiments. The recent development of adaptive polishing methods has almost solved this problem.

The main effect of scattering by an optical system is not to decrease the number of photons coming out, but to modify their angular distribution. Scattering measurements are experimentally studied to test and evaluate the spatial defect distribution. In X-rays, one first characterizes the incident beam angular distribution in measuring its angular variation intensity after a scanning slit. Performing the same measurement after the optic, across the reflected beam in the case of mirrors, provides the modified angular distribution. From such a measurement, a few theoretical models adapted to the X-ray range can be used to deduce the mirror spatial defect distribution and so to check progress in polishing methods. The simplest

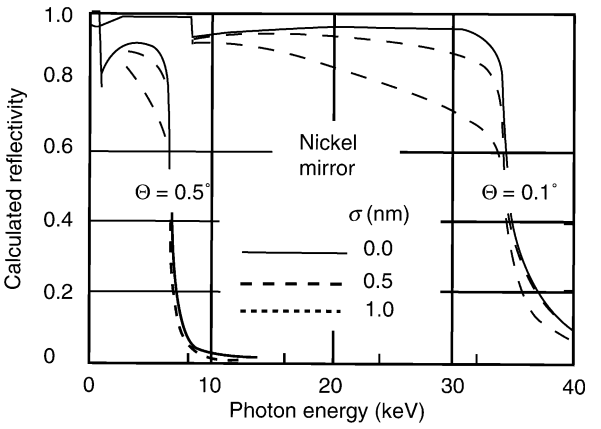

Figure 5 Calculated reflectivity variations versus photon energy, on nickel surfaces having different roughness, for different incidence angles.

model, coming from early crystal studies, is describing defects by a single parameter named roughness and denoted σ. Figure 5 shows an example of calculated reflectivity; on nickel surfaces versus photon energy and for increasing roughness; it shows how many photons have deviated from the symmetrical direction. Corresponding angular distributions can also be calculated.

The coating systems used for X-ray mirrors are material dependent. Deposition methods are similar to those used for visible optics coatings, but specific effort has been devoted to avoid nucleation growth to achieve uniform smooth layers. In general, one tries to give the evaporated particles, ions or clusters a kinetic energy lying within a specific range, which promotes mobility on the surface but is below the energy needed for implantation. In the case of electron beam deposition the energy distribution is thermal, but an auxiliary ionic bombardment can be used during deposition to provide the necessary energy to the previously deposited atomic layer (ion assisted deposition). For each material, the specific sputtering deposition and ionic bombardment conditions need to be carefully studied.

Until the 1970s, Bragg reflection by crystals and the total reflection phenomenon was the only way to reflect X-rays.

Multilayer X-Ray Mirrors

In the visible range, optics are frequently coated with stacks of dielectric multilayers obtained by periodic deposition of layers of two amorphous transparent materials. Such stacks are highly selective reflectors, or bandpass filters. They operate on the principle of

constructive interference between all the waves partially reflected by the successive interfaces. They can be regarded as analogous to two-dimensional Bragg reflectors, in which the interfaces play the same role as atomic planes in crystals. Hence the Bragg equation [1] can be applied, the relevant period d being the thickness of an individual bilayer, if the stack is truly periodic.

The concept of using artificially deposited stacks of thin films, of alternating high and low electron density, to reflect and diffract X-rays dates back at least to the 1920s. It was not until 1944, however, that DuMond and Youtz were able to demonstrate significant X-ray reflection from such an artificially layered structure. Their work used alternating layers of copper and gold, laid down by evaporation. Unfortunately these materials diffuse into one another, reducing the electron density contrast and hence the X-ray reflectivity. In 1967 Dinklage and Frerichs succeeded in making a structure of alternating layers of iron and magnesium, which do not interdiffuse quickly, and thus produced the first stable X-ray reflecting multilayer.

Since then, enormous progress has been made in the fabrication and application of such multilayer reflectors, principally because of the efforts of two pioneers. Troy Barbee, while at Stanford University, developed open loop sputtering methods for controlling the thickness of the many thin (~nm) layers required to make up such a stack, while Eberhard Spiller at IBM developed an evaporation method using *in situ* X-ray monitoring to achieve similar thickness control. Almost all of the many multilayer deposition systems in use around the world are based on one of these two methods.

As for the total reflection mirror, only recent progress in methods for deposition and controls has made this new kind of X-ray optics practical. Present applications range from the extreme ultra violet (30 eV) region to hard X-rays having energies of a few tens of keV.

Prediction of the reflectivity variations can be simulated by calculations on the same web site mentioned in the preceding section. Multilayer mirrors are based on interference, so the reflectivity coefficient and the width of the reflected bandpass are determined by the amount of absorption inside the stack and the partial reflectivity at each interface. The more efficient pairs of materials have the lowest X-ray absorption and the highest refractive index difference at the required energy. The selection of real materials is constrained by the coating conditions and the need to achieve smooth interfaces. In particular, a low interdiffusion coefficient between the successive material pairs is a requirement for temporal stability. Epitaxial deposition methods have been considered but no useful pair of materials has yet been found.

An example of a flourishing application is multilayer-coated normal incidence X-ray optics. Optical schemes used in the visible region for telescopes and microscopes have excellent optical performance and high numerical aperture but a very low reflectivity in the X-ray region if coated with a single layer. However, if coated with multilayers they can be used, providing that extremely low-roughness surfaces can be produced. The interface qualities of the deposited thin layers presently limit normal incidence optics to the soft X-ray energy range, typically below 300 eV so around the carbon edge. This corresponds to periods of about 2 nm, or a few atomic layers, and the resulting roughness seriously decreases the reflectivity.

Figure 6 is a reflectivity curve versus energy for a quasinormal incidence Mo/Si multilayer mirror optimized to get the first-order peak at 93 nm. On Mo/Si mirrors, precise control of the layer period and the quality of the interfaces allow the manufacture of mirrors with reflectivity only a few percent below the theoretical limit shown here. Considerable effort has been invested in such mirrors, with a view to applications to EUV projection lithography.

It is possible to build polarizer mirrors over the soft X-ray range. An incidence angle of 45° corresponds to the Brewster angle, because the X-ray index is close to unity. X-ray multilayer and semitransparent selective beam splitters now permit the development of Michelson interferometers for newly developed soft X-ray lasers.

Figure 7 is an example of a tungsten/carbon (W/C) reflectivity curve for a multilayer adapted to the 8 keV energy of Cu Kα, mentioned before. The curve

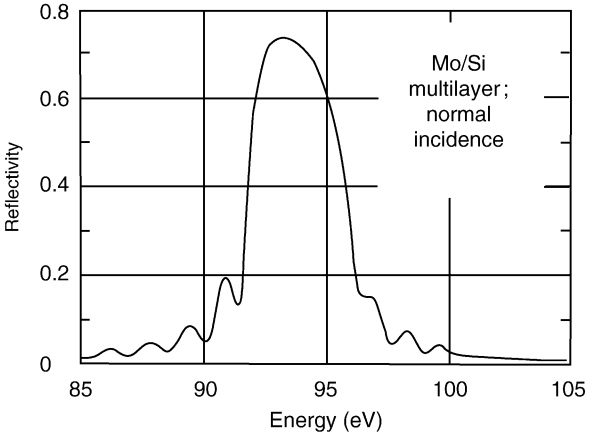

Figure 6 Calculated reflectivity versus incidence angle for a typical Mo/Si multilayer, optimized around 93 eV, under quasi-normal incidence.

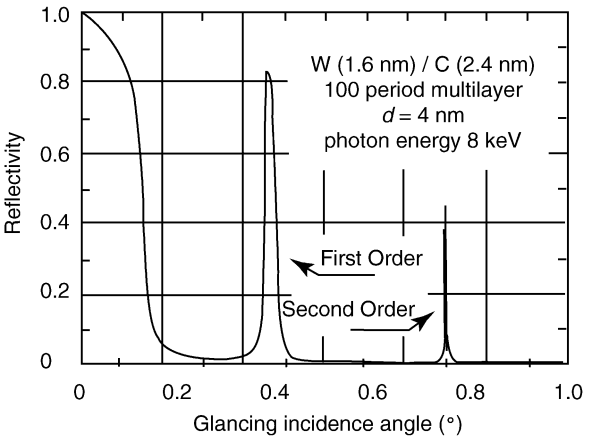

Figure 7 Calculated reflectivity versus incidence angle for a typical W/C multilayer adapted to reflect 8 keV photons.

of reflectivity versus glancing angle has been calculated from the total reflection range to the second-order peak. This kind of multilayer is being used in X-ray tubes to premonochromatize the beam and make it parallel. In such an application, the period of the coating is continuously graded laterally to satisfy locally the Bragg law at each point of the curved mirror.

As a final example of the new possibilities offered by X-ray multilayers, we mention the possibility of widening the reflected bandpass by varying continuously the period from the bottom to the top of the deposited stack. This is the equivalent of multilayer neutron 'supermirrors'. Such interference mirrors are usable at quite high X-ray energies, and give high reflectivity and a larger incidence angle than total reflection mirrors working over the same energy range.

The continuous fast development of coating technologies and X-ray multilayer applications can be followed through the proceedings of dedicated meetings at, for example, on a web site like http://PXRM.

Summary and Perspectives

After the discovery of X-rays in 1895, almost 25 years were necessary to understand their characteristics compared to the visible range. Only in 1923 did F. Holweck and R.A. Millikan demonstrate the continuity of electromagnetic radiation from X-rays to ultraviolet. The selective Bragg reflection by natural crystals is limited to energy commonly larger than about 2 keV photons. Below this energy the total reflection mirror was the only optical device to reflect and focus wavelengths shorter than the far UV until the development of adapted interferential mirrors.

During the 1960s, the EUV and X-UV ranges gained interest due to the spread of fusion research and in the astrophysics community studying the Sun and stars. For both communities, the continuum and the lines emitted at short wavelengths by ionized matter were a convenient tool to evaluate high plasma temperatures. At about the same time, the development of synchrotron radiation sources increased the need for X-ray optics. In addition, this last source offered the possibility to attempt new optical solutions with convenient intense and parallel beams from UV to X-rays. Finally, the concomitant progress in various microtechnologies afforded the necessary tools to produce new adapted optical devices for short wavelengths. At the present time, adapted optics are under development to take advantage of various applications from microscopy to interferometry over the very large electromagnetic energy X-ray range.

As a matter of fact, it is now possible to tailor a choice of mirror coatings adapted to each X-ray photon energy and application. Such coatings are specific because they must be optimized to take into account the inevitable absorption energy dependence.

Progress achieved in blank polishing and evaporation methods has led to efficient and high-quality X-ray mirrors even able to keep the spatial coherence of synchrotron sources. Such technological advances are also steps to master surfaces and interfaces at the atomic scale. They are now becoming applicable to the other spectral ranges and to various micro- and nanotechnologies.

Introduction

Since modern lightwave communication started in the 1970s, extensive efforts have been made to increase data rate and transmission distance. Recently, the bit rates for single-channel and multichannel systems have exceeded 40 and 2 Tb/s on single fibers respectively, for transoceanic distances. One revolutionary development in lightwave systems has been the deployment of erbium doped fiber amplifiers (EDFAs). These amplifiers facilitate transmission of an optical signal over long distances, by providing periodic analog-like amplification rather than digital-like regeneration. The wide bandwidth provided by EDFAs has made possible the increased use of wavelength division multiplexing (WDM) in which multiple lightwave signals, each having a different wavelength, are co-propagated on a single fiber. EDFAs and WDM techniques can enhance the lightwave system capacity, both in terms of obtainable transmission distance, and total number of data rates (see Figure 1).

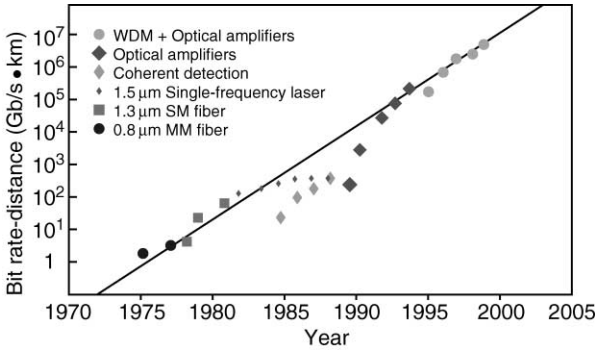

Figure 1 Bit rate product. Data from T. Li (private communication).

Optical Fiber

Most telecommunication fibers are made of silica, therefore following the attenuation of silica material. Figure 2 shows the silica fiber attenuation as a function of wavelength. The downward slope towards 1.6 μm and upward slope away from 1.6 μm, are the theoretical limits due to Rayleigh scattering and absorption of silica material, respectively. The absorption peak near 1.4 μm is due to water molecule absorption. There are two low attenuation regions: ~1.3 μm and 1.55 μm, both of which are used for communications in general, and some other wavelengths are also used for shorter distance communications. Figure 2 also shows the comparison between gain bandwidth of EDFA (~3 THz) and the low attenuation window around 1.55 μm (~25 THz). The typical values of attenuation at 1.3 μm and 1.55 μm for single-mode fiber (SMF) are ~0.35 dB/km, and 0.2 dB/km, respectively.

When an electromagnetic wave interacts with the bound electrons of a silica fiber, the medium response depends upon optical frequency (ω). This property, referred to as material dispersion, manifests itself through the frequency dependence of the refractive index $n(\omega)$. Fiber material dispersion plays a critical role in propagation of short optical pulses since different spectral components associated with the pulse travel at different speeds, given by $c/n(\omega)$. Consequently, the optical pulse at the output of the fiber is broadened in time. The commonly used system parameter is called the dispersion parameter D (the negative D value is called normal dispersion, and the positive D value is called anomalous dispersion), and is measured in ps/(nm·km); D for SMF is ~+17 ps/(nm · km) at 1.5 μm. However, because of dielectric waveguiding, the effective mode index is slightly lower than the material index $n(\omega)$, with the reduction itself being ω-dependent (waveguide dispersion). This results in a waveguide contribution that must be added to the material contribution to obtain the total dispersion (see Figure 3).

Generally, the waveguide contribution to dispersion D is to shift zero dispersion wavelength (λ_0) to longer wavelengths. Furthermore, the waveguiding can be tailored to shift the λ_0 from 1.3 μm to 1.5 μm, the wavelength at which the fiber has the minimum attenuation loss. The fiber having λ_0 in the neighborhood of 1.5 μm, is called dispersion-shifted fiber (DSF); D for DSF is usually between −2.5 and +2.5 ps/nm·km, at a wavelength of 1.5 μm. The typical dispersion parameter, D, as a function of a wavelength for both SMF and DSF, is shown in Figure 4.

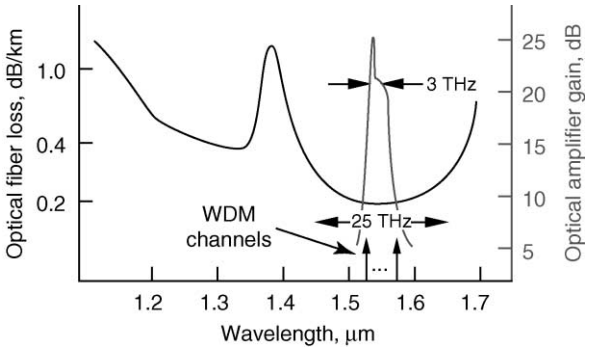

Figure 2 Silica fiber attenuation versus wavelength.

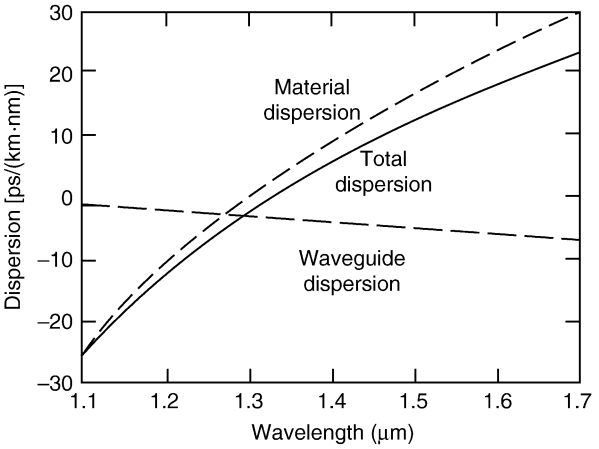

Figure 3 Total dispersion (D) and contribution of material dispersion and waveguide dispersion in conventional SMF.

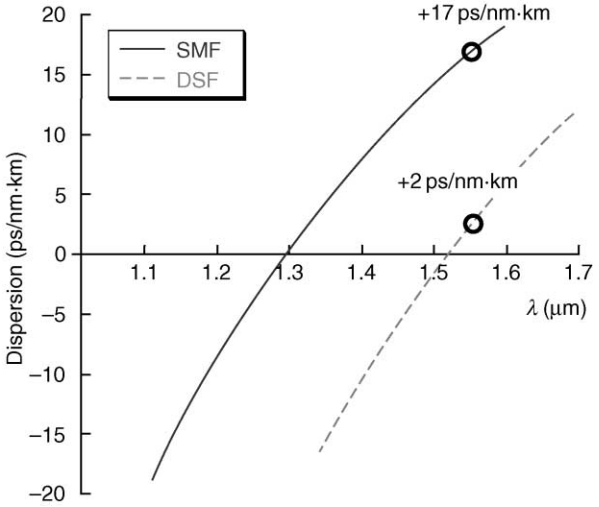

Figure 4 Dispersion versus wavelength for conventional SMF and DSF.

In addition to chromatic dispersion, optical fiber has another dispersion properties related to polarization. An optical wave of arbitrary polarization can be represented as the superposition of two orthogonally polarized modes. In an ideal fiber, these two modes are indistinguishable, and have the same propagation constants owing to the cylindrical symmetry of the waveguide. However, in real fibers there is some residual anisotropy due to unintentional circular asymmetry, usually caused by noncircular waveguide geometry or asymmetrical stress around the core, as shown in Figure 5.

In either case, the loss of circular symmetry gives rise to two distinct orthogonally-polarized modes with different propagation constants (differential phase velocity) responsible for polarization mode dispersion (PMD) in the fiber, and can be related to the difference in refractive indices (birefringence) between the two orthogonal polarization axes. The differential phase velocity indicated is accompanied by a difference in the group velocities for the two polarization modes, therefore the pulse at the end of the transmission fiber is broadened by this differential group delay (DGD). DGD is usually expressed in units of ps/km for a short length (1 m to 1 km) of birefringent fiber. However, DGD does not accumulate along a long fiber link in a linear fashion. Instead, because of random variations in the perturbations along a fiber span, the DGD in one section may either add to or subtract from another section of the fiber. As a result, average DGD in long fiber spans accumulates in a random-walk-like process that leads to a square root of transmission-length dependence. Therefore, average DGD is expressed in $ps/km^{1/2}$ in long fiber spans, referred to as the PMD of the fiber, and the typical PMD parameter has a value of 0.01 to 10 $ps/km^{1/2}$. Because of the many perturbations that act on a real-world fiber (e.g., temperature, vibration, etc.), transmission properties typically vary with time. Therefore, the PMD of the fiber link fluctuates randomly, thus causing random fluctuations in system performance.

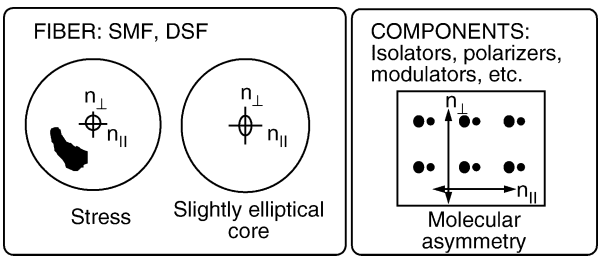

Figure 5 Origin of PMD.

It is well known that optical fibers show nonlinear behavior under conditions of high power and long interaction length. The power-times-distance products for amplified transmission systems can be large enough to make fiber nonlinear effects the dominant factor in the design of long-distance systems.

There are two categories of fundamental optical nonlinear effects: stimulated scattering effects and refractive index effects. Stimulated scattering effects arise from parametric interactions between light and acoustic or optical phonons in the fiber. Two nonlinear effects fall into this category: stimulated Brillouin scattering (SBS) and stimulated Raman scattering (SRS). The main difference between the two is that optical phonons participate in SRS, while acoustic phonons participate in SBS. In a simple quantum-mechanical picture, a photon of the incident field is annihilated to create a photon at a longer wavelength. The new photon is co-propagated and counter-propagated along the original signal in SRS, while counter-propagated in SBS. Refractive index effects are caused by modulation due to changes in light intensity. There are three types of refractive index effects: self-phase modulation (SPM), cross-phase modulation (XPM), and four-wave mixing (FWM). SPM introduces the change of optical phase by its own intensity, and, this leads to frequency chirp of the pulse, depending on the relative position from the peak. When this nonlinear frequency chirp interacts with the fiber dispersion, the pulse either broadens or compresses, depending on the sign and the amount of dispersion along the fiber. In XPM, the phase of the signal in one wavelength channel is modulated by the intensity fluctuation of the other wavelength channels. In a WDM system, XPM imposes far more damaging effects than SPM because XPM is stronger by a factor of two than SPM when the channel power is the same, and large number of WDM channels can contribute to XPM. FWM is the generation of modulation sideband at new frequencies, due to the phase modulation of channels between lights at different frequencies in multi-channel system. FWM causes penalties in a WDM system if the newly generated frequency is either equal to or close to the frequency of existing WDM channels.

Fiber nonlinearities impose significant degradation in optical transmission system, and limit the system on allowable number of channels, channel power, and channel spacing (see Figure 6). But, the effects can be well suppressed by carefully designing the fiber dispersion profile (i.e., dispersion map) in the transmission system, and controlling the optical launch power for each fiber span.

Communication Components

Distributed feedback laser (DFB) is widely used as a light source for metro, long-haul, and undersea applications, due to its narrow spectral width, and wavelength stability. Fabry–Perot (FP) lasers, and vertical cavity surface emitting lasers (VCSEL) are used for local area networks (LAN), and for access applications, because these are cheaper than DFB lasers. For an application, where the cost is the most important parameter with low data modulation speed, light-emitting diode (LED) is used as a light source.

In optical data modulation, the simplest and easiest technique is turning ON or OFF the laser, depending on the binary logic '1' or '0' (direct modulation). This type of modulation is simple and cheap compared to external modulation technique. But, its application is limited by the bandwidth of modulation, and the induced frequency chirp (i.e., difference in optical frequency at the turn ON state and just before the turn OFF state of laser) that limits the transmission distance. Two different types of external modulators are widely used for digital optical data transmission. Electro absorption modulator (EAM) uses the Franz–Keldysh effect, where it is observed that the wavelength of the optical absorption edge in a semiconductor is lengthened by applying an electric field. Electro-optic modulator (EOM) utilizes the linear electro-optic effect, called the Pokels effect, which changes the refractive index of the material caused by and proportional to an applied electric field, so therefore changes the phase of the optical signal. This phase change is used to modulate the intensity of a lightwave through a Mach–Zehnder (MZ) interferometer (see Figure 7). Because the Pockels effect exists only in crystal, lithium niobate crystal ($LiNbO_2$) or electro-optic polymers are used for EOM.

EDFA is a wideband optical amplifier that has merits in that: (i) erbium ions (Er^{3+}) emit light in the 1.55 μm loss-minimum band of optical fiber, (ii) a circular fiber-based amplifier is inherently compatible with a fiber optics system; (iii) it provides

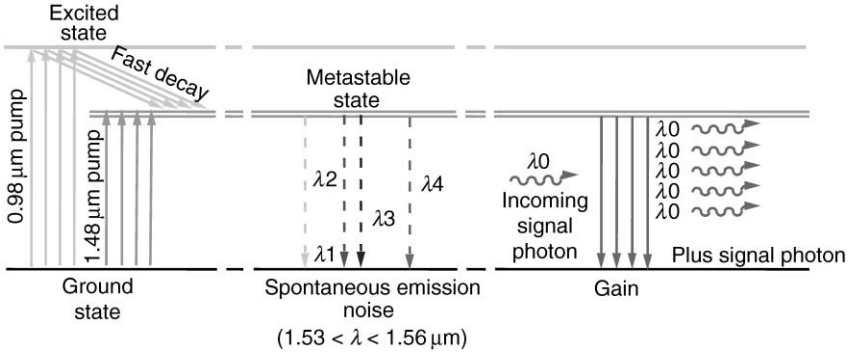

Figure 8 Energy level and transition diagram of EDFA. Reproduced with permission from Willner AE (1997) Mining the optical bandwidth for a terabit per second. *IEEE Spectrum* Apr.: 32–41. Copyright © 1997 IEEE.

amplification independent of bit-rate, modulation format, power, and wavelength; and (iv) it has low distortion and low noise during amplification. EDFA contains a gain medium (i.e., erbium-doped fiber) that must be inverted by a pump source. A signal initiates stimulated emission, resulting in gain, and spontaneous emission occurs naturally, which results in noise.

Figure 8 shows the energy level and transition diagram of EDFA. A 0.98 μm pump photon is absorbed and excites a carrier (Er^{3+} ions) into higher excited states, and the excited carrier decays rapidly to the first excited state that has a very long lifetime of ~10 ms (metastable state). In contrast, a 1.48 μm pump photon is absorbed and excites a carrier into a metastable state. This long metastable state is one of the key advantages of EDFA, and intersymbol distortion and interchannel crosstalk are negligible as a result of these slow dynamics. Depending on the external optical excitation signal, this carrier will decay in a stimulated or spontaneous fashion to the ground state and emit a photon. Both absorption and emission spectra have an associated bandwidth depending on the spread in wavelengths that can be absorbed or emitted from a given energy level. This is highly desirable because (i) a pump laser does not need to be an exact wavelength; and (ii) the signal may be at one of several wavelengths, especially in a WDM system. Figure 9 shows the bandwidth in the 1.48 μm absorption and 1.55 μm fluorescence spectrum of a typical erbium-doped amplifier.

When the noise characteristics of EDFA are considered, noise figure (NF) is an important parameter, which is defined by $NF \equiv SNR_{in}/SNR_{out}$, where SNR_{in} (SNR_{out}) is the electrical equivalent signal-to-noise ratio (SNR) of the optical wave going into (coming out) of the amplifier, if it were be detected. The typical value of NF in commercially-available EDFA is 4.5–6 dB. The importance of NF in optical communication systems is presented later in this chapter, when the required optical SNR (OSNR) for error-free optical data transmission is considered. Figure 10 shows an example of EDFA diagram.

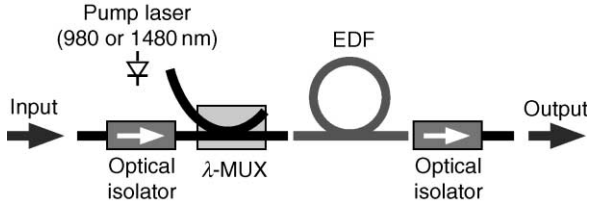

Figure 10 Typical EDFA diagram.

Recent development of EDFA in longer wavelength regimes or L-band (1570–1620 nm) has doubled the useful transmission bandwidth over the conventional band or C-band (1525–1265 nm). L-band gain of EDFA is generally achieved by proper arrangement of pump lasers through longer lengths of erbium-doped fiber than conventional C-band EDFA. Figure 11a shows the concept of wideband EDFA. The incoming

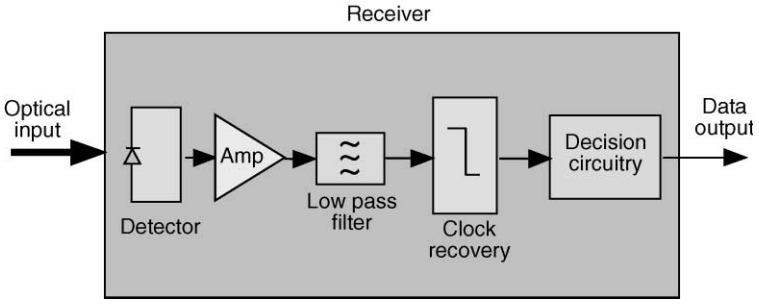

Figure 12 Block diagram of functions performed in advanced receiver packages.

WDM signal is split into two bands (C- and L-bands), amplified separately, and combined at the output. Gain and NF characteristics of this wideband EDFA is shown at Figure 11b.

Because SRS transfers the energy of a lower wavelength channel into the higher wavelength channel in the optical fiber, the transmission fiber itself can be used as a gain medium on specific channel (or channels) when the proper pump signal (or signals) are provided in the fiber. Even though Raman gain is much lower than the gain of EDFA (i.e., <0.1 dB gain/mW pump in Raman amplifier (RA) compared to a few dB gain/mW pump in EDFA), RA has several advantages over EDFA (i) RA has the capability to provide gain at any signal wavelengths, (ii) the amplification window is expandable by combining multipump wavelengths; and (iii) RA offers improved noise performance because the signal is amplified over transmission fiber (i.e., distributed amplifier). Especially improved noise performance increases system OSNR, which can be used to extend system reach or create more wavelength channels on the system. The Raman pumps are typically located ~100 nm shorter than the wavelength of the signal to be amplified, and a few 100s mW pump lasers are used to get a 10–15 dB gain.

In general, telecom receiver (RCVR) consists of photo diode (PD) with transimpedence amplifier (TIA), followed by limiting amplifier (LA) or automatic gain control amplifier (AGC), low pass filter, and clock data recovery circuit (CDR) (see Figure 12).

Vertically illuminated positive-intrinsic-negative (PIN) photodiode and avalanche photo diode (APD) are the most common PD that is used in RCVR. In PIN, incoming light is absorbed in the n^- (low doped or intrinsic) region and generates an electron-hole pair, which drifts to a depletion region and collected n^+ and p^+ regions, therefore generating electric current. APD is used for high-sensitivity detection up to 10 Gb/s. It is structured as absorption, grading, and multiplication layers. The multiplication layer of APD provides additional transit time delay compared to PIN, therefore the bandwidth of APD is smaller than PIN in general. TIA is a broadband low noise amplifier that is used to convert and amplify the weak current from PD to the desired output voltage. A low pass filter is used to suppress the noise and data distortion from high frequency components with a typical cut-off frequency ~0.7 bitrate. LA and AGC are amplifiers that limit the output voltage as a constant. LA is a nonlinear amplifier that makes a decision either to make logic '1' or '0' based on input voltage level, and limits output voltage as fixed values. AGC is a linear amplifier that limits the output voltage by adjusting the gain of the amplifier based on input voltage level. CDR consists of a phase lock loop (PLL) with a voltage controlled oscillator (VCO)

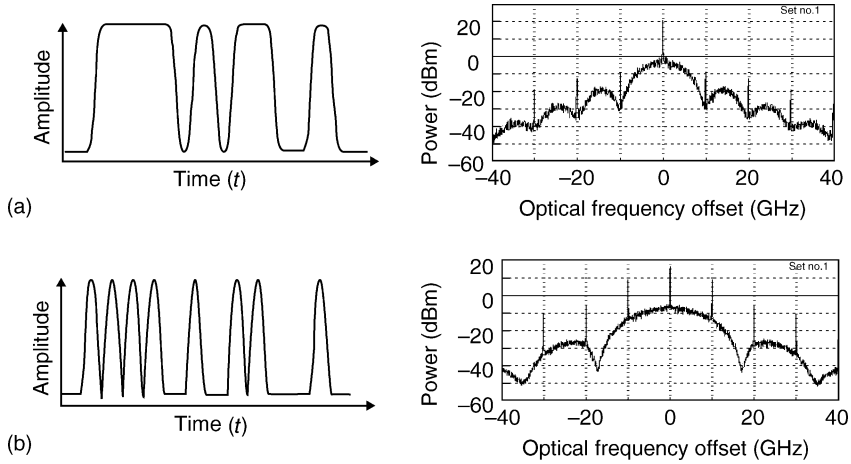

Figure 13 Amplitude modulation (a) nonreturn-to-zero (NRZ), and (b) return-to-zero (RZ).

and data flip-flop circuit. The PLL is used to synchronize the VCO to the incoming high-speed bit stream, therefore recovering the system clock. The recovered clock is used in D-FF to retime and regenerate the data.

Data Modulation Formats

In digital optical communications, numerous modulation formats have been developed and utilized, in order to achieve higher spectral efficiency (i.e., ratio of individual channel bit rate to dense WDM (DWDM) separation), and to improve system performance over fiber impairments. A simple amplitude modulation of lightwave is still the most widely used method for optical communication. The easiest amplitude modulation technique is to using a nonreturn-to-zero (NRZ) format. Figure 13a shows an example of NRZ binary sequence in time domain, and the corresponding frequency domain spectrum. In NRZ, data '1' and '0' correspond to the ON and OFF state of a lightwave transmitter, respectively, occupying entire bit time (i.e., binary symbol time). When the ON or OFF state of a lightwave transmitter does not occupy the entire bit time (T_B) (i.e., when the data pulse duration (T_d) is less then (T_B), it is called the return-to-zero (RZ). Figure 13b shows a binary sequence of RZ, and its frequency spectrum when $T_d \approx 0.5\, T_B$. The Fourier transform of the square wave is the Sinc function. Therefore, the frequency spectrum of an ideal NRZ and RZ follows the pattern of a Sinc square function. Note that the first null of frequency spectrum of RZ is about twice as high as the null of NRZ.

Even though NRZ is better in spectral efficiency than RZ, RZ has an advantage over NRZ in tolerance of fiber impairments. Figure 14 shows an example on eye closure penalty comparison between NRZ and RZ data formats at a 16-channel WDM system at 40 Gb/s data rate. It is clearly seen that the penalty of RZ is much less severe than the penalty of NRZ, as the transmission distance increases. (Note, nonlinearities and dispersion increases as the transmission distance increases.)

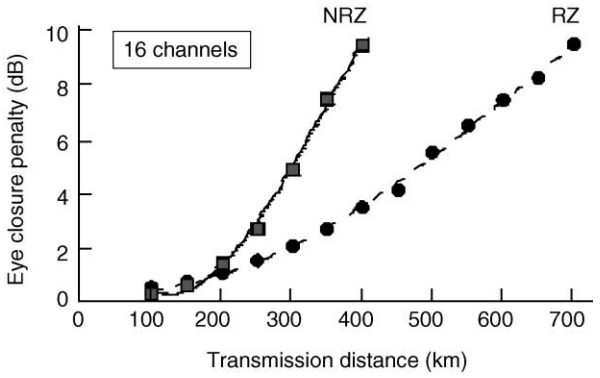

Figure 14 System performance of different modulation format (NRZ vs. RZ).

There has been much effort to increase the spectral efficiency, to improve the system performance over fiber impairments, or to achieve both simultaneously. Figure 15 shows some of examples of these. Chirped RZ (CRZ) is the modulation format inducing frequency chirp on conventional RZ. CRZ is robust on fiber impairment at the cost of losing spectral efficiency. In carrier-suppressed RZ (CS-RZ), a strong un-modulated optical carrier is removed from conventional RZ, therefore suppressing the nonlinear effects. Duo-binary is a three-level signal modulation format generated by a series of delay and added

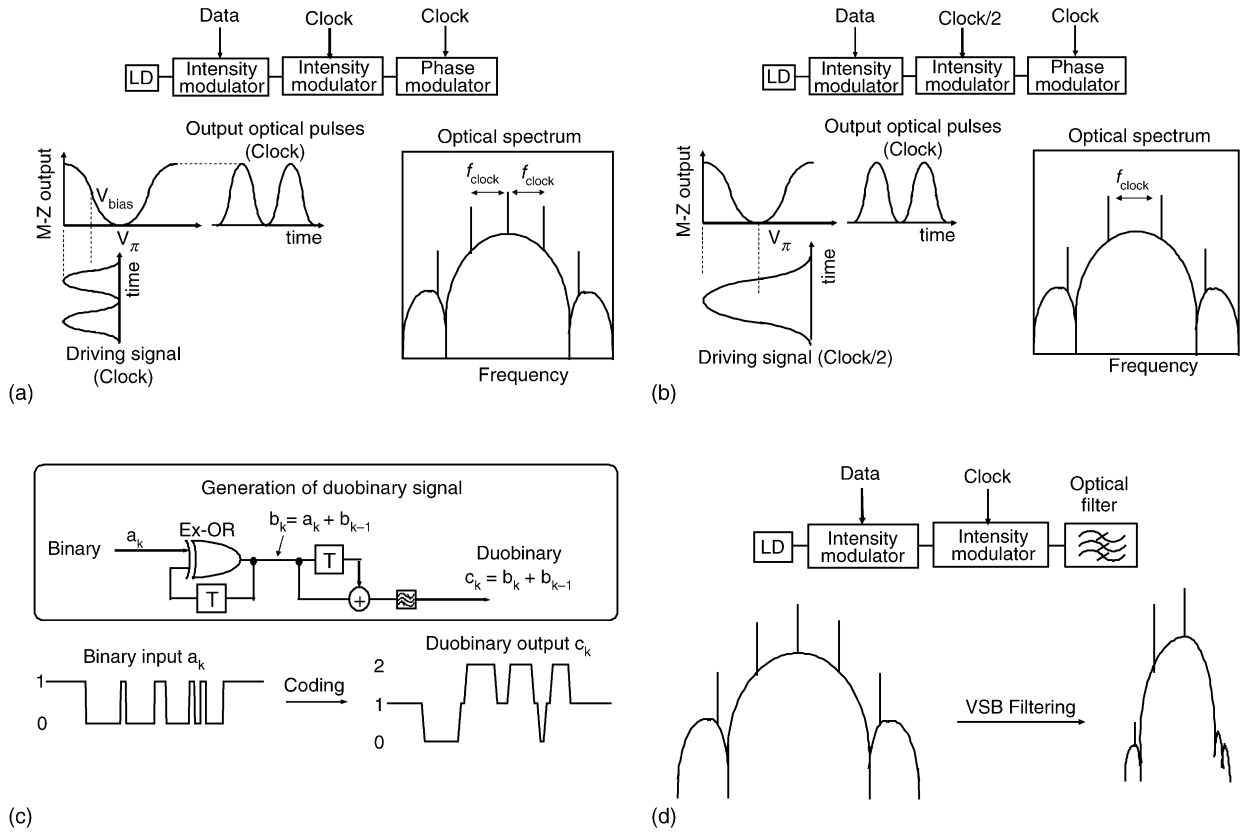

Figure 15 Examples of bandwidth efficient modulation formats. (a) Chirped RZ (CRZ) generation, (b) carrier suppressed-RZ (CS-RZ) generation, (c) duo-binary generation, and (d) vestigial single side band (VSB) RZ generation.

circuits in the transmitter. The advantage of duo-binary is that its bandwidth is reduced to one half of conventional NRZ, therefore having enhanced spectral efficiency, and has a high tolerance in chromatic dispersion, and suppression of fiber nonlinearites.

Single-sideband (SSB) or vestigial singleside band (VSB) can be generated into either NRZ or RZ, by either optically utilizing optical filtering with a sharp cut-off filter, or electrically applying tapped-delay-line filter approximation on both amplitude and phase modulators. SSB (or VSB) has about a two times higher spectral efficiency and higher tolerance on chromatic dispersion than conventional modulation formats.

Data Multiplexing

At their most basic, optical networks can imitate electrical networks in which time division multiplexing (TDM) is overwhelmingly used for digital data transmission. A fiber can carry many time-multiplexed channels, in which each channel can transmit its data in an assigned time slot. A typical TDM link is shown in Figure 16, in which N

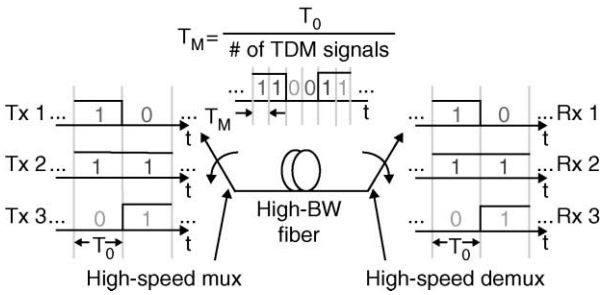

Figure 16 Concept of bit-interleaving TDM.

transmitters are sequentially polled by a fast multiplexer to transmit their data. The time-multiplexed data are sequentially and rapidly demultiplexed at the receiving node.

Time multiplexing and demultiplexing functions can be performed either electrically with an electrical time (DE)MUX switch and an optical transmitter/receiver, or optically with multiple optical transmitters/receivers and an optical time (DE)MUX switch. The major advantage of TDM is that there is no output–port contention problem (each data bit occupies its own time slot and there is only a single high-speed signal present at any given

instant). The disadvantage of TDM is that the scheme requires a ultra-high-speed switching component if the individual signals are themselves high-speed and if there are many users.

In WDM, multiple wavelength channels are transmitted through a single fiber, therefore enabling the fiber to carry more throughput. By using wavelength-selective devices for the ON and OFF ramps, independent signal routing also can be accomplished. Figure 17a shows a simple point-to-point WDM system in which several channels are multiplexed at one node, the combined signals transmitted across a distance of fiber, and the channels demultiplexed at a destination node. As shown in Figure 17b, the wavelength becomes the signature address for either the transmitter or the receivers, and the wavelength will determine the routing path through an optical network.

Many interesting challenges face the eventual implementation of WDM systems and networks. Several of these challenges involve the control and management of the data through this novel high-speed network. Figure 18 shows a small subset of critical component technologies typically required for a WDM system, including multiple-wavelength transmitters, multiport star couplers, passive and active wavelength routers, EDFAs, and tunable optical filters.

Some generic goals that a WDM-device technologist aims to achieve include; large wavelength tuning range; multi-user capability; wavelength selectivity and repeatability; low cross-talk; high extinction ratio; minimum excess losses; fast wavelength tunability; high-speed modulation bandwidth; low residual chirp; high finesse; low noise; robustness; high yield; potential low cost. Depending on system requirements, device availability and cost, WDM technologies divide into two; course-WDM (CWDM) and dense-WDM DWDM. Figure 19 shows the wavelength allocation for CWDM and

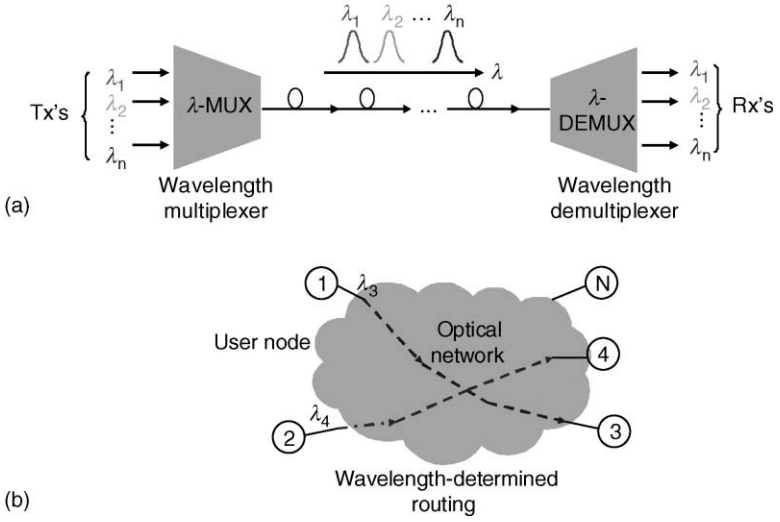

Figure 17 (a) A simple point-to-point WDM transmission system; (b) a generic multiuser network in which the communication links and routing paths are determined by the wavelengths used within the optical switching fabric.

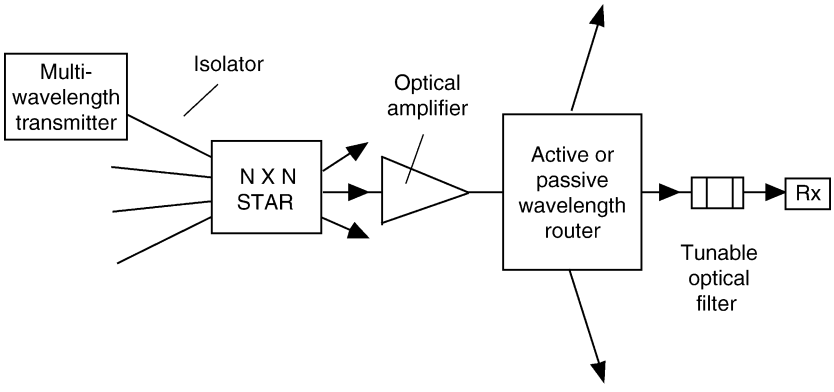

Figure 18 Schematic of a small subset of enabling device technologies for a WDM system.

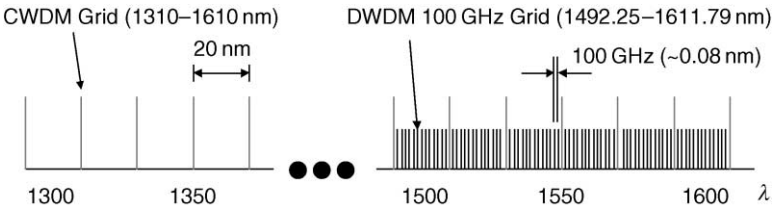

Figure 19 WDM wavelength allocation.

DWDM. CWDM technology uses an International Telecommunication Union (ITU) standard 20 nm spacing between the wavelengths from 1310 nm to 1610 nm. Also DWDM technology uses an ITU standard 100 GHz or 200 GHz between wavelengths, arranged in several bands at around 1500–1600 nm.

Dispersion Management and Compensation

As mentioned previously, chromatic dispersion is one of the most basic characteristics of fiber, although it is possible to manufacture fiber that induces zero chromatic dispersion. But such fiber is incompatible with the deployment of a WDM system since harmful nonlinear effects are generated, therefore chromatic dispersion must exist, and must be compensated for. The effect of chromatic dispersion is cumulative and increases quadratically with the data rate (see Figure 20).

The quadratic dependence of dispersion with the data rate is a result of two effects. First, a doubling of the data rate will double the Fourier-transformed frequency spectrum of the signal, thereby doubling the effect of dispersion. Second, the same doubling of the data rate makes the data pulse only half as long in time and therefore twice as sensitive to temporal spreading due to dispersion. The conventional wisdom for the maximum distance over which data can be transmitted is to consider a broadening of the pulse equal to the bit time period. For a bit period B, a dispersion value D and a spectral width $\Delta\lambda$, the dispersion-limited distance is given by $L_D = 1/(D{\cdot}B{\cdot}\Delta\lambda)$ (see Figure 21).

In theory, compensation of chromatic dispersion for high-speed or long-distance systems can be fixed in value if each link's dispersion value is known. A simple yet elegant solution is to create a dispersion 'map', in which the designer of a transmission link alternates elements that produce positive and then negative dispersion (see Figure 22). This is a very powerful concept: at each point along the fiber the dispersion has some nonzero value, effectively

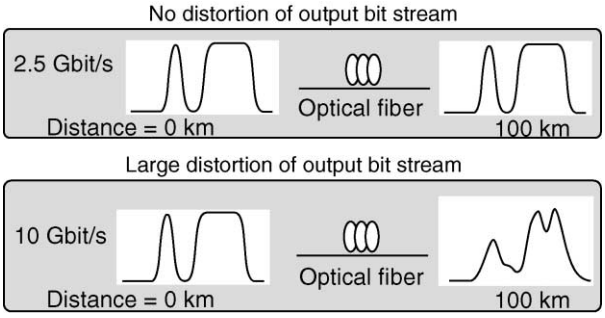

Figure 20 Pulse broadening at two different data rates (2.5 Gbit/s, and 10 Gbit/s) as a result of quadratic nature of chromatic dispersion.

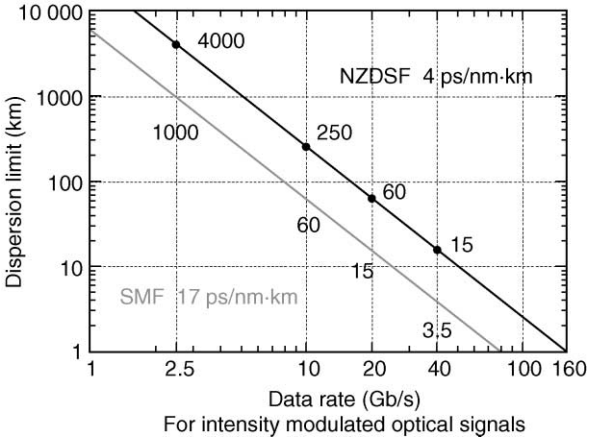

Figure 21 Dispersion-limited (uncompensated) transmission distance in single-mode fiber (SMF) as a function of data rate for intensity-modulated optical signals. Courtesy of L.D. Garrett.

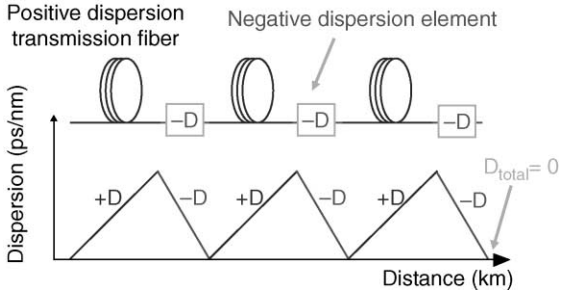

Figure 22 Typical static management of chromatic dispersion.

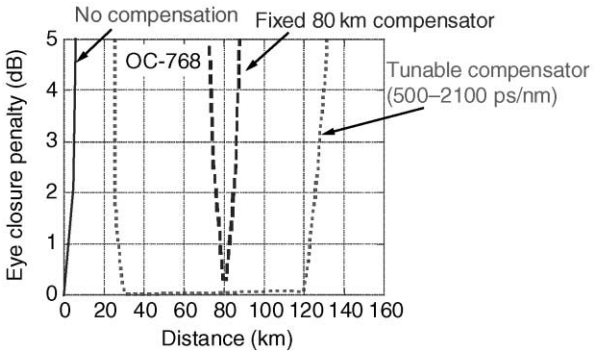

Figure 23 Effect of tunable compensation at 40 Gb/s (OC-768); it allows a wide range of transmission distance. On the contrary, the 80 km fixed compensator allows only small range of transmission around 80 km.

eliminating FWM and XPM, but the total accumulated dispersion at the end of the fiber link is zero, so that minimal pulse broadening is induced. The specific system design, as to the periodicity of management, depends on several variables, but a typical number for SMF as the embedded base is a compensation at every 80 km in a 10 Gb/s system. Dispersion-compensating fiber (DCF) has been generally used as a dispersion compensating element.

However, there are several important aspects of optical systems and networks that make tunable dispersion compensation solutions attractive, including: (i) it significantly reduces the inventory of different required types of compensation modules; (ii) it tunes to adapt to routing path changes in a reconfigurable network, (iii) it tracks dynamic changes in dispersion due to environment, and (iv) it achieves a high degree of accuracy necessary for 40 Gb/s channels (see Figure 23).

One brute-force method to achieve tunable dispersion compensation is to build a module with optical switches used to add or remove sections of fixed DCF to achieve a discrete set of dispersion compensation. Many other elegant, yet viable, approaches have been developed for tunable dispersion compensation, and these approaches include linearly chirped FBG with nonuniform heating, nonlinearly chirped Fiber Bragg grating (FBG) with a simple mechanical stretcher, virtually imaged phase array, electronic tap delay filter with weights, multiple stage all pass filter, etc.

System Performance Parameters

An eye diagram provides a simple and useful tool to visualize intersymbol interference between data bits. Figure 24a shows a perfect eye diagram. A square bit stream (i.e., series of symbol '1's and '0's) is sliced into sub-bit stream with predetermined eye intervals (i.e., several bit periods), and displayed through bit analyzing equipment (e.g., digital channel analyzer), overlapping the sliced sub-bit stream in order to obtain the eye diagram. When a perfect transmitter and receiver (i.e., infinite receiver bandwidth with zero noise characteristics and jitter), and a perfect transmission media (i.e., no dispersion and nonlinearites) are used, the received eye diagram is shaped as a perfect rectangular. In reality, the transmitter and receiver have a limited bandwidth with noise and jitter, and the transmission media (i.e., optical fiber) has dispersion and nonlinearites. Therefore, the eye diagram deviates from the perfect rectangular shape. Figure 24b shows the eye diagram close to a real situation. The shape of the eye is generally broadened and distorted (i.e., eye is closed) due to limited bandwidth and fiber impairments, and noise and timing jitter are added onto this broadened and distorted eye shape.

The Q-factor (q) is also an important system parameter widely used in long-distance optical transmission system design. It is defined as the electrical signal-to-noise ratio before the decision circuit at receiver. The Q-factor is directly related to bit-error-rate (BER: the percentage of bits that has an error relative to total number of bits received in a specific time) by: $\mathrm{BER} = 0.5 \cdot \mathrm{erfc}(q/2^{0.5})$, where $\mathrm{erfc}(x)$ is the complementary error function. The Q-factor is an unitless linear ratio, and is express in dB by $20 \cdot \log(q)$. As a conventional relationship, Q-factor of 15.6 dB (i.e., linear ratio 6) is required to achieve $\mathrm{BER} = 10^{-9}$. Figure 25 shows the relationship of eye diagram, Q-factor, and BER.

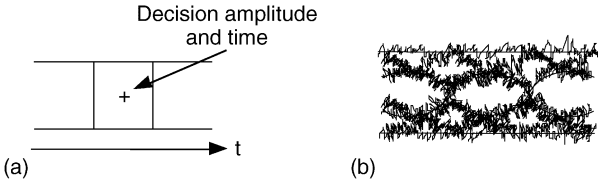

Figure 24 (a) A perfect square eye diagram, (b) a closed eye diagram due to bandwidth, fiber impairments, noise, and timing jitter.

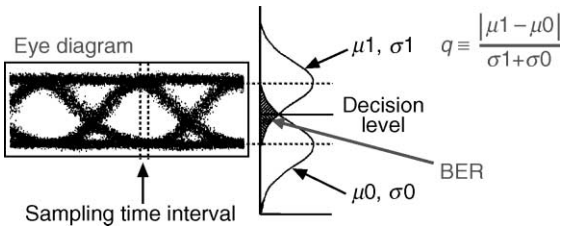

Figure 25 The relationship of eye diagram, Q-factor, and BER ($\mu 1$, $\mu 2$: mean levels of logic '1' and '0', $\sigma 1$, $\sigma 2$: standard deviation of logic '1' and '0').

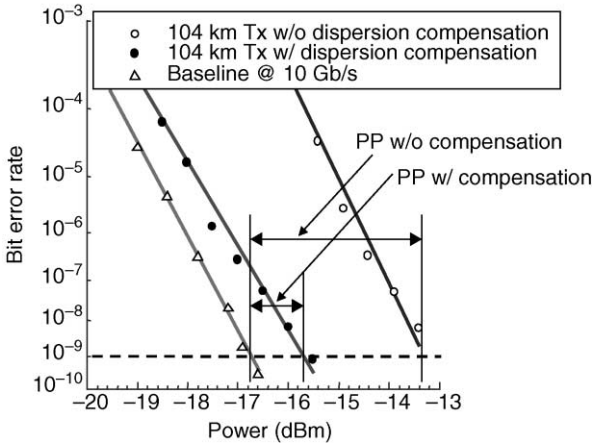

Figure 26 BER curve and power penalty.

Power penalty (PP) is one of the most important system parameters, and is defined as the received optical power difference in dB with and without signal impairments at a specified BER (conventionally 10^{-9}), from measured BER versus optical power curve. Therefore, 1 dB PP means that a system with signal impairments requires 1 dB more optical power at the receiver in order to achieve the same BER performance compared to the system without signal impairments. Figure 26 shows the typical BER curve as a function of received optical power and PP. Note that PP reduces from ~3.5 dB to ~1 dB with dispersion compensation.

In long-haul and undersea transmission system with many EDFA chains, OSNR is an important system parameter to design and characterize the optical transport system. OSNR is defined as the ratio of the power of signal channel to the power of ASE in a specified optical bandwidth (conventionally 0.1 nm). The OSNR (in dB) of a signal channel at the end of the system is approximated by: $\text{OSNR (dB)} = 58 + P_{\text{out}} - L_{\text{span}} - \text{NF} - 10\log(N_{\text{amp}})$, when the system has N_{amp} fiber spans, span loss L_{span} (in dB) followed by an optical amplifier with output power P_{out} (in dBm) per channel launched into the span and noise figure (NF) (in dB). As an example, a typical OSNR requirement for $\text{BER} = 10^{-9}$ is about 17 dB at 10 Gb/s data rate. The required OSNR should be increased by 6 dB when the data rate is increased by a factor of 4. Improving the amplifier's NF can increase OSNR, and the improved OSNR can be used to increase the system reach, reducing the channel power in order to suppress the nonlinearities, etc.

Introduction

This article describes the development of optical fiber communication systems. After describing some of the motivations for using optical fiber communications and the advantages of this technology, the key milestones and the principal people involved in developing optical fibers and compatible light sources are presented. Following this, the article looks at the evolution of fielded systems and the use of optical fiber links in undersea applications.

One of the principal needs of people since antiquity has been to communicate. This need created interests in devising communication systems for sending messages from one distant place to another. Many forms of such systems have appeared over the years. The basic motivations behind each new one were either to improve the transmission fidelity, to increase the data rate so that more information could

be sent, or to increase the transmission distance between relay stations. Prior to the nineteenth century, all communication systems operated at a very low information rate and involved only optical or acoustical means, such as signal lamps or horns. One of the earliest known optical transmission links, for example, was the use of a fire signal by the Greeks in the eighth century BC for sending alarms, calls for help, or announcements of special events.

The invention of the telegraph by Samuel FB Morse in 1838 ushered in the era of electrical communications. In the ensuing years an increasingly larger portion of the electromagnetic spectrum, shown in Figure 1, was utilized for the conveying of information from one place to another. The reason for this trend is that, in electrical systems, the data usually are transferred over the communication channel by superimposing the information onto a sinusoidally varying electromagnetic wave, which is known as the carrier. When reaching its destination the information is removed from the carrier wave and processed as desired. Since the amount of information that can be transmitted is related directly to the frequency range over which the carrier operates, increasing the carrier frequency theoretically increases the available transmission bandwidth and, consequently, provides a larger information capacity. Thus the trend in electrical communication system developments was to employ progressively higher frequencies (shorter wavelengths), which offer corresponding increases in bandwidth or information capacity. This activity led to the birth of communication mechanisms such as radio, television, microwave, and satellite links.

Another important portion of the electromagnetic spectrum encompasses the optical region shown in Figure 1. In contrast to electrical communications, transmission of information in an optical format is carried out, not by frequency modulation of the carrier but by varying the intensity of the optical power. Similar to the radio-frequency spectrum, two classes of transmission medium can be used: an atmospheric channel or a guided-wave channel. Whereas transmission of optical signals through the atmosphere was done thousands of years ago, the use of a guided-wave optical channel such as an optical fiber is a fairly recent application.

Fiber optic communication systems have a number of inherent advantages over their copper-based and radio-transmission counterparts. Fiber optic cable can transmit at a higher capacity, thereby reducing the number of physical lines and the amount of equipment needed for a given transmission span. The lower weight and smaller size of optical fibers offer a distinct advantage over heavy, bulky copper cables in crowded underground cable ducts, in ceiling-mounted cable trays, and in mobile platforms such as aircraft and ships. Their dielectric composition is an especially important feature of optical fibers, since this ensures freedom from electromagnetic interference between adjacent fibers, eliminates ground loops, and results in extremely low fiber-to-fiber crosstalk. In addition, an optical fiber affords a high degree of data security since the optical signal is well confined within the optical waveguide.

Optical Fiber Development

Since an atmospheric channel requires a line-of-sight link and because it can be adversely affected by weather conditions, a guided-wave channel is the preferred approach in most cases for communication system applications. A challenge in using an optical fiber channel is to have a flexible, low-loss medium that transfers the optical signal over long distances

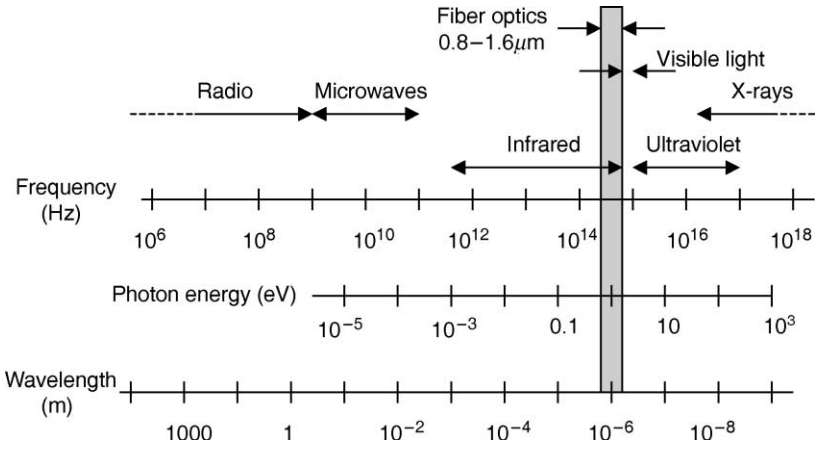

Figure 1 Electromagnetic spectrum for electrical and optical communications.

without significant attenuation and distortion. Glass is an obvious material for such applications. The earliest known glass was made around 2500 BC and glass already was drawn into fibers during the time of the Roman Empire. However, such glasses have very high attenuations and thus are not suitable for communication applications. One of the first known attempts of using optical fibers for communication purposes was a demonstration in 1930 by Heinrich Lamm of image transmission through a short bundle of optical fibers for potential medical imaging. However, no further work was done beyond the demonstration phase since the technology for producing reasonably low-loss fibers with good light confinement was not yet mature.

Further work and experiments continued on using optical fibers for image transmission and by 1960 glass-clad fibers had attenuations of about one decibel per meter. This attenuation allowed fibers to be used for medical imaging, but it was still much too high for communications. Optical fibers had attracted the attention of researchers at that time, because they were analogous in theory to plastic dielectric waveguides used in certain microwave applications. In 1961, Elias Snitzer demonstrated this similarity by drawing fibers with cores so small they carried light in only one waveguide mode. He published a classic theoretical description of single-mode fibers in May 1961. However, to be useful for communication systems, optical fibers would need to have a loss of no more than 10 or 20 decibels per kilometer.

As a reminder, decibels measure the ratio of the output power to the input power on a logarithmic scale. The abbreviation for a decibel is 'dB.' The power ratio in decibels is given by the expression '10 log (power out/power in).' As an example, a power loss of 20 dB over a 1-km distance in an optical fiber means that only 1% of the light injected into the fiber comes out of the other end. Table 1 gives some typical examples of various power ratios and their decibel equivalents.

In the early 1960s Charles Kao pursued the idea of using a clad glass fiber for an optical waveguide, building on optical waveguide research being done at the Standard Telecommunication Laboratories in England. After he and George Hockman painstakingly examined the transparency properties of various types of glass, Kao made a prediction, in 1966, that losses of no more than 20 dB/km were possible in optical fibers. In July 1966, Kao and Hockman presented a detailed analysis for achieving such a loss level. Kao then went on to actively advocate and promote the prospects of fiber communications, which generated interest in laboratories around the world to reduce fiber loss. It took four years to reach Kao's predicted goal of 20 dB/km, and the final solution was different from what many had expected.

To understand the process of making a fiber, consider the schematic of a typical fiber structure shown in Figure 2. A fiber consists of a solid dielectric (glass or plastic) cylinder of refractive index n_1 called the core. This is surrounded by a dielectric cladding which has a refractive index n_2, that is less than n_1, in order to achieve light guiding in the fiber. This structure is then encapsulated by a buffer coating to protect the fiber from abrasion and outside contaminants. The first step in making a fiber is to form the clear glass rod or tube called a preform. This normally is done by a vapor-phase oxidation process. The preform has two distinct regions that correspond to the core and cladding of the eventual fiber. Fibers are made from the preform by precision feeding it into a circular furnace that softens the end of the preform to the point where it can be drawn into a very thin filament which becomes the optical fiber.

Most researchers had tried to purify the compound glasses used for standard optics, which are easy to melt and draw into fibers. A different approach was taken at the Corning Glass Works where Robert Maurer, Donald Keck, and Peter Schultz started with fused silica. This material can be made extremely pure, but has a high melting point and a low refractive index. Silica has the approximate attenuation versus wavelength characteristic shown in Figure 3. Note that for early silica fibers there are regions of low attenuation around 850, 1310, and 1550 nm, which the literature refers to as the first, second, and third windows, respectively. The large attenuation spikes in the 1000- and 1400-nm spectral

regions are due to absorption by residual water molecules in the glass. Although ultra-pure material processing techniques can eliminate these spikes to produce what are known as full-spectrum or low-water-peak fibers, most installed fibers still have a relatively large attenuation between 1350 and 1500 nm.

Note that since the attenuation spikes no longer are present in various types of fibers, the idea of operating windows has been replaced by the concept of spectral bands. The International Telecommunications Union (ITU) has designated six spectral bands for use in intermediate-range and long-distance optical fiber communications within the 1260 to 1675-nm region. The regions, which are known by the letters O, E, S, C, L, and U, are defined as follows:

- Original Band (O-Band): 1260 to 1360 nm
- Extended Band (E-Band): 1360 to 1460 nm
- Short Band (S-Band): 1460 to 1530 nm
- Conventional Band (C-Band): 1530 to 1565 nm
- Long Band (L-Band): 1565 to 1625 nm
- Ultra-long Band (U-Band): 1625 to 1675 nm

The Corning team made cylindrical preforms by depositing purified materials from the vapor phase. To produce a fiber that has light guiding properties they carefully added controlled trace levels of titanium to the core to make its refractive index slightly higher than that of the cladding without raising the attenuation significantly. In September 1970, they announced the fabrication of single-mode fibers with an attenuation of 17 dB/km at the 633-nm helium-neon line. The fibers were fragile, but independent tests at the British Post Office Research Laboratories facility in Martlesham Heath, England confirmed the low loss.

This dramatic breakthrough was the first among the many developments that opened the door to fiber optic communications. The ensuing years saw further reductions in optical fiber attenuations. By mid-1972, Maurer, Keck, and Schultz at Corning had made multimode germania-doped fibers with a 4-dB/km loss and much greater strength than the earlier brittle titania-doped fibers. In order to couple a sufficient amount of optical power into a fiber, early applications used multimode fibers with a refractive-index gradient between core and cladding of around 2% and core diameters of 50 or 62.5 micrometers.

Single-mode fibers have much smaller core diameters on the order of 9 micrometers in order to allow only one propagation mode. This type of fiber has a much higher transmission capacity since the effect of modal dispersion is eliminated. The first single-mode fibers were optimized to have a zero dispersion value at 1310 nm, since the silica material used at that time exhibited a low loss within a spectral band around this wavelength. Figure 4 shows the dispersion characteristic of this type of fiber as a function of wavelength in the S-, C-, and L-bands. As a result of its widespread use in early single-mode transmission systems, this fiber design has been standardized by the International Telecommunication Union (ITU-T) under the designation Recommendation G.652.

Standard G.652 silica fibers provide the lowest attenuation at 1550 nm, but have a much larger signal

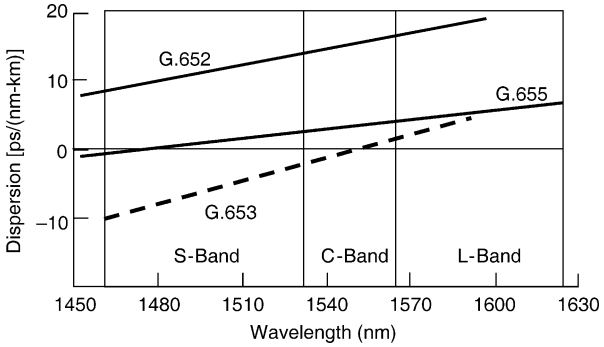

Figure 4 Dispersion characteristics of three types of standard optical fibers.

dispersion at this wavelength than at 1310 nm. Since system designers wanted to use fibers at a 1550-nm wavelength, in order to transmit high-speed data over longer distances, fiber manufacturers overcame the larger signal dispersion limitation by creating the so-called dispersion-shifted fibers. This was done through a clever manipulation of the core and cladding designs that allowed the zero-dispersion point to shift to longer wavelengths. In particular, the ITU-T created a specification for operation at 1550 nm which is designated as recommendation G.653. Figure 4 also shows the dispersion characteristic of this type of fiber as a function of wavelength.

Although the G.652 and G.653 fibers work well for single-wavelength operation, a different type of fiber, having non-zero dispersion within a broad spectral range, is needed when implementing systems that use many independent light sources simultaneously within a particular wavelength band. This led to the specification of the non-zero dispersion shifted fiber (NZDSF) in the ITU-T Recommendation G.655 that are designated to operate around 1550 nm. The main purpose of having a positive dispersion value over the entire operating spectrum is to mitigate a nonlinear optical effect called four-wave mixing (FWM), which is analogous to intermodulation distortion in electrical systems. Figure 4 shows the dispersion characteristic of the G.655 fiber in the S-, C-, and L-bands.

Light Sources

The fiber by itself is not practical unless there is a compatible optical source for launching light signals into it. The most suitable device for this is a semiconductor light-emitting diode (LED) or a laser diode. In the 1960s, a great deal of effort took place to achieve laser action in pn-junction diodes. The early devices were GaAs and GaAsP lasers that operated at a temperature of 77 K, emitted at a wavelength around 850 nm, and had high lasing threshold current densities. To make devices that were more application-friendly by operating at room temperature, structures consisting of sandwiched layers of AlGaAs and GaAs were investigated. Finally, in 1970, researchers at Bell Laboratories and a team at the Ioffe Physical Institute in Leningrad made the first semiconductor diode lasers based on a layered AlGaAs/GaAs/AlGaAs structure that were able to emit continuous-wave light in the 850-nm region at room temperature.

Major improvements in laser diode performance and reliability followed this achievement during the next decade. In addition, around 1976, room-temperature laser diodes operating at longer wavelengths, in the 1100 to 1600-nm region, started to appear. Of particular interest were GaInAsP/InP-based laser diodes emitting in the 1310-nm and 1550-nm low-loss windows of optical fibers. The progressive development of ever-improving devices during the 1980s and 1990s, included single-frequency emission with narrow linewidths under continuous operation, low levels of chirp under direct modulation, high output power, and the ability to tune specially constructed laser diodes over a wavelength range of up to 30 nm.

Fielded Systems

The bit rate-distance product $B \times L$, where B is the transmission bit rate and L is the repeater spacing, measures the transmission capacity of optical fiber links. Since the inception of optical fiber communications in the mid-1970s, the link transmission capacity has experienced a tenfold increase every four years. Several major technology advances spurred this growth. Among the technology developments are laser diodes emitting over an extremely narrow spectral band, optical amplifiers, fibers with low losses and low dispersions, and the concepts of wavelength division multiplexing.

Some of the initial telephone-system field trials in the USA were carried out in 1977 by GTE in Los Angeles and by AT&T in Chicago. These transmission links were largely for the trunking of telephone lines, which are digital links consisting of time-division-multiplexed 64-kb/s voice channels. Similar demonstrations were carried out in Europe and Japan. Applications ranged from 45 to 140 Mb/s with repeater spacings around 10 km.

With the advent of high-capacity fiber optic transmission lines in the 1980s, service providers established a standard signal format called synchronous optical network (SONET) in North America and synchronous digital hierarchy (SDH) in other

parts of the world. These standards define a synchronous frame structure for sending multiplexed digital traffic over optical fiber trunk lines. The basic building block and first level of the SONET signal hierarchy is called the synchronous transport signal–level 1 (STS-1), which has a bit rate of 51.84 Mb/s. Higher-rate SONET signals are obtained by byte-interleaving N STS-1 frames, which are then scrambled and converted to an optical carrier–level N (OC-N) signal. Thus the OC-N signal will have a line rate exactly N times that of an OC-1 signal. For SDH systems, the fundamental building block is the 155.52-Mb/s synchronous transport module–level 1 (STM-1). Again, higher-rate information streams are generated by synchronously multiplexing N different STM-1 signals to form the STM-N signal. Table 2 shows commonly used SDH and SONET signal levels.

The development of optical sources and photodetectors capable of operating at 1310 nm allowed a shift in the transmission wavelength from 850 nm to 1310 nm. This resulted in a substantial increase in the repeaterless transmission distance for long-haul telephone trunks, since optical fibers exhibit lower power loss and less signal dispersion at 1310 nm. Intercity applications first used multimode fibers, but in 1984 switched exclusively to single-mode fibers, which have a significantly larger bandwidth. Bit rates for long-haul links typically range between 155 and 622 Mb/s (OC-3 and OC-12), and in some cases up to 2.5 Gb/s (OC-48), over repeater spacings of 40 km. Both multimode and single-mode 1310-nm fibers are used in local area networks, where bit rates range from 10 Mb/s to 100 Mb/s over distances ranging from 500 m to tens of kilometers.

In the next step of system evolution, links operating in the low-loss window around 1550 nm attracted much attention for high-capacity, long-span terrestrial and undersea transmission links. These links routinely carry traffic at 2.5 Gb/s over 90-km repeaterless distances. By 1996, advances in high-quality lasers and receivers allowed single-wavelength transmission rates of 10 Gb/s (OC-192).

In 1989, the introduction of optical amplifiers gave a major boost to fiber transmission capacity. Although there are GaAlAs-based solid-state optical amplifiers for the first window and InGaAsP amplifiers for the second window, the most successful and widely used devices are erbium-doped fiber amplifiers (commonly called EDFAs) operating in the 1530 to 1560-nm range and Raman fiber amplifiers that are used for operation in the 1560 to 1600-nm region.

During the same time period, impressive demonstrations of long-distance high-capacity systems were made using optical soliton signals. A soliton is a nondispersive pulse that makes use of nonlinear dispersion properties in a fiber to cancel out chromatic dispersion effects. As an example, solitons at rates of 10 Gb/s have been sent over a 12 200-km experimental link using optical amplifiers and special modulation techniques.

Entrance of Wavelength Division Multiplexing

The use of wavelength division multiplexing (WDM) offers a further boost in fiber transmission capacity. The basis of WDM is to use multiple sources operating at slightly different wavelengths to transmit several independent information streams over the same fiber. Although researchers started looking at WDM in the 1970s, during the ensuing years it generally turned out to be easier to implement higher-speed electronic and optical devices than to invoke the greater system complexity called for in WDM. However, a dramatic surge in WDM popularity started in the early 1990s, as electronic devices neared their modulation limit and high-speed equipment became increasingly complex.

Figure 5 shows the concept of implementing many closely spaced wavelengths within a spectral band centered around 1552.524 nm. This scheme is referred to as dense WDM or DWDM. Conceptually, the DWDM scheme is the same as frequency

Table 2 Commonly used SONET and SDH transmission rates

SONET level	*Electrical level*	*Line rate (Mb/s)*	*SDH equivalent*	*Common rate name*
OC-1	STS-1	51.84	–	
OC-3	STS-3	155.52	STM-1	155 Mb/s
OC-12	STS-12	622.08	STM-4	622 Mb/s
OC-24	STS-24	1244.16	STM-8	
OC-48	STS-48	2488.32	STM-16	2.5 Gb/s
OC-96	STS-96	4976.64	STM-32	
OC-192	STS-192	9953.28	STM-64	10 Gb/s
OC-768	STS-768	39,813.12	STM-256	40 Gb/s

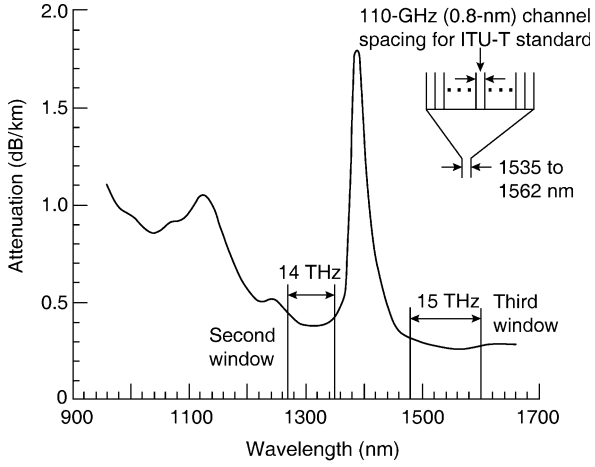

Figure 5 Wavelength division multiplexing (WDM) concept.

division multiplexing (FDM) used in microwave radio and satellite systems. Just as in FDM, the wavelengths (or optical frequencies) in a DWDM link must be properly spaced to avoid interference between channels. In an optical system this interference may arise from the fact that the center wavelength of laser diode sources and the spectral operating characteristics of other optical components in the link may drift with temperature and time, thereby giving rise to the need for a guard band between wavelength channels.

Since WDM is essentially frequency division multiplexing at optical carrier frequencies, the ITU developed DWDM standards that specify channel spacings in terms of frequency. The ITU-T Recommendation G.694.1, which is entitled 'Dense Wavelength Division Multiplexing (DWDM),' specifies WDM operation in the S-, C-, and L-bands for high-quality, high-rate metro area network (MAN) and wide area network (WAN) services. It calls out for narrow frequency spacings of 100 to 12.5 GHz (or, equivalently, 0.8 to 0.1 nm at 1550 nm). This implementation requires the use of stable, high-quality, temperature-controlled and wavelength-controlled (frequency-locked) laser diode light sources.

With the production of full-spectrum (low-water-content) fibers, the development of relatively inexpensive optical sources, and the desire to have low-cost optical links operating in metro and local area networks, came the concept of coarse WDM (CWDM). In 2002, the ITU-T released a standard aimed specifically at CWDM. This is Recommendation G.694.2, which is entitled 'Coarse Wavelength Division Multiplexing (CWDM).' The CWDM grid is made up of 18 wavelengths defined within the range 1270 nm to 1610 nm (O-through L-bands) spaced by 20 nm with wavelength-drift tolerances of ± 2 nm. This can be achieved with inexpensive light sources that are not temperature-controlled. The targeted transmission distance for CWDM is 50 km on single-mode fibers, such as those specified in ITU-T Recommendations G.652, G.653, and G.655.

Wavelength tunability of a source is an important property of WDM systems. Obviously it is not desirable or practical to maintain an inventory of dozens of lasers that emit at different wavelengths for WDM applications. The ideal tunable laser should be adjustable to emit at a specific wavelength across a broad spectral range. One such device is a distributed Bragg reflector (DBR) laser diode that can be tuned over a 10 to 20 nm spectral range. Work on perfecting such devices are still underway.

Starting in the mid-1990s, a combination of EDFAs and WDM was used to boost fiber information capacity to even higher levels and to increase the transmission distance. A major system consideration in these super-high capacity links is to ensure that there is appropriate link and equipment redundancy, so that alternate paths are available in case of disruptions in communications resulting from cable ruptures (for example, caused by errant digging from a backhoe) or equipment failures at an intermediate node. Such disruptions otherwise could have a devastating effect on a large group of users.

Undersea Optical Cable Systems

The first transoceanic fiber optic cable systems were installed in the Atlantic and Pacific Oceans in 1988 and 1989. Initially these systems operated at 280 Mb/s per fiber pair using 1310-nm lasers and single-mode fibers. The links consisted of a series of point-to-point optical fiber segments between electronic-based undersea regeneration points that were located nominally 60 km apart. Later the transmission capacity of these links was upgraded to 2.5 Gb/s and the regenerator spacing was increased to 100 km by converting the 1310-nm multiple-frequency light sources to 1550-nm single-frequency laser diodes. Later, the regenerator spacing was increased to 140 km.

Although these cable systems significantly improved the quality of the international telephone service, the optical-to-electrical conversion process at each regeneration point remained a capacity bottleneck. The introduction of erbium-doped optical fiber amplifiers (EDFA) eliminated this bottleneck from undersea lightwave systems by amplifying signals

directly in the optical domain. Since EDFAs operate over a 30-nm wavelength band, they are well suited for use with undersea WDM links, which have provided a further capacity increase. These undersea optical amplifiers are typically spaced about 45 km apart.

One example of the many worldwide installations of optically amplified WDM networks is the SEA-ME-WE-3 Cable System. This undersea network runs from Germany to Singapore, connecting more than a dozen countries in between. Hence the name SEA-ME-WE, which refers to Southeast Asia (SEA), the Middle East (ME), and Western Europe (WE). The network has two pairs of undersea fibers with a capacity of eight STM-16 wavelengths per fiber.

Simple Optical Fiber Links

The most basic optical fiber communication system architecture is a point-to-point link consisting of the elements shown in Figure 1. The key sections are a transmitter consisting of a light source and its associated drive circuitry, a cable offering mechanical and environmental protection to the optical fibers contained inside, and a receiver consisting of a photodetector plus amplification and signal-restoring circuitry. Very long links may include periodic optical amplifiers for boosting the level of the optical signal. In networks that use only simple point-to-point links, the optical fiber is used principally as a transmission medium and all the switching and processing of information bits is done by electronics.

At the transmitting end of an optical fiber link, information bits consisting of electronic pulses are used to modulate the light output of the source. The resulting light pulses are coupled into an optical fiber. As they travel along the fiber these signal pulses become progressively weakened and distorted due to attenuation and dispersion mechanism that are characteristic of an optical fiber. At the end of the fiber link a photodetector converts the optical pulses back to an electrical format for switching to another link or for processing at the end station.

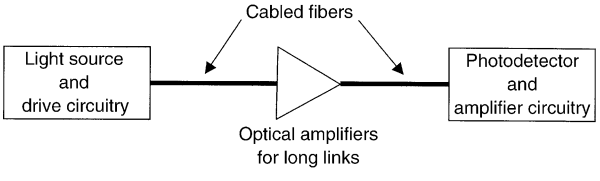

Figure 1 Basic elements of a point-to-point fiber optic link.

The cabled fiber is one of the most important elements in an optical fiber link, since it determines operational parameters such as transmission distance and achievable data rates. In addition to protecting the glass fibers during installation and service, the cable may contain copper wires for powering optical amplifiers or signal regenerators, which are needed periodically in long-distance links for amplifying and reshaping the signal.

Analogous to copper cables, the installation of optical fiber cables can be either aerial, in ducts, undersea, or buried directly in the ground. As a result of installation and/or manufacturing limitations, individual cable lengths will range from several hundred meters to several kilometers. Practical considerations such as reel size and cable weight determine the actual length of a single cable section. The shorter segments tend to be used when the cables are pulled through ducts. Longer lengths are used in aerial, direct-burial, or undersea applications. Splicing together individual cable sections forms continuous transmission lines for these long-distance links. For undersea installations, the splicing and repeater-installation functions are carried out on board a specially designed cable-laying ship.

One of the principal characteristics of an optical fiber is its attenuation as a function of wavelength, as shown in Figure 2. Early technology used the 800 to 900 nm wavelength band, since in this region the fibers made at that time exhibited a local minimum in the attenuation curve, and optical sources and photodetectors operating at these wavelengths were available. This region originally was referred to as the 'first window'. By reducing the concentration of hydroxyl ions and metallic impurities in the fiber material, in the 1980s manufacturers were able to fabricate optical fibers with very low loss in the 1100 to 1600 nm region. Two windows are defined here, these being the 'second window' centered around 1310 nm and the 'third window' centered around 1550 nm.

In 1998 a new ultra-high purifying process patented by Lucent Technologies eliminated virtually all water molecules from the glass material. The resulting fiber is designated as either a low-water-peak or a full spectrum fiber. By dramatically reducing the water-attenuation peak around 1400 nm, this process opens the transmission region between the second and third windows to provide around 100 nm more bandwidth than in conventional single-mode fibers. This particular fiber allows wider spectral tolerances on optical components, which reduces costs for moderate-distance metropolitan network applications.

Since the attenuation of low-water-peak fibers makes the designation of transmission windows obsolete, the concept of operational spectral bands arose for the 1260–1675 nm region. As shown in

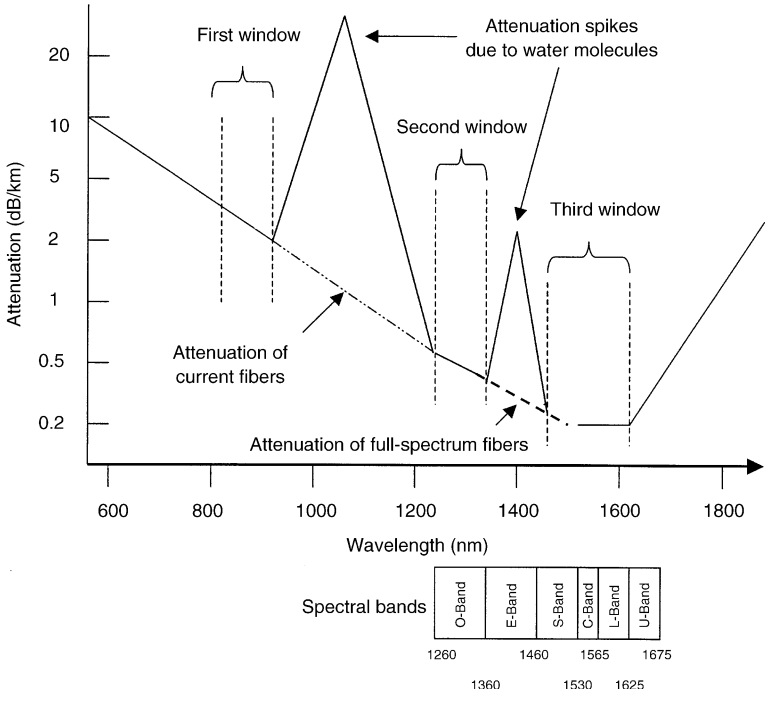

Figure 2 Attenuation versus wavelength for silica fibers and the concept of spectral bands.

Figure 2, the regions are known by the letters O, E, S, C, L, and U, which are defined as follows:

- Original band (O-Band): 1260–1360 nm;
- Extended band (E-Band): 1360–1460 nm;
- Short band (S-Band): 1460–1530 nm;
- Conventional band (C-Band): 1530–1565 nm;
- Long band (L-Band) 1565–1625 nm;
- Ultra-long band (U-Band): 1625–1675 nm.

Once the cable is installed, a light source that is dimensionally compatible with the fiber core is used to launch optical power into the fiber. Semiconductor light-emitting diodes (LEDs) and laser diodes are suitable for this purpose, since their light output can be modulated rapidly by simply varying the bias current at the desired transmission rate, thereby producing an optical signal. The electric input signals to the transmitter circuitry for the optical source can be either of an analog or digital form. For high-rate systems (nominally greater than 1 Gb/s), direct modulation of the source can lead to unacceptable signal distortion. In this case, an external modulator is used to vary the amplitude of a continuous light output from a laser diode source.

After an optical signal is launched into a fiber, it will become progressively attenuated and distorted with increasing distance because of scattering, absorption, and dispersion mechanisms in the glass material. At the receiver a photodiode will detect the weakened optical signal emerging from the fiber end and convert it to an electric current. The design of an optical receiver is inherently more complex than that of the transmitter, since it has to interpret the content of the weakened and degraded signal received by the photodetector. The principal figure of merit for a receiver is the maximum optical power necessary at the desired data rate to attain either a given error probability for digital systems or a specified signal-to-noise ratio for an analog system. The ability of a receiver to achieve a certain performance level depends on the photodetector type, the effects of noise in the system, and the characteristics of the successive amplification stages in the receiver.

Networks of Links

With the advent of fiber optic transmission lines, the next step in the evolution of the digital multiplexing scheme used by telecommunication providers was a standard signal format called synchronous optical network (SONET) in North America and synchronous digital hierarchy (SDH) in other parts of the world. In the mid-1980s, efforts started on developing a standard that would allow network engineers to interconnect fiber optic transmission equipment from various vendors through multiple-owner trunk networks. This resulted in a series of standards for SONET by the American National Standards Institute (ANSI) and a series of recommendations for SDH from the International Telecommunications Union (ITU). Examples of particular interest are the ANSI T1.105.06 standard and the ITU-T G.957 recommendation. Although there are some implementation differences between SONET and SDH, all SONET specifications conform to the SDH recommendations. A key characteristic of SONET and SDH is that they are usually configured as a ring architecture. This is done to create loop diversity for uninterrupted service protection purposes in case of link or equipment failures. The SONET/SDH rings commonly are called self-healing rings, since the traffic flowing along a certain path can be switched automatically to an alternate or standby path following failure or degradation of the link segment.

The basic building block and first level of the SONET signal hierarchy is called the Synchronous Transport Signal – Level 1 (STS-1), which has a bit rate of 51.84 Mb/s. Higher-rate SONET signals are obtained by byte-interleaving N STS-1 frames, which are then scrambled and converted to an Optical Carrier – Level N (OC-N) signal. Thus the OC-N signal will have a line rate exactly N times that of an OC-1 signal. For SDH systems the fundamental building block is the 155.52 Mb/s Synchronous Transport Module – Level 1 (STM-1). Again, higher-rate information streams are generated by synchronously multiplexing N different STM-1 signals to form the STM-N signal.

Three main features, each with two alternatives, classify all SONET/SDH rings, thus yielding eight possible combinations of ring types. First, there can be either two or four fibers running between the nodes on a ring. Second, the operating signals can travel either clockwise only (which is termed a unidirectional ring) or in both directions around the ring (which is called a bidirectional ring) Third, protection switching can be performed either via a line-switching or a path-switching scheme. Upon link failure or degradation, line switching moves all signal channels of an entire OC-N channel to a protection fiber. Conversely, path switching can move individual payload channels within an OC-N channel (e.g., an STS-1 channel within an OC-12 channel) to another path.

Of the eight possible combinations of ring types, the following two architectures have become popular for SONET and SDH networks:

- two-fiber unidirectional path-switched ring (two-fiber UPSR);
- two-fiber or four-fiber bidirectional line-switched ring (two-fiber or four-fiber BLSR).

The common abbreviations of these configurations are given in parentheses. They also are referred to as unidirectional or bidirectional self-healing rings (USHR or BSHR).

Figure 3 shows a two-fiber unidirectional path-switched ring network. By convention, in a unidirectional ring the normal working traffic travels clockwise around the ring, as indicated by the heavy arrows. For example, the connection from node 1 to node 3 uses links 1 and 2, whereas the traffic from node 3 to node 1 traverses links 3 and 4. Thus, two communicating nodes use a specific bandwidth capacity around the entire perimeter of the ring. If nodes 1 and 3 exchange information at an OC-3 rate in an OC-12 ring, then they use one-fourth of the capacity around the ring on all the primary links. In a unidirectional ring the counter-clockwise path is used as an alternate path for protection against link or node failures. To achieve this, the signal from a transmitting node is dual-fed into both the primary and protection fibers. This establishes a designated protection path on which traffic flows counter-clockwise, i.e., from node 1 to node 3 via links 5 and 6 (in that order), as shown in Figure 3b. A heavy line and a dashed line indicate the primary and protection paths, respectively.

Consequently, two identical signals from a particular node arrive at their destination from opposite directions, usually with different delays, as denoted in Figure 3b. The receiver normally selects the signal from the primary path. However, it continuously compares the fidelity of each signal and chooses the alternate signal in case of severe degradation or loss of the primary signal. Thus, each path is individually switched based on the quality of the received signal. For example, if path 2 breaks or equipment in node 2 fails, then node 3 will switch to the protection channel to receive signals from node 1.

Figure 4 illustrates the architecture of a four-fiber bidirectional line-switched ring. Here two primary fiber loops (with fiber segments labeled 1p through 8p) are used for normal bidirectional communication, and the other two secondary fiber loops are standby links for protection purposes (with fiber segments labeled 1s through 8s). In contrast to the two-fiber UPSR, the four-fiber BLSR has a capacity advantage

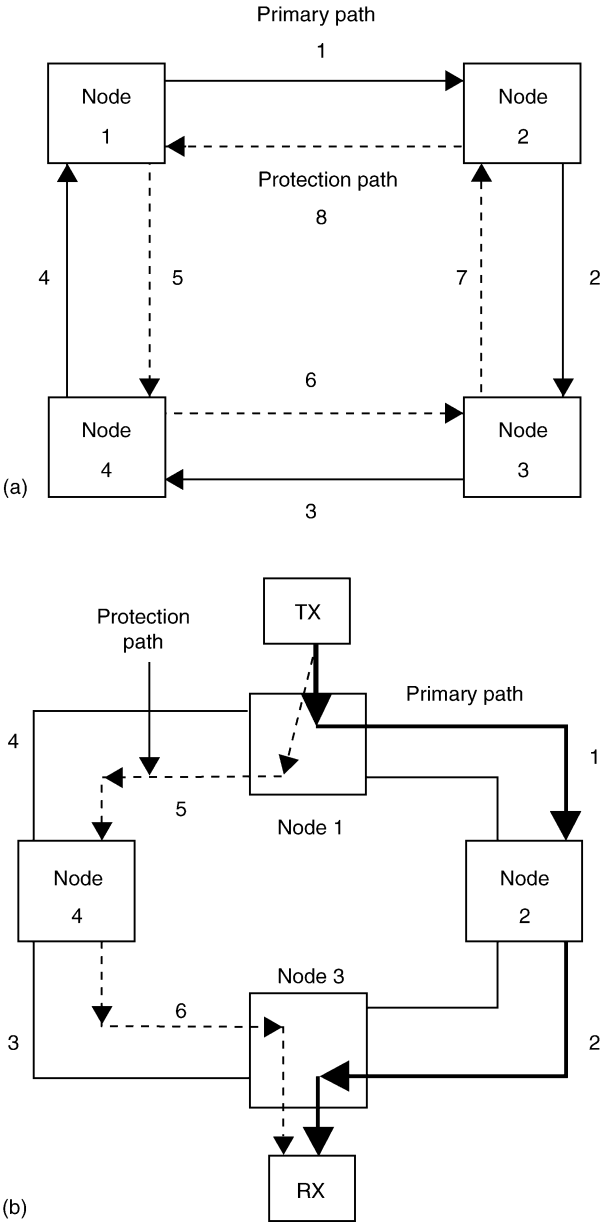

Figure 3 Schematic of a two-fiber unidirectional path-switched ring network.

since it uses twice as much fiber cabling and because traffic between two nodes is only sent partially around the ring.

To see the function and versatility of the standby links in the four-fiber BLSR, consider first the case where a transmitter or receiver circuit card used on the primary ring fails in either node 3 or 4. In this situation the affected nodes detect a loss-of-signal condition and switch both primary fibers connecting them to the secondary protection pair, as shown in Figure 5. The protection segment between nodes 3 and 4 now becomes part of the primary bidirectional loop. The exact same reconfiguration scenario will

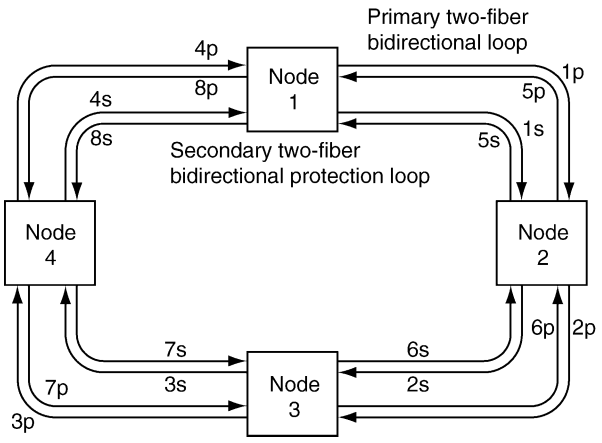

Figure 4 The architecture of a four-fiber bidirectional, line-switched ring.

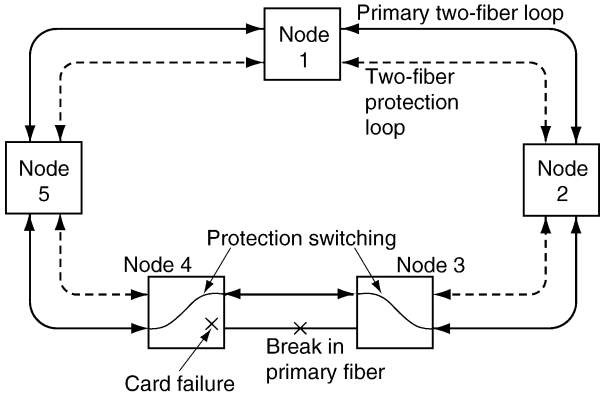

Figure 5 Reconfiguration of a four-fiber BLSR under transceiver failure.

occur when the primary fiber connecting nodes 3 and 4 breaks. Note that in either case the other links remain unaffected.

Now suppose an entire node fails, or both the primary and the protection fibers in a given span are severed, which could happen if they are in the same cable duct between two nodes. In this case the nodes on either side of the failed span internally switch the primary-path connections from their receivers and transmitters to the protection fibers, in order to loop traffic back to the previous node. This process again forms a closed ring, but now with all of the primary and protection fibers in use around the entire ring, as shown in Figure 6.

Single-Span WDM Links

An interesting and powerful aspect of an optical communication link is that many different wavelengths can be sent along a fiber simultaneously in the 1300–1600 nm spectrum. The technology of combining a number of wavelengths onto the same fiber is known as wavelength division multiplexing or WDM. Figure 7 shows the basic WDM concept. Here N independent optically formatted information streams, each transmitted at a different wavelength, are combined with an optical multiplexer and sent over the same fiber. Note that each of these streams could be at a different data rate. Each information stream maintains its individual data rate after being multiplexed with the other streams, and still operates at its unique wavelength. Conceptually, the WDM scheme is the same as frequency division multiplexing (FDM) used in microwave radio and satellite systems.

To see the potential of WDM, consider the characteristics of a high-quality optical source such as a distributed feedback (DFB) laser, which has a very narrow frequency spectrum on the order of 1 MHz, which is equivalent to a spectral linewidth of 10^{-5} nm. When using such a source, a guard band of 0.4–1.6 nm is typically employed. This is done to take into account possible drifts of the peak wavelength due to aging or temperature effects, and to give both the manufacturer and the user some leeway in specifying and choosing the precise peak emission wavelength. With such spectral band widths, simplex systems make use of only a very

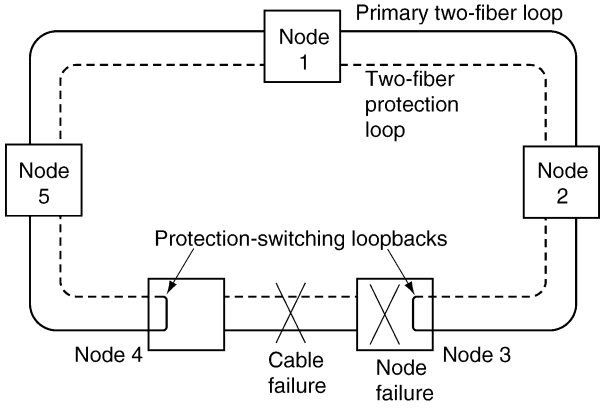

Figure 6 Reconfiguration of a four-fiber BLSR under node or fiber-cable failure.

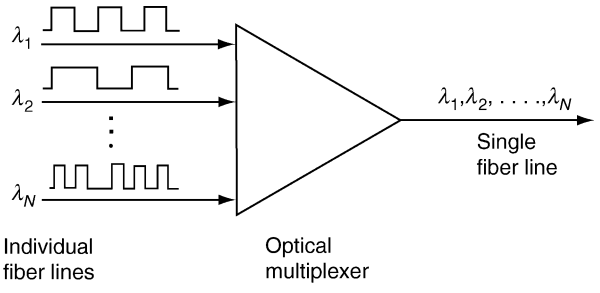

Figure 7 The basic WDM concept.

small portion of the transmission bandwidth capability of a fiber. This can be seen from Figure 2, which depicts the attenuation of light in a silica fiber as a function of wavelength. The curve shows that the two low-loss regions of a single-mode fiber extend over the wavelengths ranging from about 1260 to 1360 nm (the O-band) and from 1460 to 1625 nm (the S-, C-, and L-bands).

These regions can be viewed either in terms of spectral width (the wavelength band occupied by the light signal and its guard band) or by means of optical bandwidth (the frequency band occupied by the light signal). To find the optical bandwidth corresponding to a particular spectral width in these regions, consider the fundamental relationship $c = \lambda\nu$, which relates the wavelength λ to the carrier frequency ν, where c is the speed of light. Differentiating this yields $\Delta\nu = (c/\lambda^2)\Delta\lambda$, where the deviation in frequency $\Delta\nu$ corresponds to the wavelength deviation $\Delta\lambda$ around λ. Thus the optical bandwidth is $\Delta\nu = 14$ THz for a usable spectral band $\Delta\lambda = 80$ nm in the O-band. Similarly, $\Delta\nu = 15$ THz for a usable spectral band $\Delta\lambda = 120$ nm in the region spanning the S-, C-, and L-bands.

Since the spectral width of a high-quality source occupies only a narrow optical bandwidth, the two low-loss windows provide many additional operating regions. By using a number of light sources, each emitting at a different peak wavelength that is sufficiently spaced from its neighbor so as not to create interference, the fidelities of the independent messages from each source are maintained for subsequent conversion to electrical signals at the receiving end.

Since WDM is essentially frequency division multiplexing at optical carrier frequencies, the WDM standards developed by the ITU specify channel spacings in terms of frequency. A key reason for selecting a fixed frequency spacing, rather than a constant wavelength spacing, is that when locking a laser to a particular operating mode it is the frequency of the laser that is fixed. The ITU-T Recommendation G.692 specifies selecting the channels from a grid of frequencies referenced to 193.100 THz (1552.524 nm) and spacing them 100 GHz (0.8 nm at 1552 nm) apart. Suggested alternative spacings include 50 GHz and 200 GHz.

Historically the term dense WDM (DWDM) was used somewhat loosely and generally referred to the spacings denoted by Recommendation G.692. In 2002 the ITU-T released an updated standard aimed specifically at DWDM. This is Recommendation G.694.1, which specifies WDM operation in the S-, C-, and L-bands for high-quality, high-rate metro area network (MAN) and wide area network (WAN) services. It calls out for narrow frequency spacings of 100 to 12.5 GHz (or, equivalently, 0.8 to 0.1 nm at 1550 nm).

Alternatively, by using the larger spectral window available in low-water-content fibers, one can relax the spectral tolerances on the optical components and space the individual sources much further apart. This is the basis of coarse WDM (CWDM), which is useful for metropolitan area networks where variations in attenuation between different wavelength channels is not critical over short transmission distances. In 2002 the ITU-T released Recommendation G.694.2, which is aimed specifically at CWDM. The CWDM grid is made up of 18 wavelengths defined within the range 1270–1610 nm (O- through L-bands) spaced by 20 nm with wavelength-drift tolerances of ±2 nm.

A key feature of WDM is that the discrete wavelengths form an orthogonal set of carriers which can be separated, routed, and switched without interfering with each other. This holds as long as the total optical power intensity is kept sufficiently low to prevent nonlinear effects such as stimulated Brillouin scattering and four-wave mixing processes from degrading the link performance.

The implementation of WDM networks requires a variety of passive and/or active devices to combine, distribute, isolate, and amplify optical power at different wavelengths. Passive devices require no external control for their operation, so they are somewhat limited in their application in WDM networks. These components are mainly used to split and combine or tap off optical signals. The performance of active devices can be controlled electronically, thereby providing a large degree of network flexibility. Active WDM components include tunable optical filters, tunable sources, and optical amplifiers.

Passive Optical Networks

Another step towards realizing the full potential of optical fiber transmission capacity is the concept of all-optical WDM networks to extend the versatility of communication networks beyond architectures such as those provided by SONET. These networks can be classified as either broadcast-and-select or wavelength-routing networks. In general, broadcast-and-select techniques employing passive optical stars, buses, or wavelength routers are used for local network applications, whereas active optical components form the basis for constructing wide-area wavelength-routing networks. Broadcast-and-select networks can be categorized as single-hop or multihop networks. Single-hop refers to networks where

information transmitted in the form of light reaches its destination without being converted to an electrical form at any intermediate point. On the other hand, intermediate conversion can occur in a multihop network.

Figure 8 shows two alternate physical architectures for a WDM-based local network. Here N sets of transmitters and receivers are attached either to a star coupler or a passive bus. Each transmitter sends its information at a different fixed wavelength. All the transmissions from the various nodes are combined in a passive star coupler or coupled onto a bus and the result is sent out to all receivers.

Each receiver sees all wavelengths and uses a tunable filter to select the one wavelength addressed to it. In addition to point-to-point links, this configuration can also support multicast or broadcast services, where one transmitter sends the same information to several nodes. An interesting point is that these passive WDM networks are protocol transparent. This means that different sets of communicating nodes can use different information-exchange rules (protocols) without affecting the other nodes in the network. This is analogous to current time-division-multiplexed telephone lines in which voice, data, or facsimile services are sent in different time slots without interfering with each other.

Although the architectures of single-hop broadcast-and-select networks are fairly simple, there needs to be careful dynamic coordination between the nodes. For example, if the network is set up so that a transmitter sends its information at a unique fixed wavelength, then the destined receiver needs to be informed when a message is being sent to it, so that it can tune its selective filter to that wavelength. Also conflicts need to be resolved in cases where two stations transmitting at different wavelengths want to send information to the same recipient simultaneously.

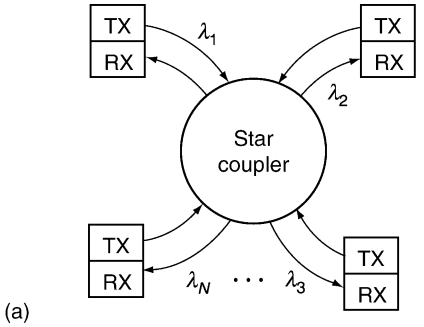

Figure 8 Two alternate physical architectures for a WDM-based local network.

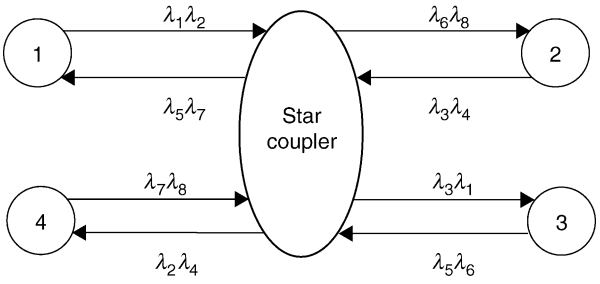

Figure 9 Example of a four-node broadcast-and-select multihop network.

A drawback of single-hop networks is the need for rapidly tunable lasers or receiver optical filters. The designs of multihop networks avoid this need. Multihop networks generally do not have direct paths between each node pair. Each node has a small number of fixed-tuned optical transmitters and receivers. Figure 9 shows an example of a four-node broadcast-and-select multihop network where each node transmits on one set of two fixed wavelengths and receives on another set of two wavelengths. Stations can send information directly only to those nodes that have a receiver tuned to one of the two transmit wavelengths. Information destined for other nodes will have to be routed through intermediate stations.

The flow of traffic can be seen from Figure 9. If node 1 wants to send a message to node 2, it first transmits the message to node 3 using λ_1. Then node 3 forwards the message to node 2 using λ_6. In contrast to single-hop networks, with this scheme there are no destination conflicts or packet collisions in the network, since each wavelength channel is dedicated to a particular source–destination link. However, for H hops between nodes, there is a network throughput penalty of at least $1/H$.

Wavelength-Routed Optical Networks

Wavelength-routed networks overcome the limitations of passive optical networks through wavelength reuse, wavelength conversion, and optical switching. The physical topology of a wavelength-routed network consists of optical wavelength routers interconnected by pairs of point-to-point fiber links

in an arbitrary mesh configuration, as illustrated in Figure 10. Each link can carry a certain number of wavelengths, which can be directed independently to different output paths at a node. Each node may have logical connections with several other nodes in the network, where each connection uses a particular wavelength. Provided the paths taken by any two connections do not overlap, they can use the same wavelength. Thereby the number of wavelengths is greatly reduced. For example, the connection from node 1 to node 2 and from node 2 to node 3 can both be on λ_1, whereas the connection between nodes 4 and 5 requires a different wavelength (λ_2).

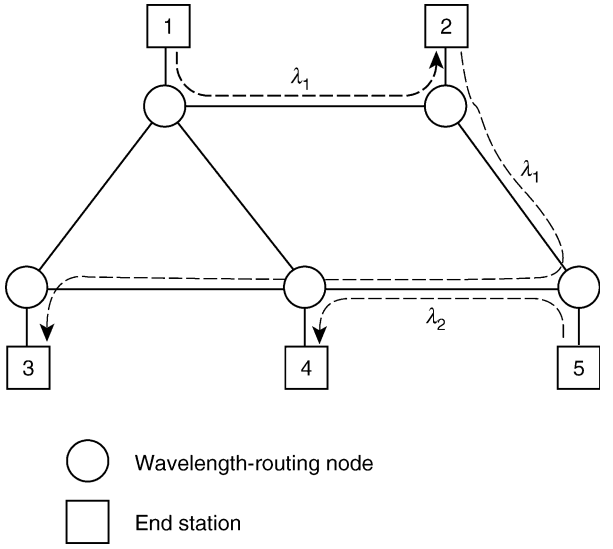

Figure 10 The physical topology of a wavelength-routed network.

A high degree of path modularity, capacity scaling, and flexibility in adding or dropping channels at a user site can be achieved by introducing the concept of an optical cross-connect architecture in the physical path structure (the so-called path layer) of an optical network. These optical cross-connects (OXCs) operate directly in the optical domain and can route very high-capacity WDM data streams over a network of interconnected optical paths.

Contentions could arise when channels having the same wavelength but traveling on different input fibers enter the OXC and need to be switched simultaneously to the same output fiber. This could be resolved by assigning a fixed wavelength to each optical path throughout the network, or by dropping one of the channels and retransmitting it at another wavelength. However, in the first case, wavelength reuse and network scalability (expandability) are reduced, and in the second case the add/drop flexibility of the OXC is lost. These blocking characteristics can be eliminated by using wavelength conversion at any output of the OXC.

As an example consider the 4×4 OXC shown in Figure 11. Here two input fibers are each carrying two wavelengths. Either wavelength can be switched to any of the four output ports. The OXC consists of three 2×2 switch elements. Suppose that λ_2 on input fiber 1 needs to be switched to output fiber 2 and that λ_1 on input fiber 2 needs to be switched to output fiber 1. This is achieved by having the first two switch elements set in the bar state (the straight-through configuration) and the third element set in the cross state, as indicated in Figure 11. Obviously without wavelength conversion there would be wavelength contention at both output ports.

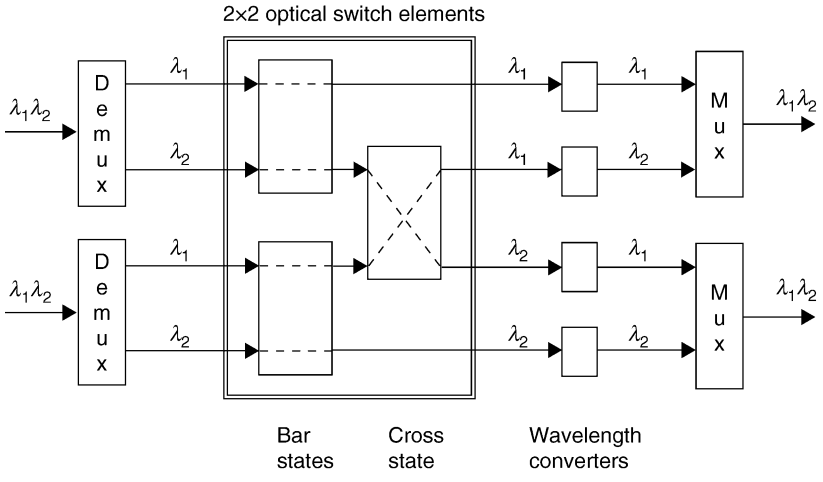

Figure 11 Example of a 4×4 optical cross-connect (OXC).

By using wavelength converters, the cross-connected channels can be converted to noncontending wavelengths.

Free Space Optical Communications

Introduction

Free space optical (FSO) communication is the wireless transmission of data via a modulated optical beam directed through free space, without fiber optics or other optical systems guiding the light. The fundamental idea goes back to ancient times, as light (or smoke) signals were used to transmit information. From a more modern point of view, Graham Bell's patent on the photophone may mark the onset of modern FSO techniques, as it transmitted audio signals (i.e., voice) via the modulation of sunlight. A renaissance of FSO systems started with the availability of lasers, light sources with high output power and high coherence, which allowed the accurate direction of the light beams over long distances. During the 1970s and 1980s the main proposed application of FSO systems was for secure and long distance (50–1000 km) communication, mainly targeted for ground–satellite or satellite–satellite communication. This focus changed drastically over the last decade as a new market for FSO grew in the establishment of high bandwidth data link and their integration over a locally restricted area.

The main competitors in this market are the fiber-based optical network, the RF communication system, as well as the low bandwidth copper cable-based system. In comparison to the closely related wireless radio frequency transmission, the higher frequency of the optical carrier ($\sim 10^{14}$–10^{15} Hz) thereby allows for much higher transmission rates, comparable to those of typical fiber optic networks. On the other hand, the use of an optical carrier also results in much more directed beam propagation, which requires an undisturbed line-of-sight between emitter and detector. This restricts the application of most FSO systems to a range between a few hundred meters up to several kilometers, which are still favorable for distribution of high bandwidth networks over a locally restricted area. This makes FSO a highly attractive candidate for the 'last-mile' distribution of high-bandwidth Ethernet to the individual homes.

The simplicity of setup of FSO links, as well as their modularity, is thereby their biggest advantage, compared to fiber-based networks. It makes them not only highly cost efficient, but it eases the maintenance or

allows for fast and easy upgrades, as it does not require any extensive and time-consuming installation – in contrast to the installation of fiber optic cables. This advantage makes FSO highly attractive for temporary installations (emergency or short-time high broadcast situations, such as the Olympic Games), as well as to overcome geometrical restraints (river, seas, etc.). As most detector and emitter systems are typically based on the same electro-optical components used for fiber optic networks, they seamlessly integrate and expand an existing network without complications in data handling.

Standard FSO System

Figure 1 shows schematically the setup for a typical FSO system connecting two separate local networks. It consists of: an electronic data input; a small but powerful light source which can be modulated; emitter optics which shape the emitted beam to a highly directed beam; the atmosphere as transmitting device; detector optics which receive the transmitted light and focus it onto a photodetector; and an electronic amplifier which serves as data output.

Compared to a fiber optical communication system, the main difference is the use of the atmosphere as the transmission medium, in contrast to guided optical propagation. The transmission properties are thereby determined by the atmospheric conditions, which can lead to degradation and/or redirection of the beam. The main influences which have to be taken into account are atmospheric scattering, molecular absorption, turbulence effects (including beam wander and fading), as well as the impact of low-visibility weather situations like rain, snow, or fog. These depend strongly on wavelength and linewidth of the used emitter system, distance between emitter and receiver, as well as the environmental conditions. As a consequence, the characteristics of the atmospheric channel determine the layout of the other FSO components – and have to be considered first.

Atmospheric Losses

The overall losses of the atmospheric transmission are determined by the Beer–Lambert absorption law:

$$I = I_0 \exp[-\alpha L] \qquad [1]$$

where I is the intensity at the receiver, I_0 the intensity of the transmission beam after the emitter optics, and L is the range (i.e., distance between emitter and detector optics). The total extinction coefficient $\alpha = \alpha_{\text{Rayleigh}} + \alpha_{\text{Mie}} + \alpha_{\text{Absorption}}$ is based on three different contributions: Rayleigh scattering, Mie scattering, and absorption.

In contrast to absorption, the losses due to scattering originate from redirection of light and will be discussed first. Depending on the size of the scattering partner, two separate regimes have to be taken into account. For scatter smaller than the wavelength, the effect can be described based on Rayleigh's classical formula. The scattering cross-section of an element with mass m, charge q, natural oscillation wavelength λ_0, is then:

$$\sigma_s = \frac{fq^4\lambda_0^4}{6\pi\varepsilon_0^2 m^2 c^4}\frac{1}{\lambda^4} \qquad [2]$$

where ε_0 is the dielectric constant, c the speed of light, and λ the wavelength of the incident light, leading to an extinction coefficient of $\alpha_{\text{Rayleigh}} = \sigma_s N_s$, where N_s is the concentration of the scattering elements. The λ^{-4} dependence in the scattering predicts stronger scattering for shorter wavelengths and Rayleigh scattering is therefore dominant for short and visible wavelengths (which gives the sky its blue color). For typical FSO

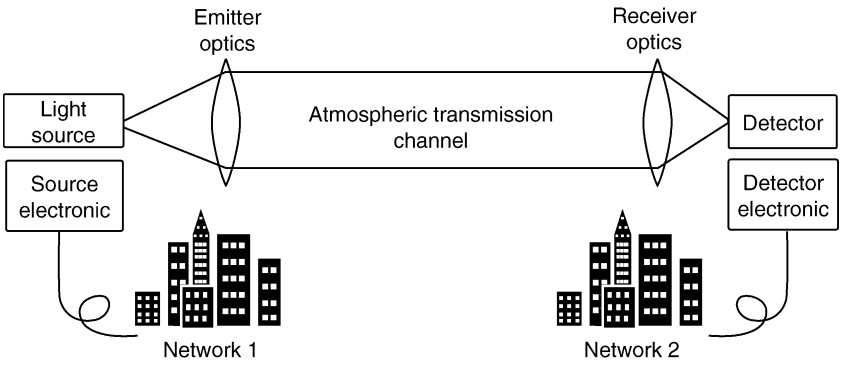

Figure 1 Typical components of a FSO system.

wavelengths in the region of near-infrared radiation (NIR, 800–2000 nm) or mid-infrared radiation (MIR, 2000–20 000 nm), the contribution of Rayleigh scattering is typically relatively low and can be neglected.

On the other hand, Mie scattering is, in most cases, the strongest contribution for FSO systems – but also the hardest to predict. It is due to resonant scattering effects, where the particle size is of the wavelength of the scattered light. For the typical FSO wavelengths these particles include water and oil droplets, dust, smog, fly ash, and aerosols (which can originate from pollution). A correct calculation of the Mie scattering coefficient is possible, but requires knowledge of the exact particle concentration as well as their size distribution. As these numbers are not only difficult to measure, but also fluctuate continuously depending on weather situation, time of day, season, temperature, climate, pollution, and other factors, a numerically correct evaluation is not possible.

Historically, most systems rely on an empirical formula, which estimates the attenuation coefficient to

$$\sigma_{\text{Mie}} = \frac{3.91}{V}\left(\frac{\lambda}{550}\right)^{-p} \qquad [3]$$

where V denotes the visibility and the value of p ranges from 1.6 for high visibility ($V > 50$ km) and 1.3 for average visibility (50 km $> V >$ 6 km) down to 0.585 $V_{1/3}$, respectively for low visibility. The formula is based on data collected in the 1950s and 1960s. More accurate measurements show that the actual scattering cross-sections differ quite strongly, especially for low-visibility cases. Especially, the predicted dependence on wavelength is not correct. The failure of such a general model is not surprising, as the actual scattering properties are strongly dependent on the weather situation and the environmental conditions. It is the focus of ongoing research to find more accurate models describing the scattering condition in multiple environments and conditions to provide the background for more accurate empirical models.

Apart from the light redirection due to scattering, absorption either by molecules or aerosols is nearly as important for the transmission calculation of a FSO system. The strongest molecular absorptions are typically due to water, carbon dioxide, as well as ozone. A typical absorption spectrum can be easily calculated using standard software together with the publicly available HITRAN database, both available from ONTAR. The upper part of Figure 2 shows a low-resolution transmission spectrum for the interesting wavelength region for a path length of 1 km.

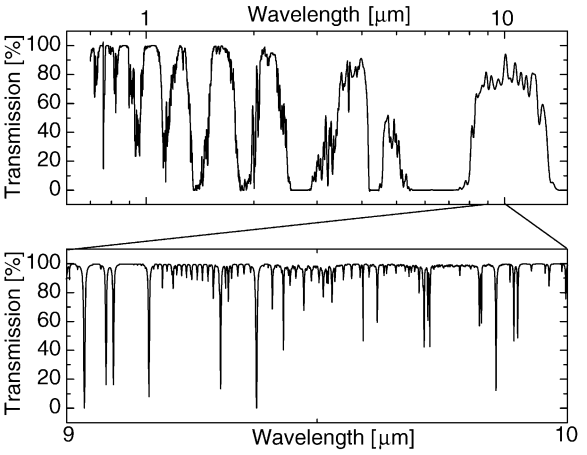

Figure 2 Upper: Low-resolution transmission spectrum of the atmosphere showing molecular absorption for a path length of 1 km. Lower: high-resolution spectrum of the atmospheric windows around 9.5 μm.

Within this spectrum, several well-known atmospheric windows exist, which are naturally preferred for FSO applications. These include the region around 830 nm, 1550 nm, and from 8 μm to 12 μm. For the exact selection of a wavelength, a closer look is needed. As an example, a high-resolution analysis of the atmospheric windows around 9.5 μm is shown in the lower part of Figure 2, which identifies additional absorption lines as well as highly transparent wavelength ranges within the window. Such substructure has to be taken carefully into account for the FSO wavelength selection, especially if lasers are employed, which have a linewidth comparable to the width of the absorption line.

Besides the molecules, aerosol particles also contribute to the absorption spectrum. Calculation of their contribution can also be performed using available software package, such as Air Force's MODTRAN and LOWTRAN program as well as OPAC from the LMU University in Munich. Figure 3 shows a typical low-resolution transmission spectrum for 50% humidity as well as 99% humidity, where by scattering as well as absorption effects have both been included in the calculation. The occurrence of sharp absorption features, as well as the increasing losses for wavelengths above 10 μm, is typically due to the aerosol absorption, whereas the scattering dominates the function for wavelengths below 3 μm. Losses due to the aforementioned Rayleigh scattering are also shown in the same diagram, demonstrating its low influence at longer wavelengths.

MODTRAN and LOWTRAN also allow the calculation of transmission spectra under rain and snow conditions, where rain and snow consist of

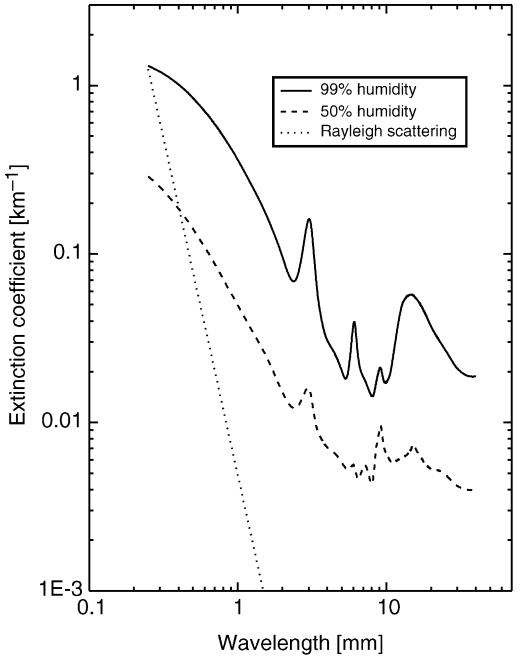

Figure 3 Typical low-resolution transmission spectrum calculated based on absorption and scattering losses from aerosols for 50% humidity (dashed line) and 99% humidity (solid line). The dotted line shows additionally the losses due to Rayleigh scattering.

clusters of water and aerosol with diameters from 200 μm to 2 mm and above. Depending on the severity of the precipitation, the losses can range from ~0.5 dB/km for light rain up to 13 dB/km for cloudbursts, requiring an additional power margin in the preparation of the FSO link. Significantly stronger is the impact of fog, as typically particles with much lower sizes are present. The losses inflicted by a moderate fog (visibility 500 m) range above 20 dB/km, surpassing the effect of a cloudburst; for thick fog the attenuation can even grow beyond 200 dB/km. However, depending on the size distribution within the fog itself, the losses can be highly wavelength dependent. Recent experiments show that long wavelength FSO systems operating in the MIR wavelength region have a much stronger stability under the influence of thick fog than one operating at NIR wavelengths.

Turbulence and Scintillation

In contrast to a static medium, the atmosphere is a dynamic mixture which undergoes continuous changes due to wind, temperature, and other influences. This creates a constant change in the parts of the atmosphere which are contributing to the FSO channel and therefore in the optical properties of the beam path. The index of refraction can differ, not only in its total value, but also within subsections of it, creating a random fluctuation in the beam paths. Such localized changes in the refractive index of the air are schematically shown in Figure 4, where turbulences of different sizes modify the beam path and disturb the beam front. The turbulence in the atmosphere can be quantified by the refractive-turbulence structure coefficient C_n^2, which can range from $10^{-13}\,\mathrm{m}^{-2/3}$ in the middle of the afternoon (highest value) to $10^{-17}\,\mathrm{m}^{-2/3}$ one hour after sunrise or sunset. As the turbulence effect is typically due to strong temperature difference, C_n^2 is strongest near hot surfaces (e.g., tar roofs or asphalt in the summer) and decreases with altitude. The effects of such turbulences on a directed light beam (such as used in FSO systems) include mainly beam wander and scintillation effects.

Beam wander is thereby based on large size turbulences which act as a lens on the propagating beam. Consequently, a narrow focused beam could be randomly steered away from the detector area, creating a fluctuation in the detected intensity.

Stronger impact for FSO links has scintillation, which is better known as the twinkling of a star or the heat shimmer of the horizon on a hot day. It is based on the continuous variation of the beam front which can lead to intensity fluctuations (like the twinkling) and loss in the image resolution (heat shimmer). Strong intensity fluctuations can thereby cause signal loss as well as receiver saturation, both resulting in downtime in the link. Such local intensity disturbances can occur up to sizes of $\sqrt{\lambda L}$, reaching, for example, 4 cm for a 1.55 μm link after 1 km. For small fluctuations, the intensity follows a classical stochastic behavior and can be described by the irradiance variation (normalized to its mean value) as

$$\sigma^2 = \exp\left[0.5\left(\frac{2\pi}{\lambda}\right)^{6/7} L^{11/6} C_n^2\right] - 1 \qquad [4]$$

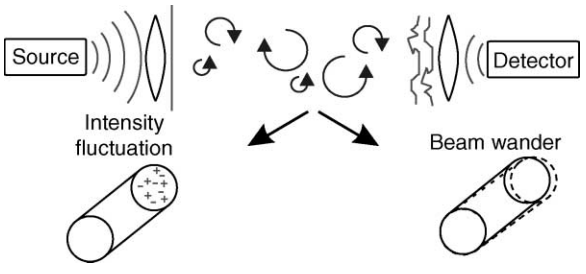

Figure 4 Schematic depiction of atmospheric turbulences with different sizes in FSO systems. Shown below are illustrations of its main effects on a directed beam causing intensity fluctuations and beam wander.

with usual values in the range from 5 to 70%. Nonetheless, it should be pointed out that actual turbulence effects can differ quite strongly from these predictions, due to local inhomogeneities in temperature distribution. Consequently, test measurements are necessary for the correct evaluation of a specific installation site.

What makes scintillation effects difficult to handle for communications systems is the relatively slow frequency of fluctuations in the order of a few hundred Hz or less. The corresponding downtimes for a link can range from 1 ms to 10 ms, or even up to seconds. This is magnitudes higher than typical downtimes in standard communications links and cannot be compensated by standard forward error correction systems. One possibility to reduce the influence of scintillation is the method of aperture averaging, whereby multiple beams originating from slightly different positions are deployed and targeted at the same receiver. Assuming that the variation in each of the separate beam paths is random and uncorrelated, the signal-to-noise ratio will decrease by the square root of the number of beams. Recent experiments have impressively demonstrated this effect and allow reduction of intensity fluctuation to an acceptable level.

Another alternative to decreasing the scintillation effects is in the application of longer wavelength FSO systems. Whereas beam wander is relatively independent from the wavelength, scintillations effects scale with $\lambda^{7/6}$, as turbulences smaller than the wavelength cannot obscure its beam front. Using a 2 times longer wavelength, for example, should have the same impact as signal averaging with 4 different beams.

Beam Spreading and Pointing

Based on optical diffraction theory, the beam leaving the emitter optics will be divergent and its beam diameter will consistently increase during transmission through the optical channel. Assuming an optimal alignment and using standard geometrical optics, the losses due to beam spreading can estimate the ratio of emitted power (P_E) to received power (P_R):

$$R_{BS} = \frac{P_R}{P_E} = \frac{D_R}{(D_E + L\theta)} \qquad [5]$$

where D_R is the diameter of the receiving optics, D_E the diameter of the emitting optics, and θ the divergence of the beam. The minimal divergence of the beam is typically determined by the light source and is given by $\theta_L = \lambda / D_L M^2$, where D_L is the initial size of the laser beam and M^2 the laser-mode structure parameter, for a typical semiconductor laser θ_L below 0.1 mrad. In many cases, the divergence of the emitted beam is commonly enlarged by slight defocusing of the emitting optics – if the power budget allows for the additional losses. The beam size at the receiver is typically several times larger than the receiving aperture, which not only eases the alignment of the system, but also reduces pointing losses. This includes the effect of beam wander due to turbulence as well as swaying of the buildings or the mount. If those effects are solely compensated for by an increased beam spread, divergence can easily reach values of 2–20 mrad for short-distance links. Obviously this is not an option for longer-distance FSO links, as the losses will increase dramatically. In these cases, active tracking systems are incorporated in the emitter optics allowing for continuously adjustment to achieve and keep an optimal alignment. Typical tracking devices are thereby based on servo-driven Gimbal mounts, steering mirrors, or recently, MEMS devices.

Laser Eye Safety

As the atmospheric transmission channel of most FSO systems is not completely isolated, there exists the possibility of a human person intercepting the beam. To allow for this, most FSO systems are designed to be eye-safe following the voluntary ANSI standard, which limits the output irradiance to a certain value depending on the deployed wavelength. As radiation below 1400 nm is still being focused on the retina, it causes a higher irradiance, which results in a lower damage threshold. For 800 nm laser systems, the minimum permissible exposure (MPE) level for a 10 s long exposure is therefore recommended not to exceed 1 mW cm^{-2}, whereas for 1.55 μm or longer wavelength systems, an MPE of 100 mW cm^{-2} is suggested. The recommendations for incoherent light sources such as LEDs are thereby less stringent as they cannot be focused quite as strongly as laser light.

The Light Source

Following the discussion above, the optimal light source for FSO system should be emitting at a wavelength away from any absorption line (or should be much broader then the absorption line), have a relatively long wavelength as well as a relative low divergence, be eye-safe, and allow for high modulation speed. In reality, most FSO systems use either GaAsAl laser diodes or LEDs emitting at 0.8 μm, or the typically more expensive 1.5 μm laser diodes

based on the InGaAsP semiconductor system. The output power of both laser systems is typically in the range of 1 mW to 100 mW, which for the longer wavelength case can be boosted to 1–10 W using erbium-doped fiber amplifiers (or even higher for specific applications). The longer wavelength system has the additional advantage of higher ANSI standards as discussed above, allowing stronger eye-safe emission power, but is typically far more expensive.

Both laser types were developed and optimized for standard fiber-based communication systems allowing direct modulation up to 10 Gbit/s. To achieve higher bandwidth in FSO systems, standard techniques known from fiber-based networks can easily be deployed, like wavelength division multiplexing which increases the bandwidth up to state-of-the-art levels of fiber-based networks.

Contrary to semiconductor lasers, LEDs provide a much less expensive alternative, but allow only for modulation up to 10–100 MHz. Their broad emission spectrum is thereby an advantage, as it is less sensitive to sharp absorption lines which – as discussed earlier – can have a drastic impact on the FSO link performance. Consequently, LEDs have been successfully implemented in several commercial FSO systems targeted at the short-range market.

Recently developed sources, which have also been applied for FSO systems, include vertical-cavity surface-emitting lasers as well as quantum cascade lasers (QCL) which emit in the mid-infrared regime. The latter devices have been predicted to have a strong impact on the FSO market, as they combine high-output power (up to 1 W) together with fundamentally high modulation bandwidth (2.5 Gbit/s recently demonstrated and higher rates predicted) at wavelengths ranging from 3.5 μm to 12 μm and beyond. They can access the long-wavelength atmospheric window atmospheric for the FSO systems (typically reserved for CO_2 lasers) with the convenience of direct semiconductor lasers like direct electrical modulation, small size, and low power consumption. Recently, first FSO experiments, employing experimental QCLs, demonstrated the predicted higher stability of the link in low-visibility situations, including strong fog as well as high dust concentration. Nonetheless, to date the high cooling requirement for QCLs restricts more general use of them, but their very fast development, recent reports of cw-operation of room-temperature QCLs as well as FSO links with TE-cooled QCLs in pulse operation, give hope for a solution to this problem.

The Detector System

Once the light reaches the receiver, it is typically collimated using a short focal length telescope or a single lens system. To optimize efficiency without sacrificing ease of alignment a compromise has to be made between a wide aperture for greater light collection and a short focal length. The concentrated light then hits the detector, which, depending on the wavelength, is either Si or InGaAs-photodiodes. Si-based devices can detect up to wavelengths of 1100 nm and InGaAs systems are typically used for the 1.5 μm region, respectively. To enhance the sensitivity of the detectors, avalanche photodiodes are preferred which internally enhance the detected signal by a factor ranging from 20 to 100. To ensure high bandwidth operation (10 MHz–10 GHz), the size of the detecting device has to be kept relatively small (20 to 100 μm) avoiding parasitical capacitance effects – but raising the requirement on the detecting optics.

The sensitivity of these NIR detectors is typically limited by the shot-noise, which is due to statistical fluctuations of the received phonons and scales with the square root of its number. For practical purposes the internal noise of the detector is quantified using the corresponding amount of incident optical power leading to a comparable signal. The values for this noise equivalent power (NEP) can range from microwatts to tens of nanowatts. Other sources for detector noise can include a background current from the detector–amplifier combination, typically referred to as Johnson noise.

Mid-infrared detectors are additionally objected to strong background radiation due to thermal emission, which peaks around the 10 μm at temperature of 300 K. The use of additional cold filters and high-resolution spectral filters can help to overcome this restriction, but still the sensitivity of those detectors is lacking compared to NIR systems.

For communication system the noise is more commonly quantified as bit error rate (BER), quantifying the average percentage of wrongly received bits (submitted '1', detected '0' or vice versa). A BER greater than 10^{-9} is usually referred to as an error-free system, as the residual errors can be corrected employing forward error correcting algorithms. In contrast, the performance of FSO systems can more easily be measured in its signal-to-noise ratio (SNR). Following standard communication theory, a peak SNR of 12 and an average SNR of 6 is required to achieve a BER of 10^{-9}, guaranteeing error-free communication. Consequently range limits for FSO links are typically based on SNR = 6.

Link Budget and FSO Range Equation

Classical link budget estimation is a commonly used tool to access the performance of FSO systems. To take into account the losses due to atmospheric absorption, scattering, turbulence, and beam spreading, as well as optical losses in the used receiver and emitter optics, they are deducted from the starting power emitted from the FSO light source. The estimated intensity at the detector is then compared with the intensity needed to establish error-free communication (for example SNR = 6), the calculated difference is the link margin of the specific system, i.e., the amount of additional losses under which the FSO link will still be working.

Comparing this number to losses from nonpredictable fluctuations (like heavy rain or fog) gives an insight under which implications the link will fail. Using weather station data, the frequency of such extremely low-visibility occurrences can be obtained and a number for the reliability of the FSO link be estimated. Typical well-installed FSO systems estimate very high reliabilities, between 99.9% and 99.999%, which have been obtained in installation and verified in long-term measurements.

Another way to estimate the performance for a given system is based on the FSO range equation, where the received power on the detector (P_R) is calculated to

$$P_R = P_E \frac{D_R}{(D_E + L\theta)^2} TK \exp[-\alpha L] \qquad [6]$$

T denotes the optical losses of the transmission and receiver system, and K denotes additional losses for incoherent lights sources and is given by the ratio of LED emitting area to detector area, and is $K = 1$ for laser light sources. This equation can also be used to estimate losses for different weather situations and obtain the maximum range L of a specific FSO system.

Recent Research and Future Considerations

Existing FSO systems have impressively demonstrated their versatility and stability, as well as their seamless integration into existing networks, on multiple occasions. A prime example is the re-establishment of communication links between Merrill–Lynch Brokerage and Wall Street in New York, in the aftermath of the terrorist attack on September 11th, which destroyed one of the central fiber optic hubs in downtown Manhattan. The installation of a commercial FSO system by Terabeam ensured a fast replacement and a stable continuation of their work.

The demonstrated performance of such links compares to standard fiber-based links. The inclusion of wavelength division multiplexing as well as other standard or nonstandard techniques in FSO systems proves the strengths of a system, which is based on identical hardware for emitter and detectors as fiber-based networks. Nonetheless, FSO allows a multitude of applications not possible in fibers, which current research projects are targeted at. This includes, for example, long wavelength FSO communication systems, continuously ground-satellite links and free-space quantum communication for extreme secure data transmission – to list only a few of the possibilities. One very obvious example is extreme wavelength division multiplexing, which uses one link operating in all atmospheric windows at the same time. Such a FSO system would not only allow very high data rates and extreme stability against weather effects, but could also employ new kinds of wavelength-based modulation and encoding schemes increasing the security of the data link. Concluding the actual state of the FSO system as well as ongoing research, free space optical communication has all the ingredients needed to be one of the mayor key ingredients of future networks – and based on the increasing demand of bandwidths they will contribute strongly.

List of Units and Nomenclature

c	speed of light
C_n	refractive-turbulence structure coefficient
D_E	diameter of the emitting optics
D_R	diameter of the receiving optics
I	intensity
L	range (i.e., distance between emitter and detector optics)
m	mass
M^2	laser-mode structure parameter
N_s	concentration
P_E	emitted power
P_R	received power
q	charge
T	optical losses of the transmission and receiver system
V	visibility
α	extinction coefficient
ε_0	dielectric constant
θ	divergence of the light beam
λ	wavelength
λ_0	natural oscillation wavelength
σ_s	scattering cross-section

Introduction

Optical fiber telecommunications has changed human society forever, providing the capacity for affordable and ubiquitous communication. It provides data rates and transport economies far in excess of those available using purely electronic means. It is doubtful whether the Internet and worldwide web, or the vast infrastructure of wireless cellular telephony, would be viable without optical fiber technology. Its rapid development and acceptance has been driven largely by contemporaneous successes in manufacturable low-loss optical fiber cables, sensitive pin-FET photoreceivers, and reliable high-performance laser diode-based transmitters. The earliest developments in silica glass fibers at Standard Telecommunication Laboratories, UK, (then part of the US-based ITT Corporation) and Corning Glass Works (USA) in the 1960s and 1970s, were pivotal in determining the directions of modern fiber technology, as were later key inventions of rare-earth doped fiber amplifiers at the University of Southampton (UK) and AT&T Bell Laboratories (USA) in the 1980s and early 1990s. However, perhaps the greatest contributors to the success of fiber optics have been semiconductor injection lasers, or laser diodes, which in various forms have made up the vast majority of all fiber optic transmitters, and the entirety of long-haul transmitters, as well as pump sources for the doped-fiber amplifiers which enable modern networks. The fascinating story of the development of fiber optics is to a large extent driven by the dramatic progress in the development of high-performance, reliable semiconductor lasers. These emitted at wavelengths near 1300 and 1550 nm, which respectively correspond to the dispersion and attenuation minima of single-mode silica optical fibers.

Semiconductor Laser Principles

Semiconductor lasers were first demonstrated in research laboratories at General Electric, IBM Corporation and the MIT Lincoln Laboratory (all USA) as early as 1962, although it took almost two decades for the basic science and engineering of materials, fabrication, reliability, and performance design issues to be developed sufficiently for their use in practical communication systems. Early successes were obtained using the GaAs/AlGaAs lattice-matched material system, in which a lightly doped GaAs or ternary compound AlGaAs active layer is sandwiched between two lattice-matched heterojunctions with n- and p-doped AlGaAs layers with higher Al fractions than the active layer, so that their refractive indices are lower and their bandgaps higher, providing optical and charge-carrier confinement. In all cases the material is epitaxially grown, meaning that the entire laser chip forms a single crystal. The gain, and hence the laser emission, occurs at the direct bandgap of the active layer, at wavelengths in the range 750–870 nm depending on the Al fraction.

Later evolutions used the quaternary compound GaInAsP clad by InP guiding layers, where the In and P fractions are chosen to match the lattice constant to the InP substrate.

In general, optical gain in a laser diode is generated by creating an electron-hole plasma in the vicinity of the forward-biased junction, a situation corresponding to population inversion in a conventional laser, and with sufficient forward current the material becomes transparent, in that the gain exactly equals the absorption and scattering losses, at a particular wavelength. When this arrangement is enclosed within a suitable optical cavity, and the forward current is increased further, the system begins to lase, that is to oscillate continuously to produce coherent optical radiation at a wavelength which satisfies two basic conditions: it must be within the set of wavelengths at which the material produces sufficient gain, and it must be close to one of the electromagnetic modes at which the optical cavity is resonant. These conditions, which define lasing threshold, are characterized by the equality of the optical gain and the total losses, that is the material losses (absorption, scattering, and free-carrier plasma) and the cavity losses which include the light output.

Early laser diodes in both the GaAs/AlGaAs and GaInAsP/InP systems were of the edge-emitting type, in which the light is emitted from the edge of the laser chip, perpendicular to the growth direction in the plane of the wafer. Although this geometry complicates laser production flow, particularly the testing function which requires that the wafer be scribed into bars to define the laser output facets, edge-emitting lasers (EELs) make up the vast majority of optical fiber transmission sources. An alternative laser diode structure is the vertical cavity surface-emitting laser (VCSEL), in which emission occurs in the growth direction perpendicular to the plane of the wafer. VCSELs offer major advantages in spectral stability, beam quality, manufacturability and cost, but their output powers are low (a few mW) and they are not yet available at the key telecommunication windows around 1300 nm and 1550 nm, due to difficulty in forming the necessary high-reflectivity Bragg mirrors in the GaInAsP/InP material system. Major initiatives are currently underway to produce long-wave VCSELs in the GaAs/AlGaAs system using InAs quantum dots, or dilute nitrides such as InGaAsN, or hybrid approaches such as InP-based gain media fused to high-reflectivity mirrors using GaAs/AlGaAs, dielectric coatings, air gaps, and others. At present, however, all long-haul optical fiber transmission is based on edge-emitting laser diodes fabricated in GaInAsP/InP.

General Structure and Requirements of Optical Fiber Communication Systems

The first optical fiber communication links were simple point-to-point affairs, consisting essentially of series-connected transmitters, fibers, and receivers. The transmitters were simple Fabry–Perot laser diodes, onto which data were encoded by direct digital modulation of the injection current at rates ~100 Mbit/s. The first commercial optical fiber link was built in 1976, a single fiber cable linking two switching centers of the Illinois Bell Telephone Co just 2.5 km apart in the Chicago metropolitan area, using 850 nm GaAs laser technology. In 1988, the first transatlantic fiber link, AT&T's TAT-8, was completed linking endpoints in New Jersey, England, and France with three fiber pairs carrying signals generated by 1300 nm GaInAsp single mode lasers. In these early systems, data were regenerated frequently by repeaters each consisting of a receiver, signal conditioner and transmitter. Each fiber in TAT-8 carried a single optical frequency modulated at 280 Mbit/s and the construction cost of the system was ~$50 k/km, resulting in an economic figure of merit of over $600 k/Mbit/s. Twenty-five years later, current systems cost the same per kilometer to build in absolute dollars despite inflation, a major effective cost reduction enabled largely by replacement of the expensive repeaters by doped-fiber optical amplifiers. Moreover, each fiber is now highly multiplexed, with the potential for hundreds of wavelengths each carrying 10 Gbit/s signals generated by 1550 nm laser transmitters, so that the unit cost has plummeted to ~$200/Mbit/s, a reduction of three and a half orders of magnitude.

In the remainder of this article, we will describe transmitters for both short- and long-haul systems where the channel spacing is only tens of GHz in the optical carrier frequency. Modern short-haul systems either feed client networks as part of bi-directional transceivers, or drive metro and local access networks connected directly by photonic switches to terminals of the long-haul systems.

DWDM Transceivers

Modern practice uses modular units containing transmitters and receivers allowing bi-directional data flow. In the send mode, data are applied to a long-haul transmitter at the local (client) source and coupled through the external fiber network to the remote long-haul receiver. In the receive mode, data arrive from a remote long-haul transmitter and are coupled (via a regenerator including signal

conditioning, clock recovery, and error correcting steps) to a local short-haul transmitter leading to the client's internal network. Each transceiver card therefore contains a long-haul transmitter and receiver set (known collectively as dense wavelength division multiplexing (DWDM) transport devices) and a short-haul transmitter and receiver set (known as client interfaces or local transport devices).

Transmitter Requirements

Short-haul transmitters may be simple Fabry–Perot edge-emitting laser diodes, or vertical cavity laser diodes, or even superluminescent LEDs for sub-Gbit/s data rates. They are generally not required to be at one of the minimum-loss telecom windows near 1550 nm, as the transmission distances are short. However, as client networks grow into large metropolitan networks, it is likely that 1300 nm sources will be used to minimize dispersion. Power requirements are modest, a few mW peak, at data rates ~1–10 Gbit/s. Single mode laser emission and polarization control are not required by present day systems, although polarization-mode dispersion may limit transmission at higher data rates. Both return-to-zero (RZ) and nonreturn-to-zero (NRZ) coding may be used, and direct modulation of the laser amplitude is the norm.

For long-haul transmitters the situation is dramatically different. Operation in one of the standard erbium-doped fiber amplifier (EDFA) bands near 1550 nm is mandatory: the C (conventional) band extends from 1530–1565 nm, the S (short-wave) band from 1460–1530 nm) and the L (long-wave) band from 1565–1625 nm. In the C-band, output powers ~10 mW are generally sufficient, and powers above ~30 mW are limited by nonlinear effects such as self-phase modulation and four-wave mixing in the fiber. In the S- and L-bands, where the available gain from EDFAs is less, lasers may need to operate close to the nonlinear limit, several tens of mW, although various schemes (differential pumping, gain-flattening filters, etc.) are being evaluated to flatten the global EDFA gain spectrum.

In current practice, a single fiber utilizing DWDM, using only the C-band, can carry up to 1 Tbit/s comprising 100 channels at 10 Gbit/s on each channel, the current standard. For such performance a channel spacing of 50 GHz in optical frequency is required. Using all three bands with similar density would enable ~3 Tbit/s, which could be doubled by using 25 GHz channel spacings. Ultimately, even higher channel densities and hence overall system data rates are possible, with a practical limit ~10 Tbit/s. The channel spacing is a key parameter in that it determines the laser design, specifically its spectral stability and linewidth, and the overall transmitter design in that laser chirp (modulation induced dynamic spectral shift) must be less than half the channel spacing. In practice, only single-wavelength and coarse wavelength division multiplexing (CWDM) systems may be modulated directly. All modern DWDM systems require external modulation, for example using electro-absorption or Mach–Zehnder interferometric devices outside the laser cavity. For the latter cases, stabilization of the laser wavelength is required for example by on-chip gratings to form distributed feedback (DFB) or distributed Bragg reflector (DBR) lasers, or by external fiber gratings.

Directly Modulated Lasers

Direct modulation of semiconductor lasers is convenient and effective: by modulating the laser injection current, one modulates the carrier density and hence the optical gain, resulting in modulation of the laser output up to ~10 Gbit/s. The actual modulation bandwidth is determined by interactions between photons and carriers, whose respective decay lifetimes, τ_s and τ_p, are determined by cavity losses and total recombination rates. The simplest form of such interactions is described by the photon and carrier rate equations for the injected carrier density N and photon density S in a single lasing mode:

$$dN/dt = J/ed - gNS - N/\tau_s \quad [1]$$

$$dP/dt = gNS + \beta N/\tau_s - S/\tau_p \quad [2]$$

where J is the injected current density, e the electronic charge, d is the thickness of the active region (hence J/ed is the rate of injection of carriers per unit volume), g is the gain coefficient per unit length and β is the fraction of the spontaneous emission coupled into the lasing mode, typically $\sim 10^{-2}$–10^{-5} for edge-emitting lasers (product of geometric and spectral overlap factors). These equations simply state that the rate of change of the carriers or photons is given by the rate of generation less the loss rate. Additional terms are required in the presence of optical feedback or coupling (in which case the photon density is replaced by the complex amplitude and phase of the optical electric field) or for extremely rapid modulation where the traveling wave nature of the disturbances in the photon fields is significant. These so-called traveling-wave rate equations for the photons are of the form:

$$dS_+/dt + cdS_+/dz = gNS_+ + \beta N/\tau_s \quad [3]$$

$$dS_-/dt - cdS_-/dz = gNS_- + \beta N/\tau_s \qquad [4]$$

with the same carrier rate equation as [1] using the total photon number S made up of the forward-traveling component S_+ and the backward-traveling component S_- : $S = S_+ + S_-$.

Both sets of rate equations are based on approximations such as homogeneous gain broadening, neglect of transverse field effects, and diffusion. These are valid in most situations but care is required when analyzing lasers with large transverse apertures, or when ultrashort (picosecond) pulses are involved.

Small-Signal Modulation

Small-signal modulation may be analyzed by a linear perturbation analysis of the rate equations, leading to a conjugate pair of poles in the response function, with damped relaxation oscillations at frequency:

$$f_R = (1/2\pi)\sqrt{(gS_0/\tau_p)} \qquad [5]$$

or, in terms of the injected current density J (assuming $S \sim G(J - J_{th})/ed$ with Γ the electromagnetic confinement factor of the mode):

$$f_R = (1/2\pi)\sqrt{[\Gamma g(J - J_{th})/ed]}$$

f_R can be regarded as the resonant frequency for the interaction between the carriers and photons. As a practical matter, lasers can be modulated up to $\sim 2f_R$ but the modulation response rolls off rapidly with increasing frequency above f_R. Using explicit expressions for the threshold gain, we can write f_R as:

$$f_R = (1/2\pi)\sqrt{[(GN_T g\tau_p + 1)(J/J_{th} - 1)/\tau_s\tau_p]} \qquad [6]$$

where N_T is the transparency carrier density $\sim 10^{18}\,\mathrm{cm}^{-3}$. f_R can take values in excess of 10 GHz for a well-designed laser. It should be noted, however, that high modulation bandwidth almost always requires high differential gain dg/dN and short τ_p. Increasing dg/dN requires p-doping (which increases optical loss) and/or some special quantum-confining structure such as wells, wires, or dots. Decreasing τ_p inevitably leads to greater optical loss and thus a higher threshold.

The damping rate of the relaxation oscillations is also important in limiting modulation bandwidth, and also (when increased) in reducing the sensitivity of the laser to optical feedback. For bulk or quantum well lasers, the condition for critical damping is $A^2 = 4B$ with $A = (S/g\tau_s) - \sigma[N - N_T]/g\tau_p$ and $B = \sigma[1 + (S_0/g\tau_s) - (1 - \beta)(N - N_T)]$. For quantum dot lasers there are additional damping terms due to carrier transport and thermalization which may restrict small-signal modulation bandwidths to a few GHz.

Experimentally, small-signal modulation properties may be determined using a simple sampling oscilloscope, low-noise tunable signal generator and spectrum analyzer. A combination of these elements with automated frequency sweeping may be found in a scalar network analyzer acting as an *s*-parameter test set. The modulated laser is connected to port 1 and a high speed photodetector connected to port 2, then a swept-frequency measurement of the transfer characteristic s_{21} is performed. In addition to the limitations on modulation response due to the carrier-photon resonance, practical lasers are limited by RC parasitics in the laser chip (junction impedance) and its package. For the highest modulation speeds, packages need to be designed as microwave transmission line components with effective impedance matching and low back reflections, as characterized by the voltage standing wave ratio (VSWR).

Large-Signal Modulation

Large-signal direct modulation can be analyzed by numerical integration of the rate equations. In general, its results are beyond the scope of this review, but for effective high-speed response, digital modulation of laser diodes should be carried out with a pre-bias close to threshold. Modulation bandwidth also increases with laser power, which is limited for systems considerations by fiber nonlinearities, and for reasons of laser reliability. In pulse code modulation, care must be taken that the laser is near critical damping, to minimize thermal patterning effects due to long strings of ones (high power) or zeros (low power). Experimentally, large signal modulation is analyzed by constructing eye diagrams, in which pulse traces on a fast oscilloscope are continuously overlaid when the laser is modulated using pseudorandom binary pulses. When the signal quality is high, the high and low digital levels are easily distinguishable, resulting in an open 'eye' in the accumulated traces.

Requirements for Externally Modulated Lasers

The requirement for external modulation occurs when the laser chirp exceeds half the desired channel spacing in the communication system. Chirp occurs due to changes in the refractive index, and hence the optical phase, during modulation. This dynamic phase shift then results in an instantaneous frequency shift.

For direct modulation we have instantaneous wavelength

$$\lambda(t) = \lambda(0)(\mu(t)/\mu(0) \quad [7]$$

Where $\mu(t)$ is the refractive index at time t. μ shifts with carrier density N due to combinations of several factors (free carrier plasma dispersion, thermal bandgap shrinkage, bandgap renormalization, dynamic Burstein–Moss effects) which give $d\mu/dN \sim -3 \times 10^{-20}\,\text{cm}^3$, which for large signal digital modulation can result in tens of GHz. The actual degree of chirp depends on the so-called antiguiding or linewidth enhancement factor a given by

$$\alpha = -2k_0(d\mu/dN)/(dg/dN) \quad [8]$$

where $k_0 = 2\pi/\lambda_0$ is the free-space wavenumber. α as defined is positive, typically in the range 2–7 depending on the material, operating carrier density, and wavelength relative to the gain peak. Distributed feedback (DFB) or distributed Bragg reflector (DBR) lasers, which use integrated gratings to control the lasing wavelength, can have lower chirp by detuning from the gain peak but therefore are likely to require careful temperature stabilization. Quantum dot lasers, based on 3D nanoclustered active regions, have the potential for very low chirp, narrow linewidths, and reduced wavelength shifts, so that directly modulated DWDM transmitters may be possible.

Integration of laser diodes with electro-absorption or Mach–Zehnder type modulators is achieved in the transmitter optical subassembly and may in some cases be accomplished by monolithic integration on the same chip. Using separate modulators allows each device to be optimized independently but requires optical assembly, alignment, and retention. Mach–Zehnder modulators in X-cut lithium niobate, for example, have essentially zero chirp and can operate to 40 Gbit/s and above, with dynamic extinction ratios (ratio between fully on and fully off) of ~20 dB. Integrated semiconductor M-Z modulators have chirp an order of magnitude less than those of directly modulated lasers, so that channel spacings ~25 GHz are possible in DWDM systems with suitable temperature and wavelength controls. Although the details of such modulators are beyond the scope of this article, the laser requirements are to generate ~10 mW of continuous power with stable center wavelength and narrow linewidth. Such lasers are usually mounted in hermetic packages (e.g., the current 14-pin butterfly standard) with integrated thermo-electric cooler, power monitor photodiode, an optical isolator to suppress optical backreflections which cause instabilities and self-pulsing, and optional wavelength locking optics.

Reliability of Lasers in Fiber Optic Systems

From the early days, when laser diode lifetimes were measured in seconds even at cryogenic temperature, enormous progress has been made in achieving materials purity and reducing crystalline defects. Today's fiber optic laser transmitters have projected lifetimes of decades. In common with electronic devices, diode lasers fail at a rate given by a 'bathtub' curve, that is the failure rate $r(t)$ defined as the probability of failure per unit time at time t, has relatively high values at low t (early failures) and high t (wearout failures) and very low values in between. In terms of the population of lasers $n(t)$ we have:

$$r(t) = (-1/n(t))\, dn(t)/dt \quad [9]$$

If Δn is the number of samples which fail in time Δt, then assuming Δt begins at $t = 0$, the effective or average failure rate r_{eff} over the interval is

$$r_{\text{eff}}(t) = \Delta t \Delta n/n(0) \quad [10]$$

In reliability science it is customary to define r_{eff} in FITs (failures integrated in time) with the time-span chosen to yield statistically significant numbers. For electronic and photonic devices, it is customary to select the time interval $\Delta t = 10^9$ h (1 billion operating hours), so that if 1% of the devices fail in 10 years ($\sim 10^5$ hours) we have $r_{\text{eff}} \sim 100$ FITs, which is the order of magnitude required by modern fiber optic laser sources.

In terms of actual statistical models, failure rates can be estimated using failure probability density functions $f(t)$. This is related to $r(t)$ by $f(t) = r(t)S(t)$ where $S(t)$ is the cumulative probability of surviving until t. When $r(t)$ is nearly constant, as in early failures due to material defects or process errors, the statistics are approximately exponential:

$$f(t) + (1/\tau) \exp(-t/\tau) \quad [11]$$

or Weibull-distributed (an exponential is a Weibull distribution with $\beta = 1$):

$$f(t) = (\beta/t^{\beta})t^{b-1} \exp[-(t/\tau)^b] \quad [12]$$

but this description is not suited to wearout failures for which $f(t)$ shows a significant increase as the population ages. For such cases, the lognormal distribution is often applicable:

$$f(t) = (1/\sigma t\sqrt{(2\pi)}) \exp[-(\ln t - \ln \tau)^2/2\sigma^2] \quad [13]$$

where in each case τ is approximately the mean time to failure (MTTF).

Laser diodes undergo standardized qualification tests to demonstrate sufficient reliability prior to being used in commercial systems. Operationally, failure statistics must be tabulated and the best fit obtained. Burn-in procedures are used to screen early failures. Chip and module failures should be distinguished clearly, as the latter includes many additional factors such as thermal and power management, light coupling, mechanical or chemical integrity.

Given that effective lifetimes of decades are required, it is clearly necessary to accelerate aging to produce statistically meaningful failure rates in reasonable times $\sim 10^3$ h. For the most common modes of laser chip degradation, due to recombination-induced aggregation of defects in the crystalline epitaxial material, these are thermally activated and current driven, so that it is customary to use a modified Arrhenius law at temperature T:

$$\tau \sim (1/J^n) \exp(E_a/k_B T) \qquad [14]$$

where J is the operating current density, n is an index ~ 2, E_a is the activation energy, and k_B is Boltzmann's constant. In terms of thermal acceleration, we have a factor $F = \tau(T_A)/\tau(T_B)$ with:

$$F = \exp[(E_a/k_B)(1/T_A - 1/T_B)] \qquad [15]$$

Typical values of E_a for laser diodes are ~ 1 eV so that acceleration factors $\sim 10^3$ are possible.

Finally, it should be noted that laser diodes are generally subject to catastrophic failure in the event of overdriving or static discharge, the failure mode being thermal facet damage at $\sim 1-10$ MW/cm^2 for continuous-wave operation, the exact value depending on the material, surface preparation and specifically surface state absorption and its temperature coefficient.

Conclusions

Laser diodes are ideal sources for optical fiber communication systems and have propelled the development of fiber optics from its origins in the 1960s to the present day. They are compact, rugged, efficient, and reliable sources of light at key wavelength ranges such as 1300–1310 nm (short haul high speed links) and 1500–1600 nm (long haul amplified systems). They are capable of direct modulation at gigabit rates for simple systems but require external modulation and careful wavelength control for dense wavelength division multiplexed terabit systems. Transmitter lasers for real systems must satisfy stringent reliability conditions.

Local Area Networks

E Wong, University of Melbourne, Melbourne, VIC, Australia

Introduction

Local area networks (LANs) are privately owned networks that are used to carry internal traffic loads within an organization. A LAN may exist on many levels categorized by its application and speed. This is illustrated in **Figure 1** whereby, at the simplest requirement, a low-speed LAN may be used to interconnect a cluster of personal computers and workstations. Such a scenario may exist in a department within a university campus, or a building within a technology park. If need be, these individual departmental or building LANs may be interconnected using a moderately high-speed backbone LAN. The backbone LAN may also provide interconnection to servers which support mass storage devices that are shared by the individual lower speed LANs. In larger organizations, a much higher speed LAN is linked to the backbone LAN to support bulk data transfer between mainframes, supercomputers, and other office equipment.

The common transmission mediums for traditional low-speed LANs are coaxial cable and twisted pairs. High-speed backbone LANs advocate the use of the optical fiber. The continuing progress in fiber-optic technology and devices, and the availability of appropriate standards have given rise to LANs that can span distances of hundreds of kilometers or more, and that operate at data rates in the order of hundreds to thousands of megabits per second (Mb/s).

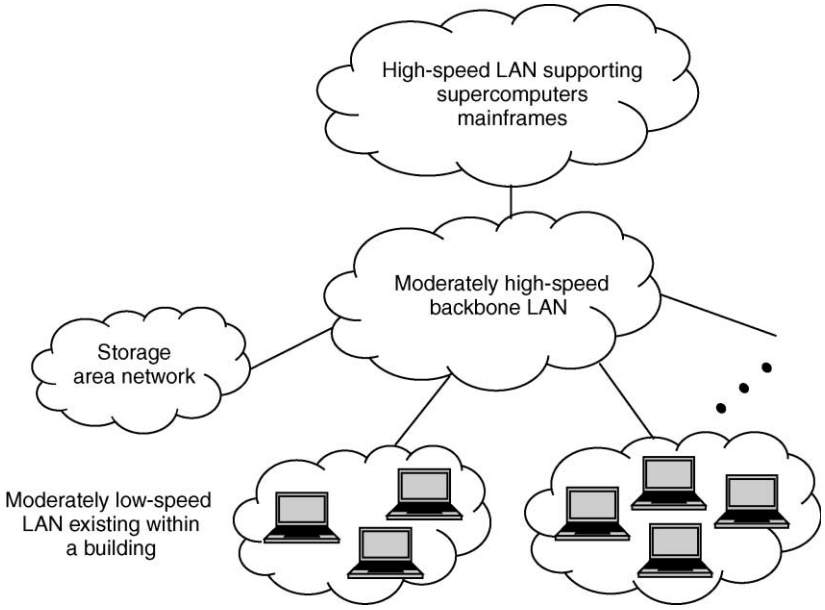

Figure 1 Interconnection of local area networks (LANs).

The increase in demand, to extend LAN capabilities towards higher data rates and across larger geographical areas, is fueled primarily by the need to provide new bandwidth intensive services such as multimedia teleconferencing, image processing, and streaming video, to a significantly higher number of end-users.

This article focuses on three existing fiber-optic LAN standards, namely Ethernet, Fiber Distributed Data Interface (FDDI), and Distributed Queue Dual Bus (DQDB). While the current uses of FDDI and DQDB are not as widespread as Ethernet, both standards have significantly contributed to the initial deployment of fiber-optics for LAN applications, with standard-based products still commercially available. In general, standards are required to ensure interoperability between components and equipment from different vendors and suppliers. Two key features are addressed by the standards: the physical topology, and the medium access control (MAC) protocol. A network's physical topology defines the way in which the users, or nodes, are interconnected to each other and to the transmission medium. Common optical LAN topologies are the star (e.g., Ethernet), bus (e.g., DQDB and Ethernet), and ring (e.g., FDDI). In comparison, the MAC protocol controls network access such that its capacity is efficiently and fairly shared amongst all nodes.

Access control can be either centralized or decentralized. In the former, a node wishing to transmit must wait until it receives permission from a controller, whereas in the latter, nodes collectively determine the transmission order. Further, capacity allocation to each node can be either synchronous or asynchronous. The synchronous approach guarantees a specific capacity to each node, e.g., using time division multiple access (TDMA), whereby nodes are allowed to transmit only during a designated time slot. In contrast, the asynchronous approach allows capacity to be dynamically allocated to each node. The asynchronous approach can be further categorized into round robin, reservation, and contention schemes. With round robin, nodes take it in turn to transmit in a cyclic manner and a node may transmit up to a maximum amount of data during its turn. With the reservation scheme, time on the medium is divided into slots, and a node wishing to transmit must reserve future slots by transmitting additional control information into the network. With the contention scheme, nodes randomly access the network. The Ethernet standard, discussed in the following section, is based on the contention scheme.

Ethernet

Overview

The IEEE (Institute of Electrical and Electronics Engineers) 802.3 standards committee first standardized 10 Mb/s Ethernet in 1985. It is now the most widely used technology for high-speed LANs, with standards extended to cater for operating speeds of 100 Mb/s, 1 Gb/s and 10 Gb/s, and encompassing the use of the optical-fiber transmission medium. Low-speed 10 Mb/s and 100 Mb/s Ethernet LANs use the

carrier-sense multiple access with collision detection (CSMA/CD) MAC protocol, whereas a switched technique is used for the 1 Gb/s and 10 Gb/s options.

In CSMA/CD, a node wishing to transmit an Ethernet frame first listens to the transmission medium by detecting the presence of signals on the channel (i.e., carrier-sense). This process allows the node to determine if another transmission is in progress. If the medium is in use, the node continues to listen until the medium is idle, and then transmits immediately. While transmitting, the node continues to listen to the medium. It may happen that two or more nodes may attempt to transmit at the same time. If this occurs, there will be a collision, and data from both transmissions will become garbled.

A collision can be indicated by a combined signal that exceeds a predefined CD threshold voltage at the carrier-sense receiver, taking into account the collision between frames from nodes that are located furthest apart. If a collision is detected during transmission (i.e., collision detection), the transmitting node ceases transmission and proceeds to transmit a brief jamming signal to notify all nodes of the collision. After transmitting the jamming signal, the node must back off before attempting to transmit the same data frame again. The back-off period is random, and is determined by a binary exponential back-off algorithm. Every time a node attempts to retransmit, the mean value of the random back-off period is doubled until the tenth attempt. After that the node is allowed to retransmit a further six times with the same mean random delay before discarding the frame and reporting an error to higher control layers.

The transmission medium remains unusable when frames collide but only until the collision is detected. As such, the minimum transmission time of a frame must be longer than the maximum propagation delay of the network so that collision is detected prior to the end of transmission. If shorter frames are used, then collision detection does not occur, and CSMA/CD thus exhibits the same performance as its less efficient predecessor protocol, CSMA. Accordingly, the CSMA/CD standards specify a minimum frame length and maximum network size, which place fundamental limitations on the practical application of a pure CSMA/CD LAN.

IEEE 802.3 10 Mb/s Ethernet

In 1993, the IEEE 802.3 committee extended the 10 Mb/s Ethernet standard to include the optical-fiber transmission medium. The standard notation of this option is 10BASE-F. Each transmission link comprises a pair of graded-index 62.5 μm core multimode optical fibers (MMF), one for each direction of transmission. The transmission wavelength is 850 nm. 10BASE-F can be further categorized into three specifications. The first, denoted 10BASE-FP (fiber passive star), specifies a broadcast star topology that can interconnect up to 33 nodes and repeaters. Each of these devices is attached to a passive star coupler via two optical-fiber links with distances up to 500 m. The passive star coupler splits the optical power of any incoming frame equally amongst its output links, allowing all nodes or repeaters in the network to receive the frame, albeit at a lower optical power level.

The second and third specifications, denoted 10BASE-FL (fiber link) and 10BASE-FB (fiber backbone) respectively, define point-to-point links over distances of up to 2 km. 10BASE-FL supports both nodes and repeaters, whereas 10BASE-FB supports only repeaters. A repeater is a device that detects the optical signals on its incoming link, performs electrical signal regeneration, and then optically retransmits the signals on its output link. Repeaters used in 10BASE-FB have an additional function in which the detected signals are retimed with a local clock before being retransmitted. This prevents the propagation of timing distortions, allowing distances of up to 15 cascaded repeater links to be implemented. The characteristics of the three specifications for 10BASE-F, along with the 100 Mb/s and 1 Gb/s specifications to be discussed in the following sections, are summarized in Table 1.

IEEE 802.3 100 Mb/s Ethernet (Fast Ethernet)

Fast Ethernet refers to the standard developed by the IEEE 802.3 committee to provide low-cost, Ethernet-compatible LANs operating at 100 Mb/s. The optical-fiber transmission medium option is denoted 100BASE-FX. Originally defined for FDDI (covered in the section on FDDI below), 100BASE-FX specifies the use of two 62.5 μm MMF links, each operating at a unidirectional rate of 100 Mb/s. While 10 Mb/s Ethernet can only operate in half-duplex mode, whereby a station can either transmit or receive a frame but cannot do both simultaneously, Fast Ethernet can operate in either half- or full-duplex modes. A node operating in full-duplex mode can simultaneously transmit and receive data frames.

In order to deploy full-duplex Fast Ethernet, all repeaters must be replaced with switching hubs. Figure 2a illustrates a repeater located in the central point in an active star topology. Each node is attached to the repeater via two optical links. The repeater retransmits frames received from any one of its input

links to all of its output links. If more than one node transmits at the same time, then collisions will occur at the repeater, as illustrated in Figure 2b. A switching hub, on the other hand, switches an incoming frame from a particular input to an appropriate output line. The same switching function can be performed simultaneously on other input–output links without interference to the frames involved, as illustrated in Figure 2c. As such, each node has a dedicated capacity equal to that of the transmission rate of the LAN, and the switching hub can support mixed capacity links, e.g., 10 Mb/s and 100 Mb/s. With dedicated access to the medium and appropriate buffering at the switch to avoid contention of the same output link, there is no need to implement the CSMA/CD access algorithm. Nonetheless, the conventional Ethernet frame format is used to ensure inter-operability between existing 10 Mb/s and 100 Mb/s LANs.

IEEE 802.3 1 Gb/s Ethernet (Gigabit Ethernet)

The IEEE 802.3 1 Gb/s Ethernet standard, commonly referred to as Gigabit Ethernet, was finalized in 1998. An example of a Gigabit Ethernet backbone LAN is shown in Figure 3, whereby a Gigabit Ethernet backbone switch connects central servers to high-speed workgroup switches. In turn, each workgroup switch supports gigabit high-performance workgroup servers, as well as 100 Mb/s workstations and hubs. As in the 100 Mb/s standard, Gigabit Ethernet uses the conventional Ethernet frame format and allows both half-duplex and full-duplex operation. For half-duplex operation, the CSMA/CD access protocol is

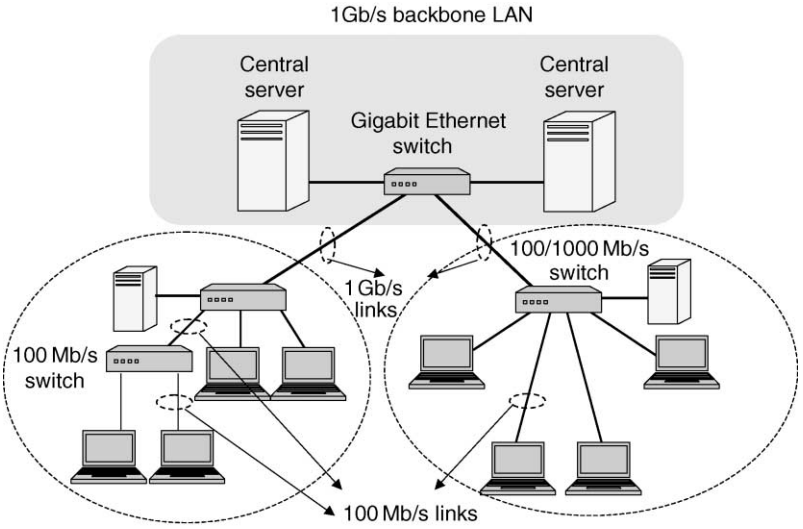

Figure 3 Gigabit Ethernet backbone network (adapted from William S (2004) *Data and Computer Communications*, 7th edn, Ch. 15–16. Upper Saddle River, NJ: Pearson Education).

equipped with two additional features. The first feature, known as carrier extension, extends the propagation time of short frames by adding nondata symbols to the end of frames. The minimum length of a frame for Gigabit Ethernet is 512 bytes as opposed to the specified minimum of 64 bytes in the preceding two standards. The second feature, known as frame bursting, allows a node to transmit multiple consecutive frames, up to a specified maximum, without having to undergo the contention process for each transmission. Both features improve the efficiency of the protocol.

There are two optical-fiber transmission medium specifications for Gigabit Ethernet. The short wavelength option, denoted 1000BASE-SX, is for 850 nm transmission. Specified maximum link distances are 275 m using 62.5 μm MMF, and 550 μm using 50 μm MMF. The long wavelength option, denoted 1000BASE-LX, is for 1310 nm transmission. Achievable duplex link distances are 550 m using 62.5 μm or 50 μm MMF, and 5 km using 10 μm SMF.

IEEE 802.3 10 Gb/s Ethernet (10GbE)

The Ethernet standard was extended to incorporate 10 Gb/s (10GbE) in 2002, fueled by ever-increasing Internet traffic and bandwidth intensive applications. 10GbE fulfills not only LAN specifications, but also metropolitan and wide-area network specifications. It is envisioned that with the emergence of 10GbE metropolitan and wide-area networks, the deployment of 10GbE LANs will enable a seamless transport of Ethernet frames across different network boundaries, thus simplifying network management and optimizing operational costs.

Unlike its predecessor standards, the physical layer options for 10GbE include only the optical-fiber transmission medium and allow only for full-duplex operation. Four specifications are defined for 10GbE. 10GBASE-S is designed for 850 nm transmission on 63.5 μm MMF, while 10BASE-L and 10BASE-LE use 10 μm single mode fiber (SMF) for 1310 nm transmission and 1550 nm transmission, respectively. The corresponding maximum achievable distances are 300 m, 10 km, and 40 km, respectively. An alternative specification, 10GBASE-LX4, is designed for wavelength division multiplexed (WDM) transmission links. The specification caters for four 2.5 Gb/s transmission channels within the 1270–1355 wavelength region on either 10 μm SMF, 50 μm MMF, or 62.5 μm MMF. Single-mode transmissions can reach distances of up to 10 km, while multimode transmissions can reach distances up to 300 m. The characteristics of these physical layer specifications are summarized in Table 2.

Fiber Distributed Data Interface (FDDI)

Overview

The Fiber Distributed Data Interface (FDDI) standard was developed by the Accredited Standards Committee X3T9.5, and approved by both ANSI (American National Standards Institute) and ISO (International Standards Organization) in 1989. While not as

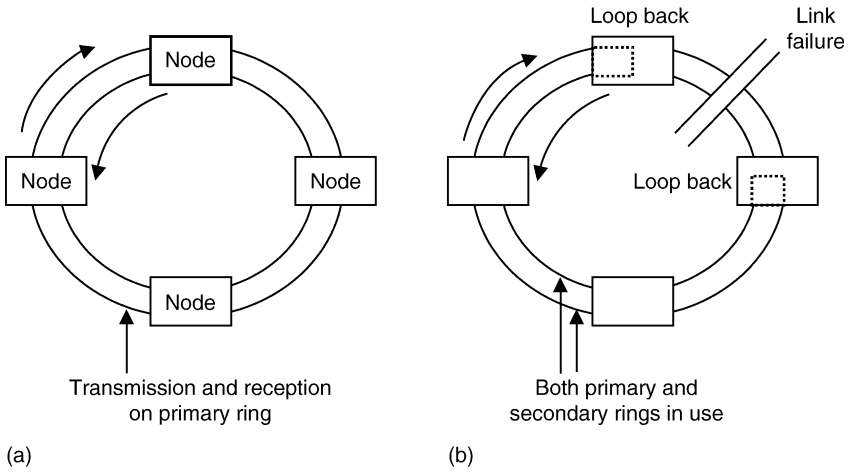

Figure 4 (a) FDDI ring network. (b) Use of secondary ring for protection against link failures.

widely deployed as the Ethernet family of LANs, due to the high cost of equipment and devices, it remains as the first to be standardized for high-speed fiber-optic LAN applications and is now mainly used to interconnect existing FDDI-compatible LANs. Extensions have been made to the FDDI standard to incorporate single-mode fiber operation for increased signal reach.

FDDI specifies a dual counter-propagating ring network as shown in Figure 4a. Each ring operates at the speed of 100 Mb/s, and can reach a maximum length of 100 km. The dual ring topology is self-healing against fiber-cuts and node failures. Under normal operation, frame transmission and reception are performed on a primary ring. The secondary ring is utilized to form a closed loop when a node or link failure occurs, as illustrated in Figure 4b. In FDDI, the interface between each node and the optical-fiber transmission medium is a repeater. Data frames, each of which carries its source and a destination address in a defined field in the frame header, are transmitted sequentially around the ring from one repeater to another. Each frame can vary in length by up to 4550 bytes. Each repeater copies the destination address field of all incoming frames and, upon recognizing the destination address as its own, additionally copies the remainder of the frame. The repeater attached to the source node also facilitates the removal of frames it has transmitted after a round-trip propagation around the ring.

FDDI employs a distributed timer-controlled, token-passing mechanism, referred to as timed token rotation protocol, to control access to the shared optical fiber ring. While Ethernet-based LANs are highly suited to support throughput sensitive services which can sustain reasonable delay in return for high throughput, FDDI provides an additional capability to support delay sensitive services such as packetised voice and video. For such services, frames must be received within a certain time interval for quality of service requirements. A node connected to an FDDI network can therefore transmit both classes of services: the former referred to as burst traffic and the latter as stream traffic. In addition, the timed token rotation protocol can limit the amount of frames that can be transmitted by a particular node for each class of service, ensuring efficient and fair network access amongst all nodes and services. FDDI is thus well-suited to carry the mixture of burst and stream traffic expected in a backbone network which supports a number of smaller LANs.

MAC Protocol

Token-passing mechanism

In FDDI, access to the shared transmission medium is governed by a timed token rotation protocol. A token is a special frame created during network (re)-initialization by a pre-assigned node. The token circulates the ring network and gives the node that holds it the right to transmit. Figure 5 gives an example of a single frame transmission from Node A to Node C, and from Node B to Node A. Node A has a frame to transmit to Node C and thus waits for a token (Figure 5a). Upon recognizing that a token frame is passing through, it aborts the token transmission without regenerating the token bits. After Node A has completely received the token, the node begins transmitting frame FA addressed to Node C, and appending a new token upon completion (Figure 5b). Meanwhile, Node B regenerates and retransmits FA as it circulates past. When FA reaches Node C, the node copies FA in addition to regenerating and retransmitting FA. Node B captures the token issued by A and transmits FB to Node A (Figure 5c). Eventually FA recirculates back to its originating node, Node A, whereby it is removed from the ring (Figure 5d). At the same time, Node B finishes transmitting FB and releases the token. Nodes C and D, with no frames to transmit or receive, regenerate and retransmit both FB and the token. When FB reaches Node A, it is copied by the node. Node A also regenerates and retransmits both FB and the token. FB is finally removed from the ring by Node B (Figure 5e), and the token remains in the ring to be received by the next node with a frame to transmit (Figure 5f).

Aside from source and destination address fields, each dataframe also contains a frame status field which comprises error detected (E), address recognized (A), and frame copied (C) indicator bits. Each node can check passing frames for errors and can set the E indicator if an error is detected using the standard cyclic redundancy check procedure. If a node detects its own address, it sets the A indicator, and upon copying the frame, the station may also set the C indicator. When a dataframe recirculates back to its source node, the indicator bits are examined. If both A and C are not set, then the destination node does not exist or is inactive. On the other hand, if the frame has not been copied by an active destination node or an error has been detected, higher control layers are notified for future retransmission.

Time-controlled mechanism

FDDI uses a time-controlled mechanism to prevent nodes from dominating the network capacity. During initialization, a target token rotation time (TTRT) is established based on the shortest allowable time between token arrivals at each node. The same TTRT value is then stored at all nodes. In addition, each node has a maximum capacity guaranteed for the transmission of its stream traffic. The total transmission time of this stream traffic and the latency of the ring (i.e., total round-trip propagation time, the transmission time of a maximum length frame and the token frame) must never exceed the TTRT. During network operation, each node measures the

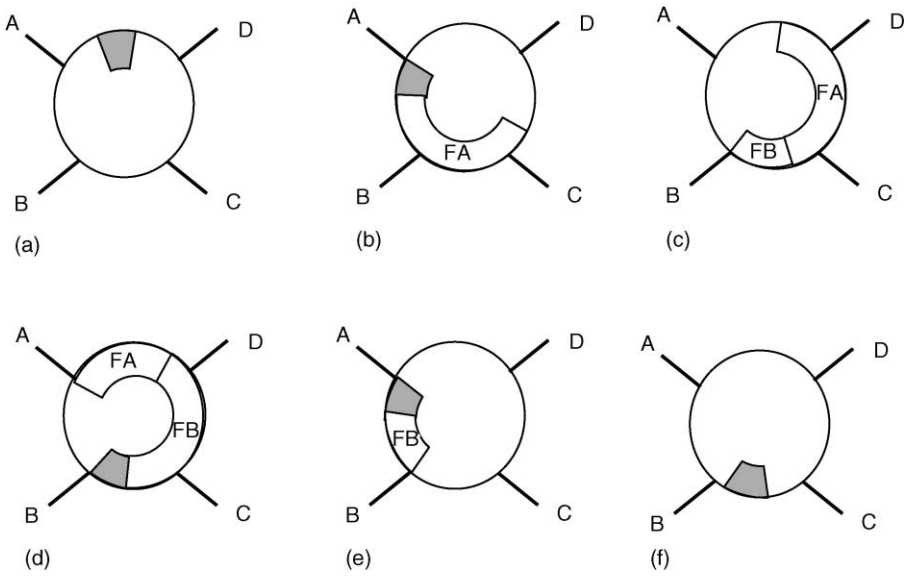

Figure 5 Fiber Distributed Data Interface (FDDI) token passing mechanism.

time interval between successive token arrivals, using a token-rotation timer (TRT). The TRT is enabled only upon a token arrival, and expires if the counter reaches the TTRT value. In turn, a late counter (LC) is incremented and TRT is reset to zero. The number of TRT expirations since a token was last received is, therefore, counted by LC. Any token that arrives at a node with a nonzero LC value is referred to as a late token. Likewise, an early token is one which arrives at a node with a zero LC value.

The action of a node when it receives a token depends on whether the token is early or late. When a late token is received, LC is reset to zero but TRT continues to run. The node then transmits for the period of time which corresponds to the predetermined bandwidth for steam traffic transmission. The node is not allowed to transmit any bursty traffic frames. In the event of an early token reception, the node transfers the current value of TRT to a second timer, the token-holding timer (THT) but does not enable it. TRT is reset to zero and is enabled to track the next rotation of the counter. The node then transmits stream traffic frames for the allocated period of time. After that, THT is enabled and bursty traffic frames are transmitted until THT reaches the TTRT value. The THT is then reset and the node releases the token into the ring. The transmission of bursty frames may be further controlled by two additional mechanisms. The restricted-token mechanism allows only two nodes in the network to use all the available bursty bandwidth, and restricts all other nodes to their stream bandwidth. This is facilitated by the use of a restricted token which is issued by one of the two nodes. The priority mechanism provides each station with the capability to transmit bursty frames according to eight priority levels. Each priority level corresponds to a different time threshold in the THT.

Note that the time-controlled mechanism of the MAC protocol guarantees a maximum response time for the ring because, in the worst case, the time between the arrival of two successive tokens will never exceed twice the value of TTRT. Most multimedia applications, such as video conferencing, real-time video, and entertainment video can be supported on FDDI with stream service and a small TTRT. However, since the TTRT cannot be less than the ring latency, applications requiring time bounds less than twice the ring latency cannot be supported by FDDI. Long and continuous isochronous services which must adhere to strict periodic access require FDDI-II.

FDDI-II

FDDI-II provides the additional circuit-switching capability to support constant bit-rate telecommunication applications. Like FDDI, the transmission bit-rate of FDDI-II is 100 Mb/s. FDDI-II can operate in either complete isochronous mode, complete packet-switching mode, or in hybrid mode in which both isochronous as well as bursty and stream services are supported. Strict periodic access required by isochronous services are accomplished with transmission opportunities repeated every 125 μs. At 100 Mb/s, time on the ring is divided into several frames, each 1562.5 bytes long. Out of the 1562.5 bytes, 1560 bytes are used for data transmission while the remaining 2.5 bytes are used as interframe gap. In turn, the 1560 bytes are divided into 16 wideband channels of 96 bytes each. Each wideband channel thus provides a bandwidth of 6.144 Mb/s, sufficiently adequate for television broadcast and multiple voice channels. For operation in the hybrid mode, some of the wideband channels are allocated for packet mode transmission. Likewise, if complete packet-switching operation is required, all wideband channels are allocated for packet switching transmission.

IEEE 802.6 Distributed Queue Dual Bus (DQDB)

Overview

The IEEE 802.6 Distributed Queue Dual Bus (DQDB) standard, finalized in 1990, specifies a dual bus network with an operating speed of 150 Mb/s. DQDB is now mainly used for MAN applications, although it can be readily deployed for LAN backbone interconnection. Figure 6 illustrates the basic architecture of a DQDB network with access nodes, Node 1 to Node N, distributed along two counter propagating buses, BUS A and BUS B. Each access node is considered to be connected to a lower speed LAN. At the head end of each bus, a slot generator continuously generates fixed-size time slots which propagate along its respective bus. The contents of each time slot are regenerated at each access node it passes, and upon reaching the end of the bus, a sink terminal receives and removes the time slots from the network. Data are transported across the network from one access node to another in the form of fixed-size segments. A node transmits a segment by changing the contents of a passing time slot. Each segment needs only be transmitted on one of the two buses, the choice depending on the locations of the transmitting and receiving nodes. For example, referring to Figure 6, a downstream transmission from Node i to Node $i+1$ requires the use of BUS A. On the contrary, an upstream transmission from Node i to Node $i-1$ uses BUS B.

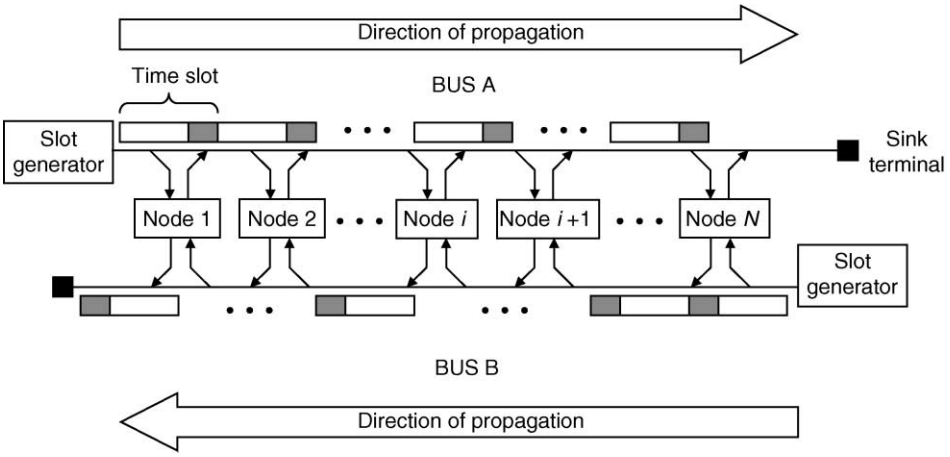

Figure 6 Distributed Queue Dual Bus (DQDB) architecture.

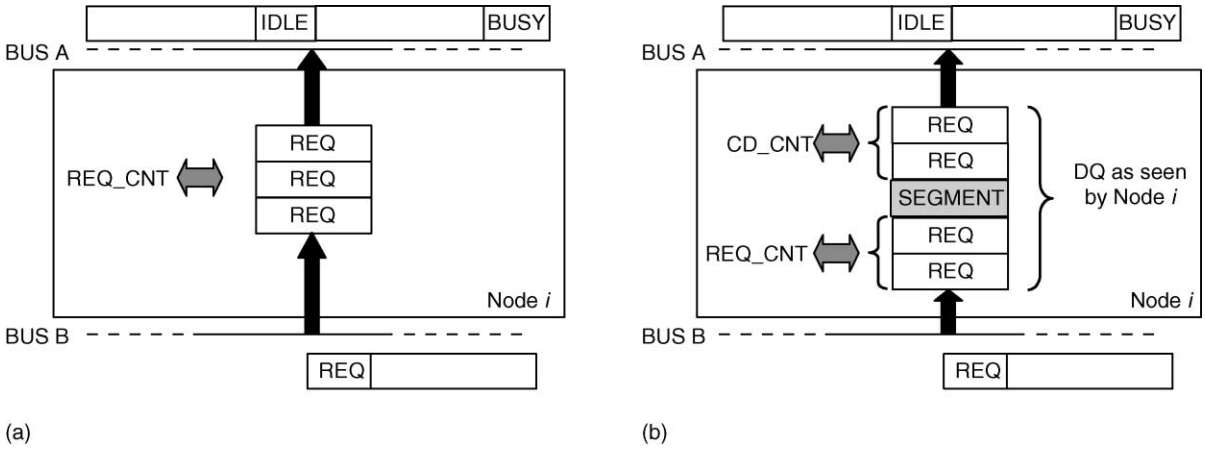

Figure 7 Behavior of Node *i* during (a) idle state; and during (b) countdown state.

MAC Protocol

In DQDB, permission to transmit segments into the network is determined by a global distributed queueing algorithm. The algorithm allows each node to continuously monitor both buses, counting the requests and available time slots that pass by. In addition to maintaining a global first-in-first-out queue (DQ) for each bus, the algorithm relies on information in the header of time slots, namely the BUSY and REQ fields, and counters at the access nodes to coordinate transmissions. A 'BUSY = 0' field represents the availability of a time slot for the transport of a segment. For example, time slots generated at the head end of each bus have default 'BUSY = 0' and 'REQ = 0' fields. The BUSY field is set to 1 when a segment is transmitted into an available time slot.

The REQ field is used in conjunction with the counters to inform nodes of an impending transmission from downstream. To simplify the explanation, consider only packets propagating on BUS A. A node wishing to transmit a segment downstream needs to queue the segment in the appropriate DQ. The node with an impending transmission must then notify all upstream nodes that it has inserted a segment in the DQ so that an available time slot can be reserved for the transmission. This is accomplished by setting the first time slot propagating in the opposite bus, BUS B, with REQ = 0 to REQ = 1. As such, the node maintains the outstanding segments in the DQ belonging to downstream nodes via the value in the REQ field.

To illustrate, Figure 7a shows an arbitrary node, Node *i*, in an idle state, whereby the node has no segments to transmit downstream on BUS A. With every 'REQ = 1' observed on BUS B, a request counter, REQ_CNT is incremented by one. However, with every empty slot, i.e., 'BUSY = 0', observed on

Table 3 Comparison of standardized local area networks

the BUS A, REQ_CNT is decremented by one. When Node *i* has a segment to transmit, it enters the countdown state as illustrated in Figure 7b. The value in REQ_CNT is transferred into an independent countdown counter, CD_CNT, and REQ_CNT is reset to zero. Node *i* also sets 'REQ = 1' in the opposite bus, BUS B. As in the idle state, each 'REQ = 1' observed on BUS B increments REQ_CNT while each 'BUSY = 1' observed on BUS A decrements it. When CD_CNT reaches zero, Node *i* transmits its segment in the first time slot with 'BUSY = 0' on BUS A and sets 'BUSY = 1'. The node returns to the idle state if there are no other segments to transmit. The algorithm allows the node to determine the number of time slots reserved by downstream nodes and the time to transmit a segment into an available time slot. Note that both the idle and countdown states are replicated for transmissions on BUS B.

The DQDB standard also specifies a limited support of isochronous services. Nodes which provide and receive such services are reserved a certain amount of time slots which are indicated with additional header information. The remaining time slots are used by all other access nodes for the transport of packet-switched traffic, and access to these time slots is managed by the global distributed queueing algorithm. A priority mechanism based on using multiple DQs, each with a different priority level, may also be implemented to guarantee access to certain segments in the network.

Summary

Due to the explosive demand for high-bandwidth applications, fiber-optics has become an essential technology in LANs. Table 3 compares the various fiber-optic LAN standards discussed in this article. The Ethernet family remains the most prevalent of LAN technologies. Its widespread use is contributed by the availability of low-cost chipsets, mature and familiar management and analysis tools. The future of fiber-optic LANs operating beyond 10 Gb/s will depend upon WDM solutions. The current usage of one transmission channel per network is impeded primarily by the limitation of the speed of electro-optic conversion, and thus does not fully exploit the massive transmission bandwidth of the optical fiber. With WDM, multiple transmission channels are concurrently transmitted on a single optical fiber, thereby greatly increasing the capacity of an optical LAN. Ongoing research efforts have been directly towards advancing WDM component technology and addressing prevailing issues such as polarization control, chromatic dispersion, and four-wave mixing among others.

Optical Time Division Multiplexing

L P Barry, Dublin City University, Dublin, Ireland

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

As the demand for bandwidth continues to grow, driven by the massive increase in Internet usage, so will the necessity to have communications networks that can handle very high data rates. The use of optical fiber networks is the clear choice for such systems given the huge available bandwidth of the fiber transmission medium. However, in a basic optical communication system comprising a laser transmitter, an optical fiber transmission medium, and a receiver, the capacity is essentially limited by the speed at which light can be modulated at the transmitter. To overcome this limitation, which is basically due to the speed of available electronics, it is necessary to use optical multiplexing techniques, and one such technique, known as optical time division multiplexing (OTDM), will be the subject of this article.

Principles of Time Division Multiplexing

Time division multiplexing (TDM) has long been the traditional method for electrically combining information channels. If we take the most fundamental data rate to be that of a simple voice call at 64 kbit/s, then the transmission of data at higher bit rates is achieved by electrically multiplexing a large number of 64 kbit/s channels in the time domain. With the evolution of standards, a number of different data rates have been specified as standard transmission rates. In Europe the synchronous digital hierarchy (SDH) has a basic data rate of 155.52 Mbit/s, which is known as the synchronous transport module – Level 1 (STM-1). This particular data rate is essentially obtained by electrically multiplexing over 2000 voice calls in the time domain (with some of the capacity required for overhead information). By subsequently multiplexing a number of STM-1 channels together we can obtain transmission at the higher standard data rates of STM-4 (622 Mbit/s), STM-16 (2.48 Gbit/s), and STM-64 (9.88 Gbit/s), as outlined in Table 1.

Figure 1 illustrates how basic electrical TDM is used in standard optical communication systems. Clearly as we approach the higher data rates of STM-64, a serious level of electrical multiplexing is required, and as the data rates increase so does the cost and complexity of the electrical equipment at the transmitter and receiver. Indeed the present state of the art in electronics seems to suggest 40 Gbit/s as the limit for electrically multiplexed communication systems. However, as we stated earlier, communications traffic has been growing explosively over the last decade and will continue to do so. In order to meet this demand for capacity, and better exploit the massive available bandwidth of optical fiber, it is necessary to use optical multiplexing techniques for communications systems. The two main optical multiplexing techniques available are wavelength division multiplexing (WDM) and optical time division multiplexing (OTDM). WDM essentially involves transmitting data at a number of different wavelengths on the same fiber. Although electrical multiplexing may be limited to data transmission rates of around 40 Gbit/s using one laser, by multiplexing together N different wavelength channels each carrying 40 Gbit/s, we can achieve overall data rates up to and beyond a terabit/s.

The second of these optical multiplexing techniques, OTDM, is the subject of this article. Whereas WDM multiplexes optical data channels in the

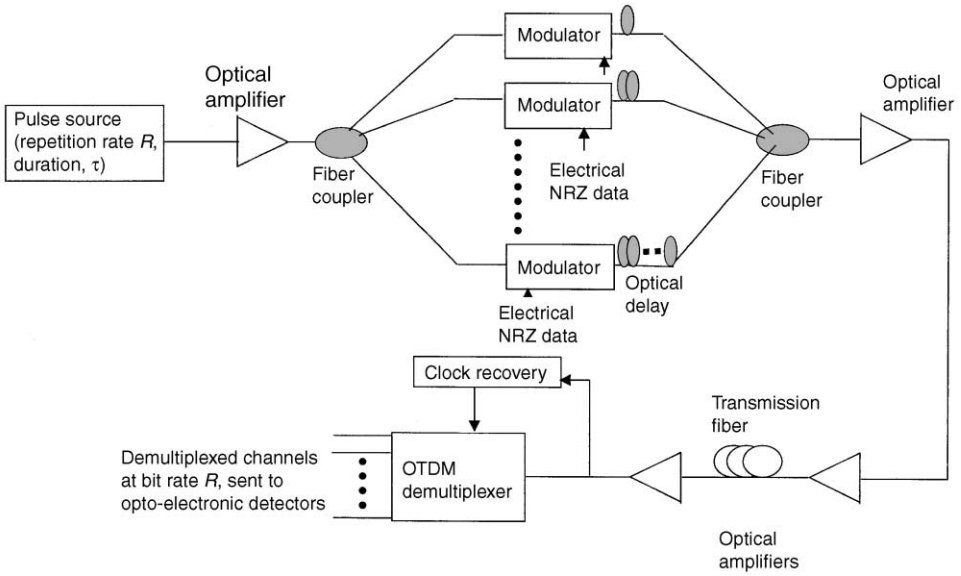

Figure 2 Basic configuration for an OTDM transmission system comprising transmitter, transmission fiber, and receiver.

wavelength domain, the basic principle of OTDM communications is to increase the system capacity by multiplexing optical data channels in the time domain. This multiplexing is usually achieved by a process known as bit-interleaving. This process can be explained by considering Figure 2, which shows a basic schematic of an OTDM based transmission system. The main component of the overall system is a source of ultrashort optical pulses (pulse duration τ) at a certain repetition rate, R. The optical pulse source is initially split into N channels using a passive fiber coupler, and each pulse train is subsequently modulated by electrical data which is at a data rate of R. The resulting output from each modulator is essentially an optical data channel where the data are represented using ultrashort optical pulses (return-to-zero data format). The data from each modulator then passes through a fixed fiber delay line which delays each channel by a time equal to $1/RN$ relative to its adjacent channel (as shown in Figure 2). The N modulated and delayed optical data channels are then recombined in another passive fiber coupler to form the OTDM data signal. We can consider that the delay lines essentially assign each data channel to a specific bit slot (of width $1/RN$) in the overall multiplexed signal. The multiplexed data signal may then be transmitted over optical fiber before arriving at the receiver which is responsible for demultiplexing the optical signal into its discrete channels.

The duration of the optical pulse source is extremely important in determining the maximum overall data rate which can be achieved. The overall data rate is basically defined by the temporal separation between channels in the multiplexor, but in order to avoid cross-channel interference, this separation must be significantly greater than the pulse duration. Thus to increase the overall data rate we must use shorter optical pulses. However, as we reduce the optical pulse width to raise the data rate we need to take into account the problems that may be encountered as this high-speed data signal propagates over optical fiber, and also the difficulty in demultiplexing a high-speed OTDM data signal. The following section will look in greater detail at

these key elements of the OTDM communication system, namely the optical pulse source, the transmission of the ultrahigh capacity signal, and the demultiplexing at the receiver.

Key Elements of an OTDM Communication System

Ultra-Short Optical Pulse Sources

As stated earlier, the optical pulse source is a key element in any OTDM-based communication system. The important characteristics of the pulse source that will affect its usefulness in an OTDM system are the pulsewidth, the spectral width, and the temporal jitter. The pulse duration clearly has to be short enough to support the desired overall transmission rate. For example, if we wish to design an OTDM system with an aggregate data rate of 100 Gbit/s (which will have a delay of 10 ps between each channel in the multiplexed signal), then the pulsewidth should normally be less the 30% of the channel spacing to avoid cross-channel interference (i.e. around 3 ps). For terabit/s OTDM systems we would require pulsewidths less than 0.5 ps. The spectral width of the pulse source is also important, as it will have a major impact on how the pulse will evolve during propagation in the fiber. A standard figure of merit which is employed is the time–bandwidth product, and ideally we require the pulse source to be transform limited, which implies that the spectral width is as small as possible for the associated pulsewidth. The impact of temporal jitter on the pulses can be easily understood by considering the above example of a 100 Gbit/s system, employing 3 ps pulses, with the multiplexed channels spaced by 10 ps. Obviously if the jitter on the pulses becomes significant in relation to the channel spacing, then this can also lead to interference between adjacent channels in the overall OTDM system. A large number of techniques have been employed to develop ultrashort pulse sources suitable for use in OTDM systems, but the three main methods which will be described below are active mode-locking, gain-switching, and external modulation of a CW light signal.

Active mode-locking of laser diodes normally involves modulating the amplitude of the optical field inside the laser cavity at a frequency which is equal to the mode spacing of the laser. This can be achieved by applying an electrical sinusoidal signal at the correct frequency, and results in the generation of optical pulses at the repetition rate of the applied signal. This technique has been successfully employed in the generation of subpicosecond pulses at repetition rates up to and beyond 40 GHz, with excellent spectral and temporal jitter characteristics. However, an inherent problem in all mode-locked pulse sources is the difficulty in synchronizing the mode-locked frequency to a specific SDH standard data rate.

Gain switching of semiconductor laser diodes is probably the simplest and most reliable technique to generate optical pulses. The technique, which is presented in Figure 3, involves applying a high-power electrical pulse (or electrical sinusoidal signal) to the laser in conjunction with a certain bias current. By ensuring that the electrical pulse signal and the bias signal have the correct level, the relaxation oscillation phenomenon of the laser results in the production of optical pulses with durations between 10 and 30 ps, at the repetition rate of the applied electrical signal. The frequency of the electrical signal applied to the laser is essentially arbitrary (provided it is not larger than the modulation bandwidth of the diode), thus making it straightforward to synchronize the optical pulse train to a SDH line-rate. The main problem with this technique is that the spectral width of the pulses generated is such that the pulses are far from transform-limited, which would affect their subsequent propagation in the fiber. In addition, temporal jitter on gain-switched pulses can also be a problem. However, by using novel arrangements such as external injection into the gain-switched laser, this difficulty can be overcome.

The third pulse generation technique mentioned above involves external modulation of a cw light signal with an electro-absorption modulator. The experimental configuration for this pulse generation technique is shown in Figure 4. By biasing the modulator around its null point, and applying an electrical sinusoidal signal to it, the cw light passing through the modulator becomes shaped into optical pulses. The optical pulse train which is generated due

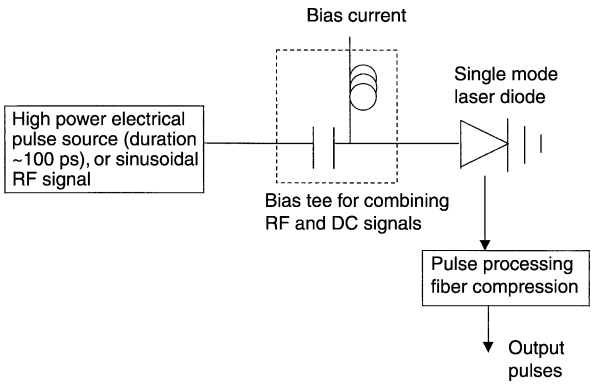

Figure 3 Pulse generation using the gain-switching technique followed by pulse compression.

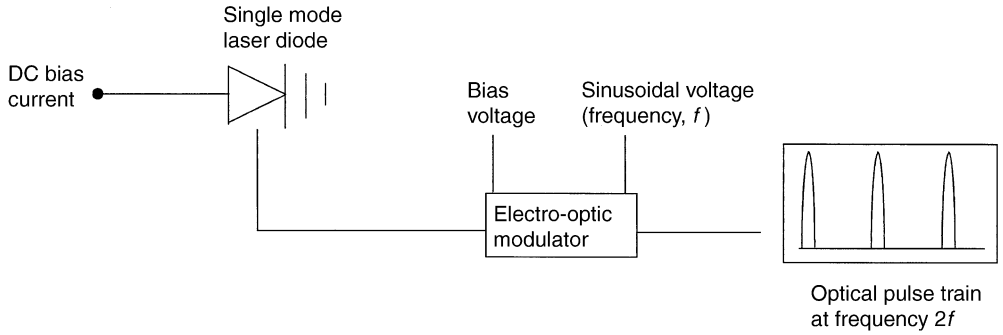

Figure 4 Pulse generation based on shaping of cw light using the nonlinear response of an external modulator biased about its null point.

the nonlinear response of the electro-absorption modulator is at a repetition rate of twice the applied electrical signal. The pulses generated are normally transform limited with extremely low temporal jitter, and the repetition rate is arbitrary as in the gain-switching technique (with the limit being ultimately determined by the modulation bandwidth of the modulator). This method may be readily used to generate pulses at repetition rates up to 40 GHz with pulsewidth around 5 ps, and it has the advantage that the optical source and the modulator can be integrated in a single device to form a compact pulse source suitable for OTDM communication systems.

It should also be noted that in addition to the various techniques that have been outlined, it is possible to use pulse compression in order to reduce the pulse width. The main issues concerned with pulse compression are the shape and spectral width of the optical pulses after compression. One of the most attractive methods of achieving pulse compression involves using nonlinear compression in dispersion-decreasing fiber, with the main advantage of this technique being the ability to maintain a transform limited pulse after compression. By employing this compression scheme, optical pulse sources at 10 GHz with pulsewidths below 200 fs have been developed, and such pulsewidths would be suitable for use in Tbit/s OTDM systems.

Transmission of an OTDM Signal over Fiber

The transmission performance of an OTDM data signal is vital in determining the distance over which the data can be transmitted successfully. The main fiber parameters, which will affect the signal transmission, are attenuation and dispersion. If we consider OTDM systems operating at a wavelength of around 1550 nm (minimum loss wavelength), to overcome the fiber attenuation and maintain a suitable optical power budget for the system, optical amplifiers are normally employed. If we thus assume that the amplifiers overcome the fiber loss problem, then the maximum transmission distance will be limited by the fiber dispersion. In a very basic OTDM system operating at 1550 nm, with transmitter and receiver linked using standard fiber (dispersion parameter of about 16 ps km^{-1} nm^{-1}), the maximum transmission distance will be limited by the overall data rate, and the pulsewidth and spectral width of the optical pulse source. For example, consider a 40 Gbit/s OTDM data signal which is formed using 8 ps optical pulses with a spectral width of 40 GHz (0.32 nm). From the spectral width we can calculate the signal broadening due to dispersion to be around 5 ps km^{-1}, and as the pulses broaden and spread into adjacent channels of the OTDM signal then this interference will make it increasingly difficult to correctly detect the signal at the receiver. In this case after propagation through 5 km of fiber, the signal pulses will have already dispersed to around 25 ps duration, the same value as the temporal bit slot into which each channel is placed. This will clearly result in serious loss of signal integrity. A straightforward possibility to increase the transmission distance of OTDM systems is to employ dispersion shifted fiber; the dispersion parameter is now around 1–2 ps km^{-1} nm^{-1}, at an operating wavelength of 1550 nm. This reduction in dispersion will obviously increase the allowed transmission distance by about an order of magnitude for the example described above. However, to develop ultrahigh-speed, long-haul OTDM communications we require more complex transmission schemes. Two possibilities for this include dispersion compensation, and soliton transmission techniques.

Dispersion compensation basically involves compensating for the dispersion that has been encountered during transmission by using some fiber with a total dispersion of opposite sign but equal magnitude to the transmission fiber. Dispersion compensation

may also be achieved using a suitably designed fiber grating. For a long-haul OTDM system, a dispersion compensator may be used every 50 or 60 km, in conjunction with the optical amplifier, thus allowing us to compensate both fiber loss and attenuation periodically along the link. The main limitation, however, with the dispersion compensation technique is caused by the dispersion slope of the fiber, as for ideal compensation it is necessary to compensate completely for the dispersion slope in addition to the overall fiber dispersion. The second technique that may be employed to greatly extend the transmission distance of high-speed OTDM communication systems is the use of soliton transmission. The basic principle of soliton transmission is to use optical data pulses with a particular shape, pulsewidth, and peak power, such that as the pulse propagates, the effects of fiber dispersion and nonlinearity counterbalance to allow the signal to propagate undistorted. By using optical amplifiers to ensure that the optical pulse peak power does not vary too much along the transmission link, OTDM transmission at data rates greater than 100 Gbit/s, over distances approaching 500 km have been demonstrated.

Demultiplexing of OTDM Signal at Receiver

For OTDM communication systems with data rates above 40 Gbit/s, it is not feasible to use electrical switching. Indeed for ultrahigh-speed systems operating at 100 Gbit/s and beyond, the only solution for demultiplexing is to use all-optical switching in which optical control signals are used to switch the OTDM data signal. All-optical switches normally use nonlinear optical effects either in optical fiber or semiconductors. A typical scenario (as presented in Figure 5) involves the injection of both the OTDM data signal and an optical control signal into the nonlinear device. The control signal consists of high-power ultrashort pulses at the repetition rate of the individual channels within the temporally multiplexed signal, and by synchronizing it with one of the OTDM channels it is possible to demultiplex this channel from the high-speed OTDM signal.

Two of the most popular all-optical demultiplexers are the nonlinear optical loop mirror (NOLM), and the terahertz optical asymmetric demultiplexer (TOAD). The NOLM is based on the nonlinear refractive index of optical fiber. It essentially consists of a 2×2 fiber coupler with its two outputs joined using a certain length of fiber. When an OTDM signal is injected into an input port of the coupler, it splits into two counterpropagating components in the fiber loop, and when these components recombine and interfere at the coupler, the overall signal is output through its initial input port. If we now inject a high-power control signal directly into the loop, such that it propagates unidirectionally, and is

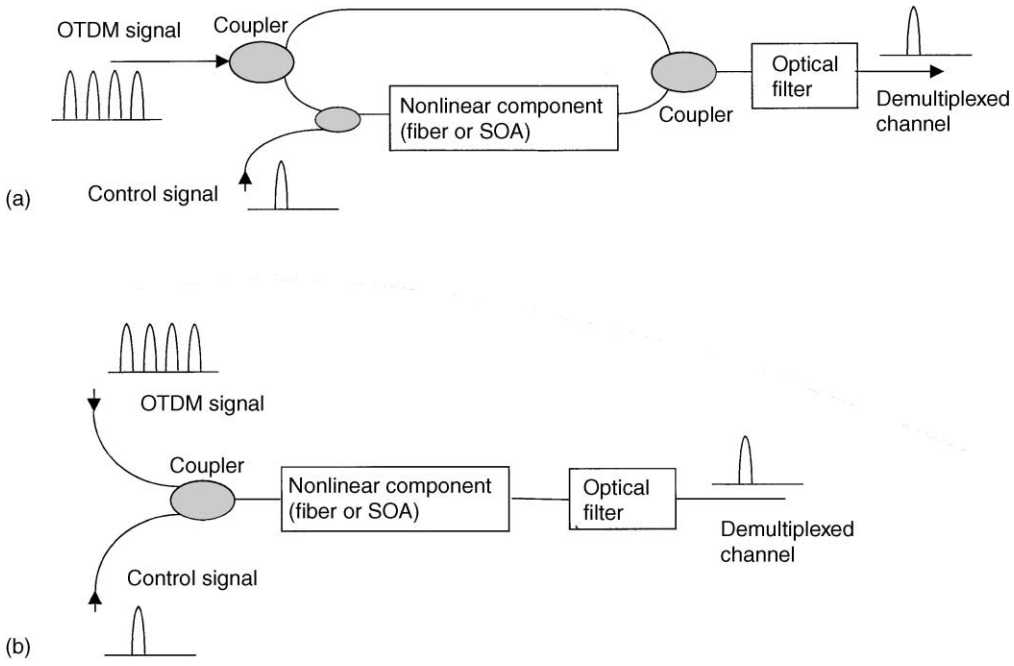

Figure 5 Configuration of OTDM demultiplexers using (a) an interferometer based on nonlinear phase shift in fiber or semiconductor optical amplifiers, and (b) four-wave mixing in fiber or semiconductor optical amplifiers.

synchronized with one of the OTDM data channels, then the phase shift induced by the control on the copropagating signal channel (via the nonlinear refractive index of the fiber) results in that particular channel being switched out to the second input port of the coupler. The remaining data channels of the OTDM signal are once again output through the same port that they entered the coupler. As this particular nonlinear effect in fiber (known as the Kerr effect) has a femtosecond response time, it should be possible to realize extremely high-speed switching with the NOLM. Demultiplexing at data rates in excess of 100 Gbit/s has already been achieved using this technique. One disadvantage of this method is that the nonlinear index coefficient of standard fiber is very small, so in order to achieve the required phase shift from the control pulse, it is necessary to use a fiber loop of around 1 km in length (depending on the power of the control pulse used). This length may affect the overall stability of the demultiplexer and its ability to be readily integrated into high-speed OTDM systems. However, it should be noted that recent developments in the design of high-nonlinearity fibers may reduce this problem.

The second all-optical switch mentioned above is known as a TOAD. Whereas the NOLM is based on the nonlinear refractive index of the fiber, the TOAD is based on a nonlinear optical effect in semiconductor optical amplifiers (SOA). The overall setup for a TOAD is very similar to that for a NOLM, except that a semiconductor amplifier, as shown in Figure 5, replaces the length of fiber in the loop. As for the NOLM, the OTDM data signal is injected into the TOAD using one input of the coupler, such that it splits into two counterpropagating signals, while the control signal propagates unidirectionally in the loop containing the SOA. By synchronizing the control with one channel in the OTDM signal, this particular channel is switched out. Although the response time of a TOAD-based switch may not be as fast as the NOLM, it does have the major advantage that it can be developed into a very compact demultiplexer, suitable for deployment in OTDM-based communication systems.

In addition to the NOLM and the TOAD structures, which are both interferometric-based switches, it is also possible to use four-wavemixing (FWM) in optical fiber or semiconductor optical amplifiers to carry out the demultiplexing of OTDM signals. In this case, the high-power control pulse is synchronized with one of the OTDM channels such that the wavelength of this channel is shifted as it passes through the nonlinear device. Optical filtering may then be used to select out the demultiplexed channel.

As we discussed in the section on demultiplexing, whatever specific all-optical switching technique is employed, we need to generate an optical clock signal for use as the control pulses. This implies that it is necessary to extract a clock at the base rate of the individual data channels from the high-speed OTDM signal. Depending on the base data rate, which may be anywhere from 2.5 to 40 Gbit/s for typical OTDM systems, different clock recovery techniques have been demonstrated. These range from basic electronic clock recovery schemes to more advanced techniques based on self-pulsating laser diodes and optical phase-locked loops.

OTDM Networking Issues

The previous section has predominantly dealt with the basic elements required to implement a high-speed OTDM transmission link. However, if we are to use OTDM technology for high-speed networking, then additional elements will be required. One of the most important of these is an add/drop multiplexer (ADM). The ADM allows us to switch out one channel from the OTDM signal, and then insert another data channel for transmission in the vacant bit slot. If we consider employing OTDM in a ring configuration network, then a typical architecture for the network will be as shown in Figure 6. The high-speed OTDM data signal propagates around the closed fiber loop, and each node in the network is responsible for switching out the data it requires, in addition to inserting the data it wishes to transmit onto the fiber ring. Add/drop multiplexing is thus imperative in developing such an OTDM ring network.

The configuration for each node in an OTDM ring network is shown in Figure 7. At each node it is initially necessary to recover the base rate clock signal. The recovered clock is then used in conjunction with the OTDM signal to switch out the required data channel from the multiplexed signal. When an add/drop multiplexer is used for this purpose we obtain two outputs, one being the demultiplexed data, and the other being the OTDM signal less the switched-out data channel. A simple fiber coupler can subsequently be used to allow this particular node to insert the data it wishes to send into the free bit slot of the overall OTDM signal. This obviously requires control of the relative delay between the OTDM signal and the local data channel to be inserted onto the fiber ring, to ensure that the local data are inserted into the vacant bit slot. A number of techniques have been used for implementing add/drop multiplexers in

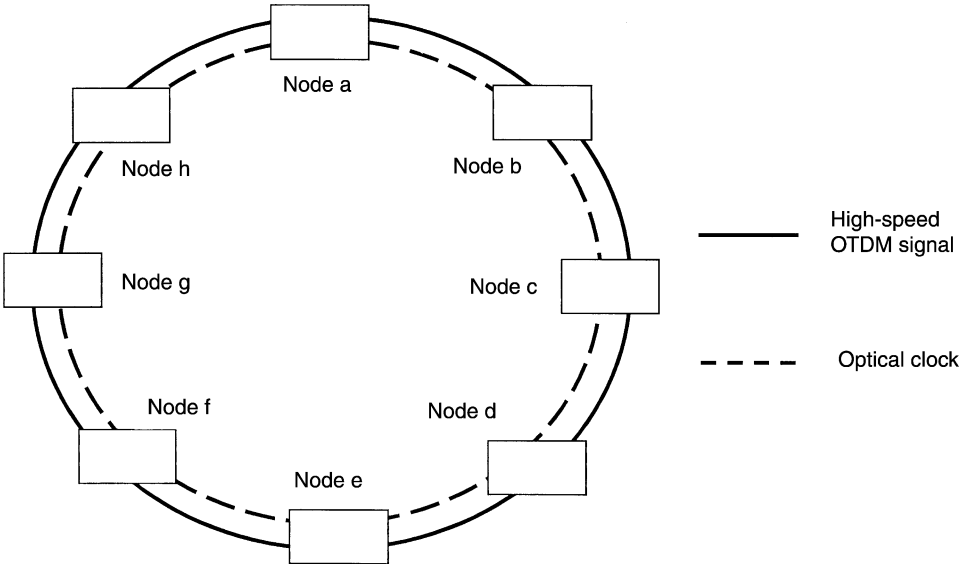

Figure 6 Schematic representation of a ring network employing OTDM with a separate fiber for clock distribution.

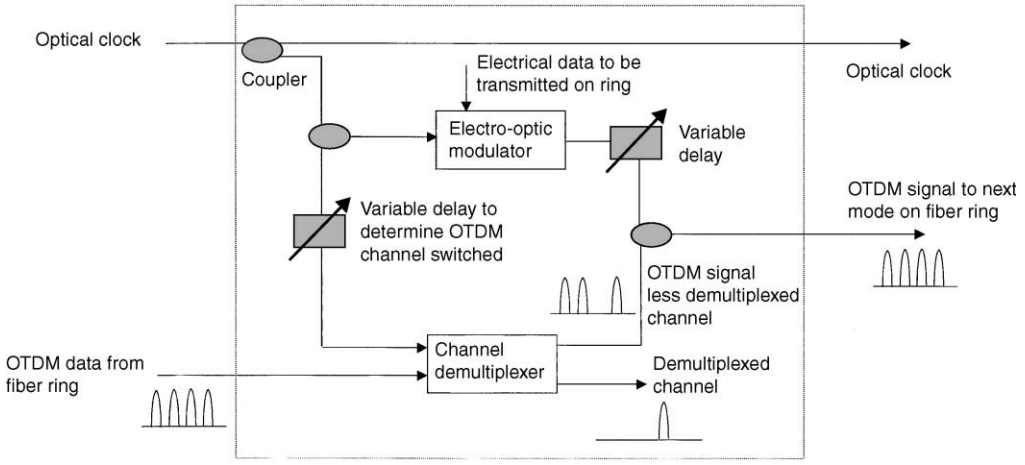

Figure 7 Configuration of an add/drop multiplexing node for use in OTDM-based communication systems.

OTDM-based networks. These have used either fiber interferometers, or interferometers using semiconductor optical amplifiers, in which we obtain both the demultiplexed data signal and the OTDM signal less the switched-out channel (to which the local data channel is then added). The continuing development and enhancement of ADM devices for OTDM systems will be vital for the future implementation of OTDM communication systems.

Conclusion

In this article we have explained the main ideas involved in building OTDM communication systems, and also introduced the principal technologies which are required to do so. OTDM is an extremely wavelength-efficient technique for delivering high-capacity data signals, and it may be used both for long-haul transmission and networking around metropolitan areas. In addition, unlike WDM, it does not require a different wavelength source for each channel in the multiplexed signal. Despite these and other advantages, OTDM is still way behind WDM when it comes to commercial maturity, with no OTDM systems currently available in the telecommunications market. However, the technologies required to implement high-speed OTDM systems (outlined in Table 2), including ultrashort pulse sources, clock extraction circuitry, and demultiplexing devices, are developing rapidly. It therefore seems

Table 2 Main elements of an OTDM communications system

Device	*Principal function*	*Technical implementation*
Optical pulse source	Generate ultrashort optical pulses suitable for transmission in high-speed OTDM systems	Gain-switching, mode-locking, or external modulation techniques
Multiplexer	Multiplex individual pulse data channels in the temporal domain using appropriate delays to achieve an OTDM signal	Passive couplers with fixed fiber delay lines, or planar waveguide circuits (for accurate control of delays)
Optical amplifier	Amplify the OTDM signal during fiber transmission to overcome fiber loss	Fiber doped with rare earth materials (e.g. erbium) in conjunction with pump laser
Transmission fiber	Transmit the OTDM data signal from transmission site to required receiver	Standard single-mode fiber, dispersion shifted fiber, or other specialty fiber may be used
Clock recovery	Extract clock (at base rate of individual channels) from OTDM data signal at receiver, for use in demultiplexing	Electronic or optical phase-locked loops, self-pulsating lasers, or mode-locked ring laser techniques
Demultiplexer	Demultiplex one of the channels from the overall OTDM signal	Interferometric or four-wave mixing techniques based on fiber or semiconductor nonlinearity
Add/drop demultiplexer	Extract one channel from OTDM data signal, and insert a local channel into the empty time slot for transmission	Similar technical implementations to demultiplexer described above

likely that in the future, OTDM technology may be used for enhancing the overall capacity of optical communication systems.

One possibility for employing OTDM systems would be for upgrading installed WDM networks. The current method for improving WDM networks involves using more wavelength channels, but it may also be feasible to increase the overall capacity by developing hybrid WDM/OTDM communications systems. In such a system, each wavelength channel may carry aggregate data rates in excess of 100 Gbit/s, achieved using OTDM. The design of these hybrid networks would permit switching of the optical data signals to be carried out at two different levels in the overall network. The WDM signals could be switched coarsely using passive filtering devices, and the OTDM data channels could be switched with fine granularity using one of the all-optical switching techniques available.

Introduction

Wavelength division multiplexing (WDM) has enabled a revolution in communications technology. This article describes the technology, critical components of WDM systems, and transmission impairment and limits to transmission distance and capacity.

Multiplexing

There are three techniques used in fiber optics to multiplex the information that is transmitted from one point to another. The first is space division multiplexing (SDM), which simply consists of having multiple fibers in a cable or conduit. In a typical installation, there may be between 8 and 1000 fibers in parallel. The second approach is time division multiplexing (TDM) (*see* **Optical Communication Systems:** Optical Time Division Multiplexing), which consist of interleaving multiple data streams into one higher bit rate stream. For example, 672 voice channels (DS0) at 64 kbit/s are multiplexed into one T1 data stream at 1.544 Mbit/s. Eighty-four of these T1 channels are then multiplexed into a SONET (Synchronous Optical NETwork) OC-3 signal at 155 Mbit/s. The third multiplexing approach is wavelength division multiplexing (WDM), which consists of sending multiple signals at different wavelengths. These signals can be used to fill up the entire low loss transmission band of an optical fiber (Figure 1). The low loss transmission band extends from 1200 nm to 1600 nm, which corresponds to over 40 THz. One approach is to pack the signals densely together, as in dense wavelength division multiplexing (DWDM). This is a relatively expensive, but very high capacity approach. The other approach is to space the signals widely apart, (coarse WDM or CWDM) resulting in very low cost components, but with fairly limited transmission capacity.

Dense Wavelength Division Multiplexing (DWDM)

Most DWDM systems use multiple beams spaced at 100 GHz spacing centered at 193.1 GHz as defined by an International Telecommunications Union (ITU) standard (Figure 2a). Some higher capacity systems use finer spacing, 50, 25, or even 12.5 GHz spacing to pack more information into the fiber. The 100 GHz spacing used in DWDM systems corresponds to 0.8 nm spacing at 1.55 mm. In principle, 40 THz of information can be sent down an optical fiber. If high spectral efficiency (~1 bit/Hz) is maintained across the band, then this would correspond to 40 Tbit/s. Practical DWDM systems are limited by the bandwidth of erbium-doped fiber amplifiers (EDFAs) and by signal impairments discussed below. Consequently, most systems utilize a single band, typically the C-band extending from 1530 nm to 1565 nm. Additionally some transmission systems use multiplexers to combine other bands, typically C and L bands for additional transmission capability. The wavelength definitions are shown in Figure 1. Subbands are often used within a band to facilitate adding and dropping a group of wavelengths within a band. Typically 40 10 Gbit/s signals spaced at 100 GHz are used to fill the C-band. Higher capacity

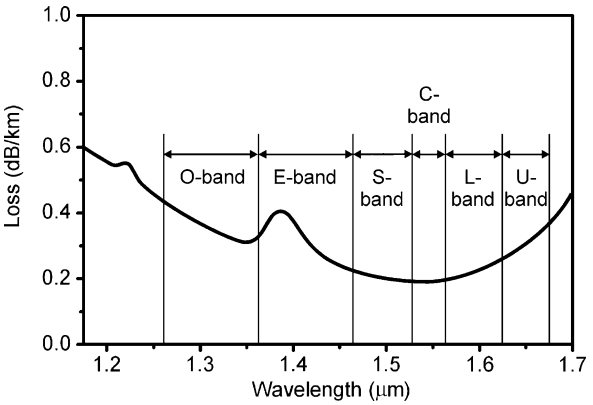

Figure 1 Transmission spectrum of optical fiber. Also shown are the standard transmission bands.

systems with 80 to 200 wavelengths have also been deployed commercially.

The historical evolution of optical transmission systems can be seen in Figure 3. The lower line shows the increasing bit rate demonstrated in experimental TDM systems, which began in 1978 with 45 Mbit/s systems and has now reached 1.28 Tbit/s. The upper line shows what has been demonstrated with DWDM with over 10 Tbit/s transmission demonstrated.

Coarse Wavelength Division Multiplexing (CWDM)

The fine frequency requirements of DWDM systems result in significant cost for transmitters, multiplexers and other components. A low-cost approach is to space the colors widely apart. The ITU standard is 20 nm spacing from 1271 to 1611 nm (Figure 2b). Note that the spacing is uniform in wavelength, but varies in frequency because the frequency spacing is related to the wavelength spacing by

$$\Delta f = -\frac{c}{\lambda^2}\Delta\lambda \qquad [1]$$

The wide spacing of signal wavelengths means that temperature stabilization of elements is not needed and the yield of components is high, resulting in a lower-cost system.

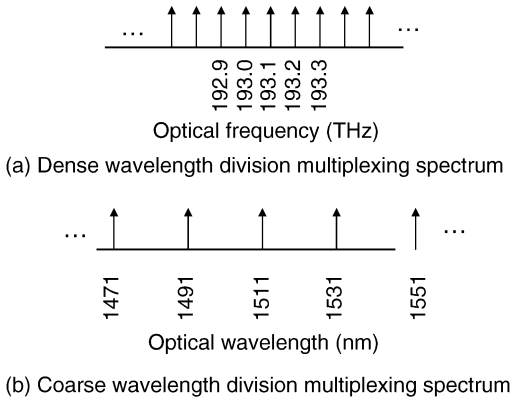

Figure 2 (a) DWDM spectrum (b) CWDM spectrum.

Point-to-Point DWDM Links

Point-to-point DWDM links were widely deployed during the 1990s. The essential elements are shown in Figure 4, namely single frequency lasers, optical multiplexers and demultiplexers, optical amplifiers, optical add drop multiplexers (OADM), and optical receivers. These will be described in more detail in subsequent sections. Essential parts of the design of these links are managing the signal-to-noise ratio and managing the pulse broadening. With periodic amplification in EDFAs and dispersion compensation, links of 1000 km are common. The widespread use of forward error correction (FEC) circuits allows error-free transmission over a link with limited signal-to-noise ratio. With careful design, ultra-long-haul

transmission over 5000 km is possible, even with many 10 Gbit/s channels.

DWDM Networks

Point-to-point DWDM links are widely deployed in opaque networks with electronic regeneration and switching at nodes. The next stage in optical networks is the deployment of DWDM transparent ring and mesh networks. An example of a simple ring network is shown in Figure 5a where most of the light signals transit nodes transparently. The OADM elements drop particular wavelengths at each node. As more wavelengths are deployed in these ring networks, it becomes necessary to dynamically reallocate wavelengths and resources. Reconfigurable optical add/drop multiplexers (ROADMs) and optical switches have been developed to allow for dynamic transparent mesh networks (Figure 5b). This allows service providers to provision their networks remotely and quickly adapt to changing demand and restore vital connections when service interruptions occur.

Critical WDM Components

The previous sections described WDM networks. This section describes in more detail the critical components used in these networks.

Multiplexers/Demultiplexers

Multiplexers (MUXs) are used to combine multiple wavelength channels into a single fiber. They are usually wavelength selective and utilize wave phenomena such as diffraction and interference. A simple cascade of 3 dB couplers is not a practical multiplexer since the output power decreases exponentially with channel count. Due to the reciprocity of electromagnetic waves, most MUXs can also serve as a DEMUX. For high channel count systems, a multistage design may be necessary to overcome the limitations of a single MUX/DEMUX. This approach also provides a more flexible upgrading plan. In this case, wavelength channels can be grouped into bands or interleaved. Diffraction gratings and arrayed waveguide gratings (AWGs) are among the available technologies for MUX/DEMUX.

In a diffraction grating, narrow slits or micro structures are spaced evenly on the grating plane and serve as a secondary light source for the input light. The transmitted or reflected light (depending on the design) forms a diffraction pattern on the image plane. The locations of peak intensity on the image plane depend on the wavelength and the grating pitch. Therefore, wavelength channels can be separated in space and fibers can be positioned properly to couple individual channels. An AWG is a planar integrated and digitized form of diffraction grating as shown in Figure 6. It is usually fabricated on a silicon substrate with silica waveguides (silica-on-silicon). The input light is coupled into an array of waveguides with incremental difference in length. These tributaries are then combined in a free-propagating output coupler to several output waveguides. Due to the interference of these tributaries from the arrayed waveguides, different wavelength channels are focused to different output waveguides.

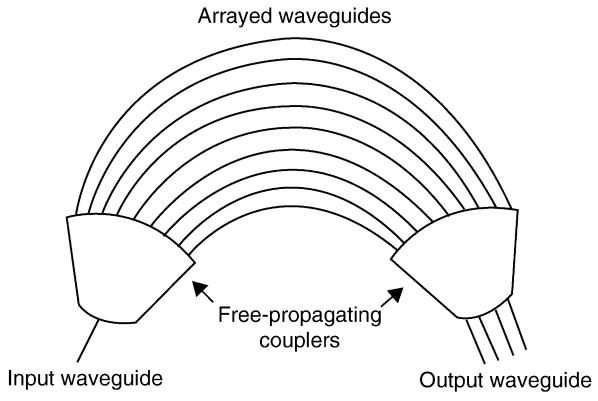

Figure 6 Schematic diagram of an AWG.

Optical Add/Drop Multiplexer

An optical add/drop multiplexer (OADM) provides critical networking capability for WDM systems. In an OADM, some of the wavelength channels are dropped from the input and are either terminated or routed. New channels at these wavelengths are then added with the through channels. This function can be done with the combination of a MUX and a DEMUX of any kind as shown in Figure 7a. However, if only one wavelength channel needs to be processed while others pass through, a simpler configuration can be used where a circulator drops the reflected wavelength from the fiber Bragg grating and a new channel is added with a coupler (Figure 7b).

The two approaches described above are termed static since the wavelength processed is fixed. To enable a more flexible network, reconfigurable OADM (ROADM) are required, where the wavelengths to be added or dropped can be dynamically specified. Figure 7c shows a configuration of ROADM based on a high port-count optical switch and a set of MUX/DEMUX. A tunable laser is highly desirable in this scenario since the wavelength of the added channel can be reconfigured to resolve wavelength contention in the network.

Optical Amplifiers

Erbium-doped fiber amplifiers (EDFA) (*see* **Optical Amplifiers:** Erbrium Doped Fiber Amplifiers for Lightwave Systems) provide simultaneous amplification of wavelength channels in the entire C-band (1530 to 1565 nm) and part of the L-band (1565 to 1605 nm). EDFAs were a key enabling technology for the deployment of WDM systems, especially for long-haul transmission where costly regenerators were eliminated. Both 980 nm and 1480 nm pumps can be utilized to achieve gain in erbium-doped fibers. The 980 nm pumps provide low-noise and high-gain operation while the 1480 nm pumps are more favorable for high-output power. One of the most significant advantages of an EDFA over a semiconductor optical amplifier (SOA) is that crosstalk among wavelength channels is much smaller in EDFA due to a millisecond-scale spontaneous emission lifetime. One critical issue for EDFAs is that the gain is not flat over the operation wavelength range and peaks around 1532 nm. However, this can be equalized by specially designed filters.

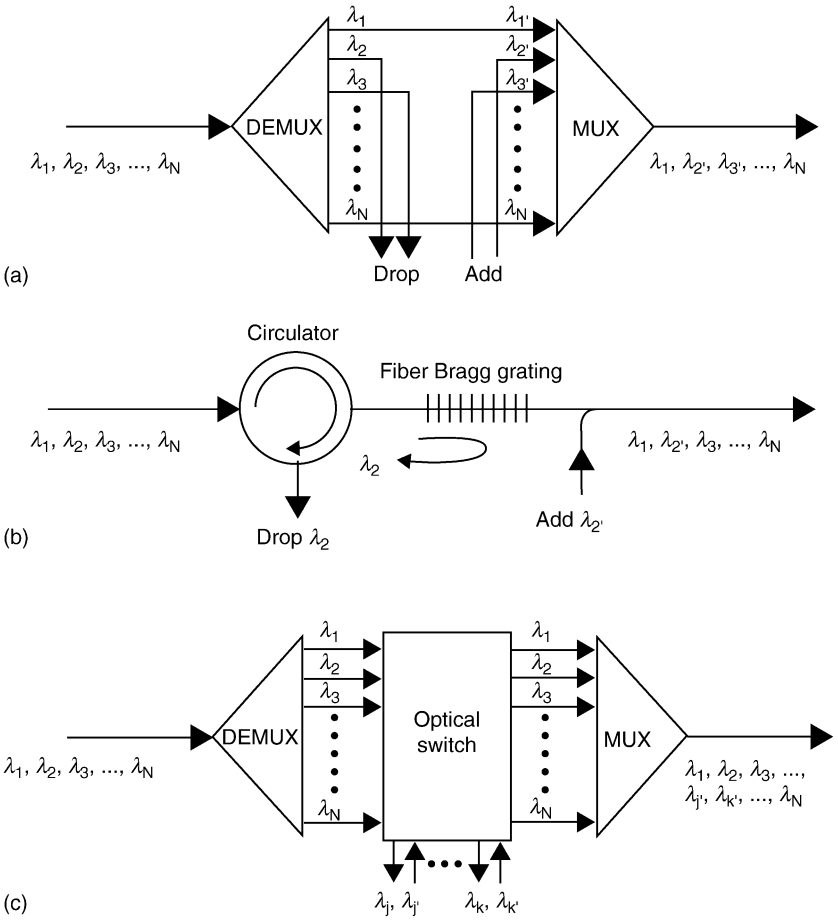

Figure 7 (a) A parallel OADM architecture which allows multiple simultaneous add's and drop's; (b) a linear OADM architecture for processing a single channel; (c) an ROADM which enables reconfigurable processing of multiple wavelength channels.

Outside the gain spectrum of EDFAs, Raman amplifiers can be used, where the gain peak is about 13 THz (100 nm) below the frequency of the pump signal. Also, Raman amplification occurs in the same fiber used for transmission so that it can provide a distributed gain over the span of the fiber, which results in a better signal-to-noise ratio. This is particularly important for ultra-long-haul transmission. A counter-propagating pump scheme is preferable to reduce the influence of pump noise and depletion. The biggest challenge for Raman amplifiers is the availability of high-power pump lasers at the required wavelengths.

Optical Filters

Filters can find many applications in WDM systems, such as in multiplexers, demultiplexers, OADM, receivers and optical amplifiers. Fiber Bragg grating, Fabry–Perot filter, and multilayer thin-film filters are among the most widely used filters and utilize the interference property of optical waves. There are some general requirements for filters in WDM systems. First, the top of the pass-band must be flat enough so that cascading of filters in the network does not lead to a significant decrease of bandwidth. In addition, the roll-off of the pass-band must be sharp so that cross-talk from other channels is minimized.

A fiber Bragg grating has a periodic perturbation of refractive index made by exposing a photosensitive fiber to interfering ultraviolet lights. These perturbations reflect the input light as it propagates. At a specific wavelength, these reflected beams add in phase, which results in a strong overall reflection. The reflections at other wavelengths do not add up and these wavelengths will eventually pass through the grating. In short, the fiber Bragg grating acts as a wavelength-selective reflector and is usually used with a circulator or isolator to manage the reflected light. A Fabry–Perot filter is composed of two partially transmitting interfaces and a cavity in between. The underlying mechanism is similar to the fiber Bragg grating but the transmission is periodic in optical frequency. The spacing is called

the free spectral range, which depends on the optical length of the cavity. The bandwidth of the passband is a strong function of the reflectivity of the partially transmitting interfaces. A multilayer thin-film filter is an extended form of Fabry–Perot filter where several layers of dielectric reflectors are formed with dielectric cavities in between. This allows for more tuning dimensions in the design of the passband shape in order to meet the requirements of WDM systems and the temperature tolerance is better than other kinds of filter.

Laser Sources

Semiconductor lasers (*see* **Lasers:** Semiconductor Lasers) are widely used in optical communication because they are compact, low cost and efficient. As a light source for transmission, single frequency operation is necessary for high-capacity WDM systems. Multilongitudinal mode lasers such as Fabry–Perot lasers have excess bandwidth which causes excessive penalty due to dispersion unless the transmission distance is short. They also result in crosstalk in DWDM systems. The most widely used single-frequency laser in WDM systems is the distributed-feedback laser (DFB), where a corrugated grating structure is fabricated on top of the gain region and only the wavelength which satisfies the Bragg condition can oscillate in the laser cavity and all other modes are suppressed.

As WDM networks advance, tunable lasers are strongly desired to reduce the excessive inventory of fixed wavelength lasers for DWDM and also to provide reconfigurability in the network. One possible structure is the distributed Bragg reflector (DBR) laser, in which the Bragg grating is decoupled from the gain region and the Bragg wavelength can be tuned independently by isolated current injection. More complicated variations of this concept such as the three-section DBR laser and the sampled grating DBR laser can provide more continuous and wider tuning in wavelength.

Photonic Switches

Photonic switches are necessary in transparent networks to allow reconfigurability in networks, and allow rapid provisioning and fault recovery. They provide connectivity between rings and between point-to-point links without requiring the DWDM signal to be broken into individual wavelengths and to be electronically regenerated. Photonic switches can be used to switch fibers, wavebands, or individual wavelengths. They are inherently transparent to bit-rate and data format. A number of different technologies have been developed.

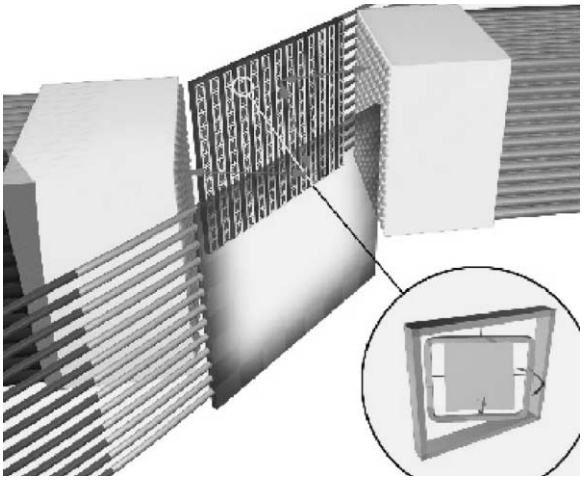

Figure 8 3D MEMS optical switch.

Microelectromechanical system (MEMS) switches are widely used for 2×2 protection switches, wavelength selective switches and for nonblocking crossbar switches with sizes from 8×8 to 1024×1024. The technology usually used for large switches is called 3D MEMS switches (Figure 8), in contrast to 2D technologies where the optical beams are confined to a two-dimensional plane.

Transmission Issues

Chromatic Dispersion

Chromatic dispersion (*see* **Fiber and Guided Wave Optics:** Dispersion) means that the group velocity, which is the propagation speed of an optical signal, changes with wavelength. Since every real pulse has a finite bandwidth, each slice of wavelength within this bandwidth propagates with a different speed and results in the distortion of the pulse as it propagates along the fiber. Depending on the sign of the dispersion and the initial phase distribution, the pulse can either be broadened or compressed. However, if the fiber is long and nonlinear effects are small, the pulses will eventually be broadened and result in intersymbol interference. Dispersion compensating fibers (DCFs), which have an opposite sign of dispersion, can be used to reverse this process and restore the original pulse shape. In general, it is advantageous to minimize the length of DCF by keeping the dispersion low. Dispersion-shifted fibers (DSF) have a zero-crossing of dispersion around 1.5 μm and hence a reduced dispersion for the C-band.

For a WDM system, a very low dispersion will result in more severe nonlinear impairments since the distance pulses can overlap with each other along the fiber is long. Nonzero-dispersion-shifted fibers

(NZ-DSF), which introduce a suitable amount of dispersion, can be used instead to solve this issue. Chirped fiber Bragg grating can also be used, where different wavelengths are reflected at different positions in the grating so as to compensate the dispersion caused by transmission. It is capable of compensating a given amount of dispersion with a much shorter length when compared to DCF. For high channel count WDM systems, the dispersion experienced by each channel may be different and dispersion compensation needs to be implemented on a per-channel basis after a demultiplexer.

Polarization Mode Dispersion

Polarization mode dispersion (PMD) means that the group velocity dispersion of the two orthogonal polarizations in the fiber are different and cannot be simultaneously compensated by a single DCF. It is usually manifested as the splitting of a pulse at the receiver even after chromatic dispersion compensation and causes intersymbol interference. PMD can originate from the imperfections in the fiber or environmental factors like temperature and mechanical pressure. Therefore, the amount of PMD can vary with time for a given link, which means that dynamic compensation is necessary. Traditional electrical equalization after the optical signal is detected can be used for compensation but the highest bit-rate achievable is limited by the speed of electronics. Optical compensation is another choice. The optical signal is split into fast and slow components and the fast component is delayed properly before being recombined with the slow component.

Nonlinear Impairments

The most important nonlinear impairments for WDM systems are the cross-phase modulation (CPM) and the four-wave mixing (FWM). They are both third-order nonlinear effects, where the nonlinear dielectric polarization is proportional to the third power of the electric field of the signal. In CPM, the phase of a wavelength channel can be modified by other channels, which increases the chirp and results in more dispersion penalty. On the other hand, FWM can generate new waves at other wavelengths, causing unwanted crosstalk if the generated wave happens to coincide with another channel. The existence of dispersion in fiber can help to reduce the effects of both impairments since the pulses at different wavelengths propagate at different speeds and walk away from each other so that nonlinear interactions are reduced. This is why NZ-DSF is preferred over DSF. Self-phase modulation (SPM) is another third-order nonlinearity, where the phase distribution of a pulse is altered by its intensity profile. It will lead to the distortion of the pulse. Other nonlinear effects include stimulated Brillouin scattering and stimulated Raman scattering. Both originate from the interactions of phonons and photons in the fiber and cause power fluctuations at different wavelengths.

Forward Error Correction

To reduce the errors of a transmission link, extra information relating to the data can be sent by the transmitter and used by the receiver to detect and correct errors in the received data. This technique is called forward error correction (FEC) and imposes redundancy to the transmission which means that the bit-rate transmitted will be higher than the actual data rate. A measure of performance for FEC is the coding gain, which is defined as the decrease in receiver sensitivity at a given bit-error-rate. Reed–Solomon codes are one of these codes. With a 7% redundancy, up to 6 dB of coding gain can be achieved. This could correspond to more than 9 orders of magnitude improvement in bit-error-rate. Therefore, the use of FEC can increase the spacing between regenerators in ultra-long-haul transmission and reduces the cost. It is also useful to overcome error floor problems due to crosstalk in a WDM system, where a further increase in received power cannot reduce the bit-error-rate. Crosstalk among wavelength channels can happen due to nonlinear impairments during fiber transmission or due to imperfect channel isolation in components like multiplexers, demultiplexers, filters, and switches. The use of FEC can greatly increase the system margin.

Conclusions

WDM technology has enabled a huge increase in the transmission capacity of optical fibers and a huge reduction in the cost of fiber optic transmission since the cost of the installed fiber is shared between the signals traveling on different wavelengths. As new components have been developed, WDM technology has expanded simple point-to-point links to transparent networks. Great progress has been made over the past 20 years to solve transmission impairments and extend the reach and bandwidth of these systems. This is likely to continue to meet the increasing communication needs of our society.

Color Filter and Absorption Glasses

J E Shelby, Alfred University, Alfred, NY, USA

Introduction

Optical filter and absorbing glasses can be categorized by either the optical behavior of the filter, for example, bandpass, shortpass or longpass, neutral density, or interference filters – or by the method used to filter the light, i.e., glasses which absorb light themselves and those which serve as high quality, transparent substrates for coatings which either absorb or reflect light. The term 'filter' usually refers to glasses used in optical systems, to either transmit or prevent transmission of specific wavelengths. The term 'absorber' is usually reserved for glasses which are used for controlling light to provide protection from damage to humans, for example, for eye protection, as in sunglasses, or welder and laser goggles, or to materials exposed to light, for example, plastics and other components in the passenger compartment of automobiles. Manufacturing technology is normally based on the method used to produce the device, such as control of absorbing species in the glass or method of application of optical coatings. Terminology for optical applications is almost always based on optical behavior and not on the method used to produce that behavior.

Bandpass Filters

The first glasses used to filter light were colored by inclusion of ions from the first row of transition metals. These colored glasses still provide most of

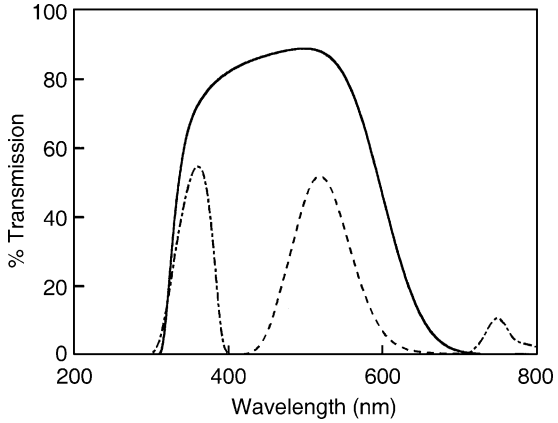

Figure 1 Transmission spectra for bandpass filters with a large bandwidth (solid line), medium bandwidth (dashed line), and narrow bandwidth (dot dash line).

the glasses used to control the wavelength of light. They are widely used as absorbers in windows in buildings and automobiles, to control the entrance of ultraviolet and infrared light into these environments. These filters allow the passage of light over a significant range of wavelengths, while absorbing wavelengths outside that range. They are designated by the peak transmission wavelength, or central wavelength, and the bandwidth, or wavelength range, over which light is transmitted with at least some designated transmission value. Filters based on absorption by transition metal or rare earth ions usually have larger bandwidths and somewhat diffuse cutoffs at the edges of the transmitted spectral region (Figure 1).

The most common bandpass filters absorb radiation in a desired wavelength region. Historically, the first bandpass filters, which are still the most common, relied on absorption of light as a result of ligand field (also known as crystal field) effects and/or charge transfer processes within a glass, to create absorption bands in the spectrum.

Ligand field effects will produce optical absorption bands in glasses which contain transition metal (usually row 3d) or rare earth (lanthanide, or 4f) ions. The differences in the electronic structures of the transition metal and rare earth ions result in very different absorption spectra. Absorption spectra, due to transition metal ions, are characterized by broad bands and are frequently accompanied by charge transfer bands, due to the same ions, while the bands due to absorption of light by rare earth ions are very sharp and are not accompanied by charge transfer absorption bands.

Iron oxide was probably the first, and is still the most widely used additive for production of glasses which primarily transmit light in the visible portion of the spectrum. A large, broad absorption band due to ferrous ions is centered at $\approx$1050 nm in common soda-lime-silica glasses. The tails of this band extend into the visible portion of the spectrum, allowing passage of the blue-green portion of the spectrum, but absorbing much of the red light, and to wavelengths in excess of 2000 nm, absorbing much of the near infrared spectrum.

Ferric iron produces relatively small ligand-field absorption bands in the region from 380 to 440 nm. These bands remove most of the blue part of the spectrum, allowing passage of light with longer wavelengths. Both ferrous and ferric ions also display charge transfer bands in the ultraviolet, effectively eliminating transmission of light with a wavelength $<$300 nm. Glasses containing enough iron oxide, to effectively eliminate both ultraviolet and near infrared transmission, exhibit various shades of green, depending on the ratio of ferrous to ferric ions present. Melting under strongly reducing conditions yields blue-green glasses, whereas melting under strongly oxidizing conditions yields yellow-green glasses. Glasses containing $\geqq$0.5 wt% iron oxide are used in windows of automobiles to minimize the amount of ultraviolet and infrared radiation entering the passenger compartment.

Copper oxide is also used to remove a portion of the near infrared spectrum from sunlight and to produce glasses which transmit in the green and blue region. The primary ligand-field absorption band of copper is due to cupric ions and is located near 800 nm. This band in similar in shape to that due to ferrous ions, with tails extending into the visible and near infrared regions of the spectrum. The shift in band position toward the visible, however, results in less absorption in the infrared and more in the visible than for ferrous iron. As a result, glasses containing copper are more strongly colored than those containing ferrous iron and are less effective filters for infrared light. Glasses colored with cupric ions can be used to produce a transmission window from about 350 to 600 nm in soda-lime-silica glasses. Cuprous ions do not create any significant absorption bands.

Glasses containing hexavalent chromium, which must be produced in a strongly oxidizing environment, effectively remove ultraviolet light between 300 and 400 nm, but allow transmission of ultraviolet light in a narrow range centered around 300 nm. A small tail of the charge transfer band due to Cr^{6+}extends into the visible, producing a yellow-green glass. The presence of a set of much weaker ligand-field bands, centered around 650 nm due to trivalent chromium, also contributes to the green color of these glasses. Combining chromium with copper ions in a glass yields a filter with a small transmission window centered at about 520 nm.

Combination of chromium with iron results in suppression of both hexavalent chromium and ferrous iron, yielding a green glass without either the strong ultraviolet absorption of hexavalent chromium or the strong near infrared absorption of ferrous iron.

Manganese oxide can be used to produce bandpass filters which block most of the visible, but allow transmission of ultraviolet and infrared light. Addition of manganese ions to a glass results in a set of absorption bands with a maximum intensity at about 500 nm and a tail extending to around 900 nm. Since these ions do not absorb in the ultraviolet, the transmission spectra of these glasses has a window between about 300 and 400 nm, which overlaps the transmission window due hexavalent chromium. The absorption bands due to manganese ions are relatively weak, so that concentrations of manganese oxide in excess of 1 wt% are needed to effectively block visible transmission.

Cobalt oxide is the strongest colorant of the oxides of 3d transition metals. A small addition of cobalt oxide to silicate glasses creates strong absorption bands between about 450 and 700 nm. The optical window of these glasses in the ultraviolet is centered near 380 nm and is somewhat broader than that of glasses containing manganese oxide, which have similar spectra. Since cobalt oxide is such a strong absorber, black glasses are easily produced by use of cobalt oxide in combination with other oxides. If cobalt oxide is combined with nickel oxide, the resulting glass retains a bandpass in the ultraviolet, while combining cobalt oxide with iron oxide, which has a complementary absorption spectrum, yields a black glass which also effectively eliminates transmission in the ultraviolet and near infrared.

The optical spectra of glasses containing most rare earth ions are characterized by sharp absorption bands. Some rare earth ions create spectra with many absorption bands, while others display only a few bands. The band structures which result from rare earth ions are not particularly useful for creation of bandpass filters, although Yb^{3+} ions do effectively remove light around 1100 nm, without absorbing light in the rest of the spectrum.

While not commonly used for filters, glasses containing rare earth ions have been used for wavelength calibration standards for uv-vis spectrophotometers. A common wavelength standard called a 'didymium' glass contains a combination of neodymium and prasedymium oxides. Since the optical spectrum from each of these ions contains many sharp bands, these glasses provide known wavelengths for absorption bands over a wide region of the spectrum. Neodymium ions, which have absorption bands near the D line of sodium, are used in goggles for eye protection for glassblowers, to remove the intense yellow light resulting from the sodium in the glass.

Interference Filters

Interference filters are a special case of bandpass filters which are created by application of dielectric films to glass substrates. The dielectric films are deposited on a glass substrate in alternating layers of high and low refractive index materials. The combination of refractive indices and thickness of the dielectric films determines the wavelength regions where constructive and destructive interference occur, i.e., those wavelength regions which will transmit or reflect the incident light. Since the choice of materials will control the indices, production of filters for different wavelengths usually relies on deposition of layers of differing thicknesses.

These filters can be produced with very narrow bandwidths ($\pm$10 nm) or with broader bandwidths (commonly $\pm$50 or $\pm$80 nm). The peak transmission frequently does not occur at the midpoint of the bandwidth. Since the wavelengths for constructive and destructive interference depend upon the path length through the dielectric layers, these filters are extremely dependent upon the incident light angle, with a shift toward lower wavelengths for incident angles other than normal to the filter surface. Interference filters typically reduce throughput of light as compared to absorption-based bandpass filters, but provide for much narrower transmission windows. If the dielectric layers are deposited in such a manner that their thickness varies along the length of the substrate, interference filters can be produced with a continually varying central transmission wavelength along the length of the substrate. While convenient for applications, which might otherwise require several filters of different central wavelengths, these linearly variable interference filters are much more expensive than those designed to block specific wavelengths.

Dispersion Filters

Dispersion filters are based on the passage of light through a medium consisting of a matrix material and dispersed, very small particles of a material which has a very different dispersion curve. The original version of these filters, called a Christiansen filter, consists of small glass particles with a controlled particle size suspended in a liquid. The dispersion curve for the glass is much less wavelength-dependent than that of the liquid. Transmission of light occurs at the wavelength where the refractive index of the glass and the liquid are equal, while light of other

wavelengths is scattered. Since the refractive index of a typical liquid is highly temperature sensitive, the transmitted, or peak, wavelength can be shifted over a wide region by controlling the temperature of the mixture. The bandwidth of dispersion filters can be very narrow ($<\pm 10$ nm).

The large temperature dependence of the traditional dispersion filter can be useful in that it provides an optical filter with an adjustable peak wavelength. On the other hand, this sensitivity to temperature also results in a serious control problem, since a temperature change of only a few degrees can shift the transmission window by up to 100 nm. This problem can be decreased or even eliminated by making a solid dispersion filter using two glasses of different dispersions, with one glass distributed in the other, or a glass dispersed in some other transparent solid such as a polymer with a similar thermal expansion coefficient. Since the refractive index of solids tends to vary with thermal expansion coefficient, these solid state dispersion filters can be almost temperature independent.

Neutral Density Filters

Neutral density filters are used to reduce the throughput of light to some desired value over a wide spectral region. Gray glasses are used to reduce the intensity of light from a bright source such as the sun. Black glasses are used to completely block light in the visible region. Neutral density filters can be produced using a combination of transition metal ions or by use of optical coatings. They are characterized by their percent transmission, range of wavelength where the transmission is constant, and the 'ripple', or spectral flatness, within the designated spectral region (Figure 2).

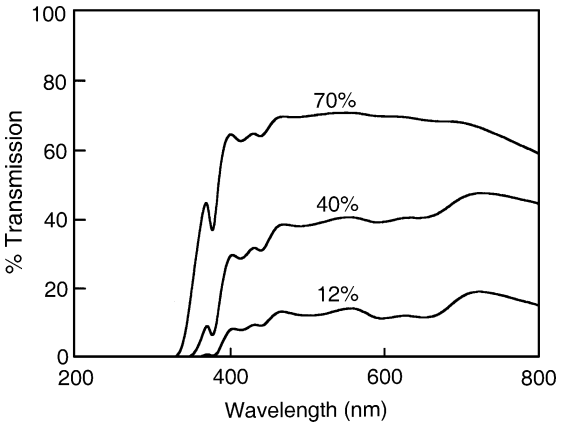

Figure 2 Transmission spectra for neutral density filters with different % transmission.

An approximation to a neutral density filter for visible light is often created by combining the absorptions in the ultraviolet and near infrared from ferrous and ferric ions, with the multiple absorption bands centered in the region of 500 to 600 nm due to divalent cobalt ions. While the resulting absorption spectrum displays small ripples throughout the region from 350 nm to beyond 1200 nm, the transmission of the glass can be controlled to within a few percent by the proper balance of ferric and ferrous ions combined with the desired concentration of CoO. These glasses are generally gray, or, if enough of iron and cobalt oxides are present, black. Combination of CoO with NiO can produce similar filters covering a smaller wavelength range which maintain transmission in the ultraviolet. Filters with different transmission values can be produced by either varying the composition of the glass or by use of different glass thicknesses. A continuously graded neutral filter can be produced from a single piece of glass by etching or polishing to form a wedge. With more effort, a step-graded filter can be produced by etching or polishing to form sharply delineated thickness steps along the length of a glass plate.

Neutral density filters can also be produced by coating a glass substrate with a metal film. Coated neutral density filters have less ripple than absorptive filters based on iron and cobalt oxides dissolved in the glass. In order to produce a constant transmission throughout the desired wavelength region, the metal used (commonly inconel) should have a constant reflectance across the desired wavelength region. Use of a metal with a varying wavelength dependence in its reflectivity, such as silver, will result in a wavelength dependent transmission. Continuously graded neutral filters can be produced by varying the thickness of the film along the length of a strip of glass.

Longpass/Shortpass Filters

Longpass filters are designed to pass light with wavelengths longer than the specified cutoff value. They are frequently used to block ultraviolet light while transmitting visible light or to block visible light while transmitting infrared light. Shortpass filters provide the opposite effect, i.e. they pass light with wavelengths shorter than the specified cutoff value, while blocking light with longer wavelengths. Shortpass filters are often used to block passage of heat (infrared light), while allowing transmission of visible light (Figure 3).

Ultraviolet blocking longpass filters can be produced by varying the basic composition of a glass or

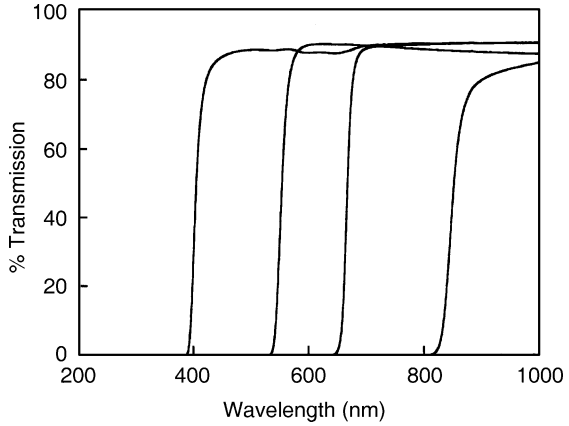

Figure 3 Transmission spectra for longpass filters with different cutoff wavelengths.

by addition of specific ions which absorb strongly in the ultraviolet. Varying the primary glassforming oxide can alter the ultraviolet cutoff frequency of a glass. Vitreous silica, for example, has an ultraviolet cutoff beyond 200 nm, so that it is a very effective transmitter of ultraviolet light. Vitreous germania, on the other hand, has an ultraviolet cutoff near 400 nm, so that it acts as an effective longpass filter for most ultraviolet light. While vitreous silica is widely used as an optical material, the poor chemical durability of vitreous germania prevents its use in most optical applications.

The ultraviolet cutoff wavelength of silicate glasses is shifted toward the visible by addition of alkali and alkaline earth oxides to silica. The addition of these oxides creates nonbridging oxygens in the vitreous network, which shift the ultraviolet cutoff toward the visible. These glasses are effectively opaque beyond their cutoff wavelength, creating longpass filter glasses with cutoff wavelengths which vary with the nonbridging oxygen concentration. Impurities such as iron or copper can also reduce the ultraviolet transmission of silicate glasses due to the creation of charge transfer bands, producing longpass filters with cutoffs in the range of 250 to 300 nm.

Longpass filters with tightly controlled ultraviolet cutoff wavelengths are often made by adding either cerium or a combination of cerium and titanium oxides to silicate glasses. Additions of cerium oxide result in a strong absorption band near 320 nm, which provides protection from ultraviolet light. Cerium also is routinely used to reduce radiation-induced coloration of glasses exposed to high energy radiation. An absorption band due to trivalent titanium also serves to cut off ultraviolet light, while producing a yellow glass. The use of a combination of cerium and titanium produces a very effective ultraviolet filter which eliminates transmission of almost all ultraviolet light.

Long bandpass absorption filters can also be based on precipitation of colloids of metals or semi-conductors in an otherwise colorless glass. The glasses are initially prepared in a colorless state, with the materials which will form the colloids dissolved as ions. The glasses are then reheated into the glass transformation region, where the desired ions are reduced to the atomic state and precipitated as colloids. Since this process is known as 'striking', these filters are known as striking filters. Colloids can be produced by striking from several elements, including silver, gold, copper, arsenic, antimony, lead, and bismuth, and from a number of compounds, including the cadmium chalcogenides and ZnS.

Formation of silver colloids in common soda-lime-silicate glasses results in a very strong optical absorption band centered near 400 nm. Glasses containing silver colloids are yellow, with a bandpass window in the ultraviolet. Since these glasses absorb so strongly at a wavelength commonly used to irradiate photosensitive polymers in the production of electrical circuit boards, they are frequently used for the production of beam masks. A pattern of silver colloids is easily produced in the surface of common float glasses by depositing metallic silver through a mask onto the surface of the glass and then heating the glass to 500 °C for a short time.

Copper can also be used to form longpass filters with a cutoff in the red portion of the spectrum by a similar process to that used to form the silver colloid filters. In this case, it is necessary to use a copper salt in place of the metallic silver, but the remainder of the process is essentially the same (Figure 4).

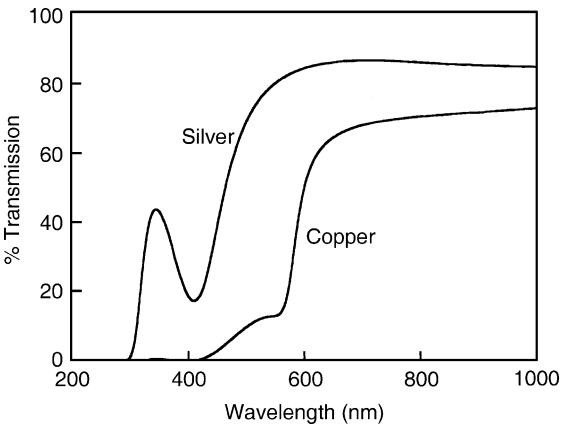

Figure 4 Transmission spectra for longpass filters containing silver or copper colloids.

Precipitation of semi-conducting colloids containing CdS, CdSe, and CdTe in silicate glasses results in sharp cutoffs in the range from the near ultraviolet to the near infrared. The cutoff is the direct result of the bandgap of these crystallites. Since these materials form a broad series of solid solutions, the desired cutoff wavelength can be obtained by use of an appropriate mixture of two of these compounds in the glass batch. Glasses containing only CdS, for example, have cutoffs in the range of 400 to 500 nm. Combining CdS with CdSe will shift the cutoff toward the infrared, with cutoffs in the range of 500 to 700 nm. Combining CdS with CdTe produces glasses with cutoffs near the edge of the visible region. Use of CdTe alone results in filters with cutoffs around 800 nm.

While the most common explanation for the shift in the cutoff in glasses containing the cadmium chalcogenides is based on solid solution arguments, it has been shown that the size of the particles also strongly affects the position of the cutoff for glasses containing CdSe. In this case, the energy gap, which determines the cutoff wavelength, varies inversely with the square of the particle size.

Glasses containing CdS and ZnS can be heat-treated to form filters with cutoffs in the range from 340 to 518 nm. Heat treatment at lower temperatures yields CdS colloids, with a cutoff around 500 nm. At higher heat treatment temperatures, the absorption edge shifts toward the ultraviolet, approaching the value of 340 nm representative of the lattice absorption of ZnS. This behavior has been interpreted as indicating that CdS crystals precipitate at lower temperatures, while at higher temperatures, solid solution crystals of ZnS and CdS are formed.

Colloids of arsenic, antimony, bismuth, and lead form less interesting filter glasses. The optical properties of these metals are such that there is no sharp cutoff wavelength. Growth of colloids produces wavelength-dependent scattering, with a long tail extending into the visible or infrared. These glasses can be produced in colors ranging from light tan to black by progressive heat treatments of the originally colorless glasses in hydrogen. The hydrogen serves to reduce the ions to the atomic state. The atoms then diffuse to form colloids. The growth process creates a sharp interface between the colored and colorless region of the glass, which can be used to produce windows for visible light of highly transmitting glass surrounded by essentially opaque glass.

Absorber Glasses

Glass filters are used to remove unwanted wavelengths from light. When the application is less demanding than those of complex optical devices or systems, the glasses are commonly called 'absorbers' rather than filters. These applications usually involve protection of humans or materials from damage by light, for example, sunglasses and goggles for welders and glassworkers, or to enhance the environment by controlling the entrance or exit of ultraviolet and infrared light. Most of these applications are variations on the filters discussed above.

The most common use of glass as an absorber for both protection from damage and enhancement of the environment is found in the soda-lime-silicate glasses used as windows in buildings and automobiles. The presence of a relatively large concentration of iron oxide provides absorption in both the ultraviolet and infrared regions of the spectrum. Since glasses containing iron do absorb some light in the visible, a compromise between total absorption of unwanted, nonvisible light and the desired visible light must be made. As a result, these glasses usually contain between 0.5 and 2 wt% iron oxide. Changes in melting conditions which alter the ratio of ferrous to ferric ions in the glass are used to tune the glass for specific applications. While these glasses are technically broad bandpass filters, their common applications are based on the favorable location and bandwidth of their transmission window, which roughly corresponds to the visible region.

Iron is also used for protection from ultraviolet and infrared radiation in welder goggles. These glasses contain much more iron (up to 8 wt% or more) than those used for windows, since the demand for protection from the intense light created in welding is much greater. The high absorption coefficient for infrared light results in considerable heating of the glass during lengthy use. A thin film of gold is often applied to the glass to reflect infrared radiation and reduce heating of the glass.

Other absorber applications are more demanding in terms of absorption wavelength. As mentioned earlier, glasses containing neodymium have a strong absorption band at the wavelength of the yellow sodium emission line. These glasses transmit visible light at other wavelengths, allowing their use by glassblowers, who need to be able to see the unheated part of the glass and their immediate surrounding area, while simultaneously reducing the intense yellow light given off by the sodium in the glasses normally used for glassworking.

Protection of the eye from laser radiation is even more demanding due to the very high intensity over very narrow wavelength ranges. Common ultraviolet longpass filters are usually satisfactory for absorption of light from ultraviolet lasers. Specific ions must be added to glasses to provide protection from many

visible and near infrared lasers, since the glass must simultaneously permit transmission of visible light of other wavelengths and total absorption at the laser wavelengths. Light from lasers which operate in the far infrared is readily absorbed by most glasses, since the infrared cutoff of oxide glasses lies around 5 micrometers. Great caution should always be used in selecting glasses for eye protection from lasers. No assumptions regarding the degree of protection should ever be made without insuring that the glass is designed for the conditions under which it will be used.

Heterogeneous Materials

U Kreibig and M Quinten, Aachen University of Technology, Aachen, Germany

Introduction

The term heterogeneous materials – being a quite diffuse classification of matter with discrete building units of different kinds, irrespective of their sizes – is defined here by scaling these inhomogeneities in relation to optical light wavelengths. Matter consisting of atoms in a regular structural order (or, alternatively, in fully statistical disorder) is classified as homogeneous since the inhomogeneities are too small to effect optical fields. This applies to crystalline, liquid, and glassy or amorphous matter likewise.

All geometrical/topological and chemical heterogeneities on a larger length-scale than the atomic scale, i.e., single crystallites, organic macromolecules, domains, extended lattice defects, clusters, and nanoparticles of chemical compositions differing from their host material, etc., result in a macroscopic material that is heterogeneous, in optical properties and optical experiments. Examples are multilayer-structures, heterogeneous in one dimension, three-dimensional heterogeneous composites, i.e., isometric building units distributed in some homogeneous host (photographic systems, drugs, cosmetics, color pigments in binders, etc.), and three-dimensional heterogeneous densely packed systems (poly- or nanocrystalline materials, ceramics, or nanoceramics, etc.).

The materials most intensively investigated, in the field of nanoscience, represent a subclass of heterogeneous materials.

Most of the common materials in our everyday environment have heterogeneous structures, often on larger characteristic size-scales. More generally, heterogeneous materials are so widespread that they are much more frequent than homogeneous materials. Some more examples, relevant for their optical properties, may illustrate this: pigment colors, photovoltaic composites, aerosol-systems, hydrosol-systems, many minerals, photonic crystals, island film devices, nanosensors, special biosystems, and polymer-systems. Most interesting optical features arise when these inhomogeneities are below or of the order of light wavelengths. Recent research has concentrated on a narrow size region on the lower nanometer scale where many-atoms-systems change from molecular to solid-state behavior with increasing sizes. This 'transition' is accompanied by drastic changes of almost all physical and chemical

properties, hence these properties develop strong dependences on particle size in that size region, and materials with uncommon properties can be developed.

In contrast to the widespread applications and research perspectives, the basic theoretical understanding of heterogeneous material is generally still poor. One reason is that, since the beginning of the development of optics as a science, the homogeneous materials like glass, water, etc. were preferentially treated since they were easier to describe theoretically. Another reason is the extremely wide variability of existing heterogeneous structures usually based upon low symmetries. This variability is too large, and the resulting optical properties too complex and multifarious to enable a general and uniform description of heterogeneous matter on a quantitative level, like the one successfully developed for the much simpler topology of homogeneous crystals.

Qualitative general features, however, can be obtained from investigations of model systems, with especially simplified topological structures. In the following we describe the model system of nanoparticle/host-matter (or, synonymously, cluster-matter), which is based upon nanoparticles/clusters packed closely in a host material, thus forming macroscopic or microscopic heterogeneous many-particle systems. Even this model system exhibits broad variability of topologies and of chemical compositions, as shown in Figure 1.

The restriction in the present contribution to this topologically simple model system appears to be justified by the fact that the optical properties discussed below for this system are also qualitatively characteristic of other arbitrary heterogeneous materials. We also admit that the nanos may consist of a nucleus and a surrounding shell of different structure and/or different material.

Heterogeneous matter can be defined by its heterogeneous building units and by the borders of these units and by the host material and the borders between building units and host, i.e., the internal interfaces.

It is a general feature that structures are visible because of property changes at their terminating borders: borders create structures, and structures require borders. The more refined the structures are, the more increases the topological extent of the borders. This means that when sizes of building units, for example, in cluster matter decrease, the relative amount and the effects of surface/interface regions increase. Such interfaces in heterogeneous matter are not two-dimensional (as suggested by the term 'interface') but consist of three-dimensional

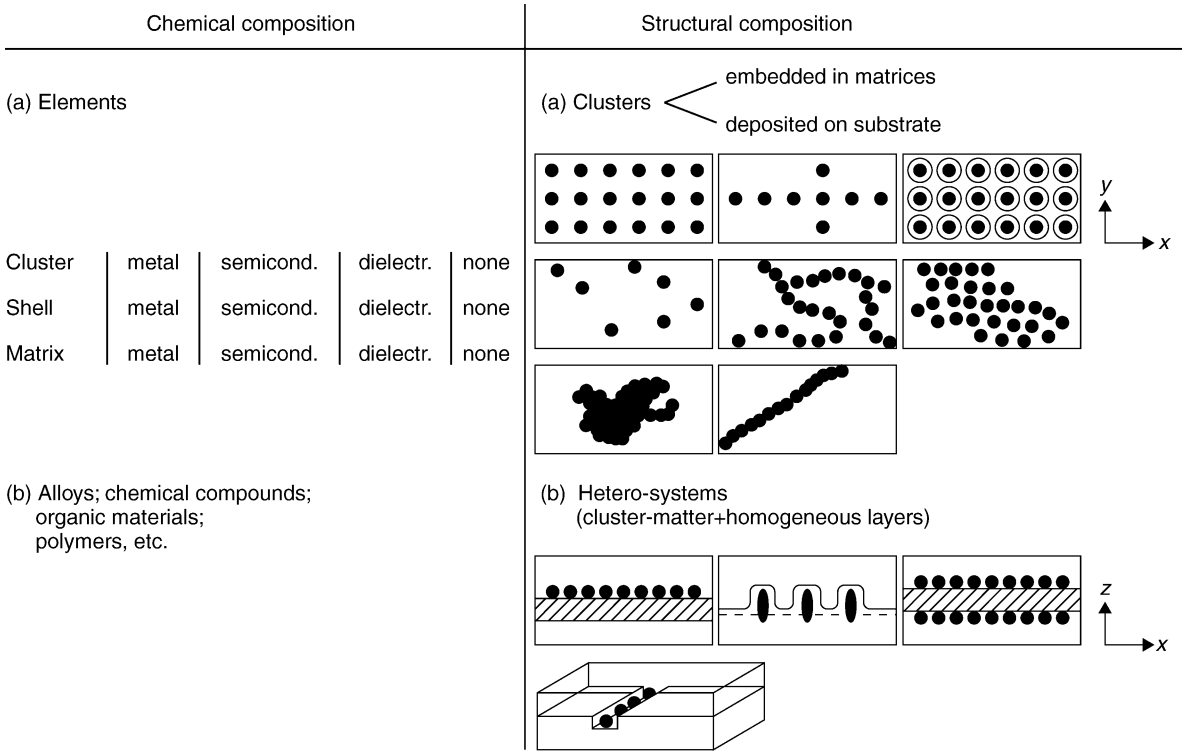

Figure 1 Examples of heterogeneous nanoparticle/host materials. Left: possible material combinations of the three building units: cluster, shell, matrix. Right: some examples of sample topologies.

interlayers, the atomic and electronic structure and the chemical composition of which are usually in complex disorder. In the case of very small particles the interface volume can easily exceed the volume of the building units themselves. There are, however, also examples where the atomic arrangement forms regular interfaces, such as at coherent grain boundaries.

Hence, heterogeneous materials are characterized by various building units, homogeneous matrices and the interface regions. To describe them, we will focus on our introduced model system of nanoparticle/host matter, where we further specialize to spherical shapes of the particles.

The investigation and description of optical properties of heterogeneous materials have to deal with the interior of the building units, e.g., characteristic optical size effects, and with the interfaces, e.g., optical interface effects. The importance of both increase with decreasing characterizing structural lengths. The role of the host materials, when present, can be different, depending on their concentration: in dilute particle systems they may act as bulk-like homogeneous matter (e.g., the electrolyte in colloidal liquid systems); at low amounts, the host may also develop size effects (e.g., the water layers in the opal).

General Optical Properties

Among the experimental characterization methods most frequently applied to heterogeneous matter, the optical ones are essential, ranging from spectroscopy in the frequency domain (from FIR to UV), to femtosecond analysis in the time domain.

Optics can mean physical optics, i.e., the science of optical material properties, including light emission (the 'active' properties) and light absorption (the 'passive' properties), and instrumental optics, i.e., special experimental techniques based upon propagation of light to analyze such samples.

The most usual experiments for the investigation of linear optical response are refraction, absorption, reflection, and elastic scattering. Also, there are the emission responses and the broad field of nonlinear optical responses.

Refraction, reflection, and absorption are typical of homogeneous matter. Elastic light scattering, on the other hand, can be used to define optical heterogeneous matter, since elastic scattering is a direct consequence of the existence of interior interfaces forming deviations from the homogeneous structure. While the grainy structure on the atomic level in homogeneous matter does not give rise to disturbances of the shape of a plane interacting optical wave, this does occur with heterogeneous matter. Each inhomogeneity gives rise to a wavefront deformation and, hence, to light scattering. Scattering spectra and intensities provide important information about the heterogeneous material, so such optical methods are frequently used for its identification.

Besides scattering, the electrical charging of the interior interfaces induced by the light field, can lead to spectacular multipolar optical absorption features, unseen in related macroscopic homogeneous materials, such as Mie resonance, discussed below.

The optical properties of our model system are composed of various contributions which all act together in a complex way, which can be described as:

1. the optical properties of the single building units. In the case of solid state units, they are characterized by the optical material properties, frequency dependent and, generally, complex dielectric function $\varepsilon(\omega)$ or, alternatively, the (generally complex) refraction index $n(\omega)$, which, in the nanometer-size region, both develop strong variations with size.
2. the optical interactions among all building units in the sample. There are different effects:
   - interference effects among the scattering radiation of the units;
   - electromagnetic coupling effects;
   - the contributions of host materials, if present; and
   - the interactions between heterogeneous building units and host.

The Optical Nanoparticle Resonances (Mie Resonances)

Metallic and semiconductor nanoparticles can exhibit special, spectrally selective absorption and scattering bands which do not have counterparts in the molecular state, in thin film structures, or in the extended bulk. They represent the most spectacular optical properties of matter with nanosized heterogeneities. Therefore they will now be treated in more detail in the frame of our model material of spherical inclusions in a homogeneous embedding medium. We begin with a comparison to thin film structures.

The interband transitions (in Ag below 325 nm) are almost equal in both spectra shown in Figure 2, of a thin Ag film and spherical Ag nanoparticles, respectively, while above 325 nm the flat relaxator spectrum of the conduction electrons in the metal film differs strongly from the oscillator spectrum of the same electrons in the clusters. The inset demonstrates the excitation of the dipolar surface oscillator mode by

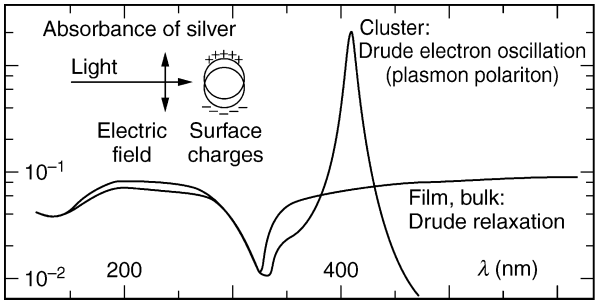

Figure 2 Comparison of absorbances of a thin Ag film and spherical small Ag nanoparticles.

incident polarized light. This figure exemplifies the above-mentioned effect that charging of interfaces by the incident electromagnetic lightwave can give rise to electromagnetic multipole resonances, the Mie-resonances.

The monotonic conduction electron absorption spectrum of the thin film, ranging from UV to zero frequency (the dc current), is thereby compressed in the nanoparticles into the narrow Mie-absorption band with peak position in the blue, containing almost the whole oscillator strength of the conduction electrons. In particular, the Ag-spheres are therefore transparent in the low frequency region, and if we assume the conductivity according to the Drude model as being definitive for a metal, we must assume that these particles are no longer metallic. The conduction electrons no longer follow the Drude relaxator behavior; instead the narrow peak indicates the properties of an oscillator.

The origin of this oscillator and its excitation can be described, being a quantum phenomenon; due to the incident electrical field, the electron plasma, the 'electronic particle', is shifted against the fixed ionic background, the 'ionic particle', causing surface charges modulated with the light frequency. The surface charges produce restoring forces to the plasma, following the periodic field strength, which is the condition required for oscillator behavior. As every free oscillator the particle develops resonances at special eigenfrequencies, and in the case of our metal clusters these are close to the peak frequency of the Mie-absorption, the oscillations of which not being free but forced by the incident field. Analogous to the mechanical case, the resulting resonance frequencies of free and forced oscillations differ slightly. To distinguish them, Mie resonances in metallic particles, coupled to the external electromagnetic field, are called plasmon polaritons.

In the frame of classical electrodynamics each single particle in the heterogeneous material acts as a spherical nano-antenna. This acts as receiving antenna by absorption and, as with every other kinds of antenna, simultaneously becomes a transmitting antenna by re-radiating elastically scattered light.

In the case of Cu, Ag, and Au, and many other metals, these absorption frequencies are in the visible, hence beautiful colors appear. However, there are a lot of metals where this oscillator is overdamped due to low electron mobility. Under particular conditions, such resonances also occur in semiconductor nanoparticles, but due to the lower charge densities, in the IR. At weak fields, the optical response of the oscillator is linear. At higher fields it becomes nonlinear, and thus second and higher harmonics can be excited.

Such unique collective excitations are not restricted to electrons but also spherical surface phonon polaritons can be excited if the particles are nonmetallic (in this case, free electron excitations do not cover the spectral region of phonon excitations). Only in the most simple case of particles which are extremely small compared to wavelength ($R/\lambda \leq 1/20$), the dipolar mode of excitation described so far (i.e., homogeneous polarization of the whole particle) comprises the whole response. For larger particle sizes, a complicated, nonhomogeneous polarization of the whole particle occurs, which can be described by an orthogonal multipole expansion, i.e., multipolar oscillations. The according size (R-) dependent multipolar contributions, which are excited simultaneously and sum up to the total optical response. Further complications arise in larger particles by retardation-induced phase shifts of the lightwaves along the particles.

A complete description of this complex multipole excitation was given by Gustav Mie on the basis of classical electrodynamics. Mie's theory is the exact solution within the frame of Maxwell theory for spherical symmetry, as are the Fresnel-formulae for the planar geometry. However Mie's theory does not describe exactly the conditions which we observe in real heterogeneous systems, hence several extensions of Mie's theory will be presented in the section entitled *Beyond Mie's Theory,* below.

Mie's theory also gives some qualitative insight into the optical behaviour of other kinds of heterogeneous matter. A highly abridged summary of this theory will be presented below.

The Theory of Mie

In the following, an outline of the Mie theory for one spherical particle is given by listing the mathematical steps:

1. Introduction of spherical coordinates r, θ, ϕ. Particle radius R;

2. Incidence of a plane, monochromatic, harmonic electromagnetic wave (circular frequency ω, wavelength λ);
3. Solution of Maxwell's equations for the incident and scattered fields in the surrounding dielectric host medium with (real) dielectric constant $\varepsilon_{\text{matrix}}$, and in the interior of an arbitrary spherical particle of (complex) dielectric function $\varepsilon(\omega)$.

   There are two solutions for transverse fields: one with the radial component of the electric field $E_r = 0$, called 'transverse electric (TE) solution', and one with the radial component of the magnetic field $H_r = 0$, called 'transverse magnetic (TM) solution'. These solutions can be obtained in terms of vector spherical harmonics which can be derived from corresponding scalar potentials Π_E and Π_H. These are solutions of the Helmholtz-equation:

$$\nabla^2\Pi_{E,H} + K^2_{\text{transverse}} \times \Pi_{E,H} = 0, \qquad K^2_{\text{transverse}} = \varepsilon_{\text{transverse}}\omega^2/c^2 \qquad [1a]$$

   In spherical coordinates, the Helmholtz equation is solved by a separation of variables ansatz and a multipole expansion, yielding an infinite number of independent partial solutions with multipolar order L, the TM partial waves or 'electric partial waves', and the TE partial waves or 'magnetic partial waves'.

   A third solution, the potential Γ, that only affects the electric field, can be found as the solution of

$$\nabla^2\Gamma = 0, \qquad \varepsilon_{\text{longitudinal}} = 0 \qquad [1b]$$

   and represents longitudinal excitations in the particle.
4. Boundary conditions at $r = R$:

   for the transverse fields:

$$E_\theta^{\text{incident}} + E_\theta^{\text{scattered}} = E_\theta^{\text{interior}}$$
$$E_\phi^{\text{incident}} + E_\phi^{\text{scattered}} = E_\phi^{\text{interior}} \qquad [2a]$$

$$H_\theta^{\text{incident}} + H_\theta^{\text{scattered}} = H_\theta^{\text{interior}}$$
$$H_\phi^{\text{incident}} + H_\phi^{\text{scattered}} = H_\phi^{\text{interior}} \qquad [2b]$$

   for the longitudinal fields:

$$E_r^{\text{incident}} + E_r^{\text{scattered}} = E_r^{\text{interior}} \qquad [3]$$

   (Sauter–Forstmann condition)

   The linear response function of the particle material used here, is ε, where $\varepsilon = \varepsilon_1 + i\varepsilon_2$ is averaged over the particle volume, including the surface–interface region.

   The magnetic permeability μ is set 1 for the investigated high frequency regions.
5. Computation of cross-sections for extinction, scattering, and absorption from Poynting's law:

   - Extinction, i.e., the sum of absorption and scattering losses:

$$\sigma_{\text{ext}} = \frac{2\pi}{k^2}\sum_{L=1}^{\infty}(2L+1)\text{Re}\{a_L + b_L\} \qquad [4]$$

   - Elastic scattering:

$$\sigma_{\text{sca}} = \frac{2\pi}{k^2}\sum_{L=1}^{\infty}(2L+1)(|a_L|^2 + |b_L|^2) \qquad [5]$$

   - Absorption, i.e., the energy dissipation (production of heat and thermal radiation):

$$\sigma_{\text{abs}} = \sigma_{\text{ext}} - \sigma_{\text{sca}} \qquad [6]$$

   L indicates the multipolar order of the Mie resonances.

The coefficients a_L and b_L, following from the Maxwell boundary conditions for transverse fields, are

$$a_L = \frac{m\psi_L(mx)\psi'_L(x) - \psi'_L(mx)\psi_L(x)}{m\psi_L(mx)\eta'_L(x) - \psi'_L(mx)\eta_L(x)} \qquad [7a]$$

$$b_L = \frac{\psi_L(mx)\psi'_L(x) - m\psi'_L(mx)\psi_L(x)}{\psi_L(mx)\eta'_L(x) - m\psi'_L(mx)\eta_L(x)} \qquad [7b]$$

with $m = 2x/n_{\text{Matrix}}$, where m denotes the complex-valued index of refraction of the particle $\varepsilon = n'^2$ and n_{matrix} the real-valued index of refraction of surrounding medium. k is the wavevector and $x = k{\cdot}R$, the size parameter. $\Psi_L(z)$ and $\eta_L(z)$ are Riccati–Bessel functions of the first and third kind. The prime indicates differentiation with respect to the argument in parentheses. Including longitudinal fields, eqn [7] will be slightly modified.

Applying Lambert–Beer's law, these cross-sections are related to the absorption-, scattering-, and extinction-constant $A(\omega)$, $S(\omega)$, and $E(\omega)$, respectively, and the resulting intensity loss ΔI of a many-particle system of number-density Z of the (noninteracting) particles, is

$$\Delta I = I_0(1 - \exp(-Z{\cdot}\sigma_{\text{ext}}{\cdot}d)), \qquad d = \text{sample thickness} \qquad [8]$$

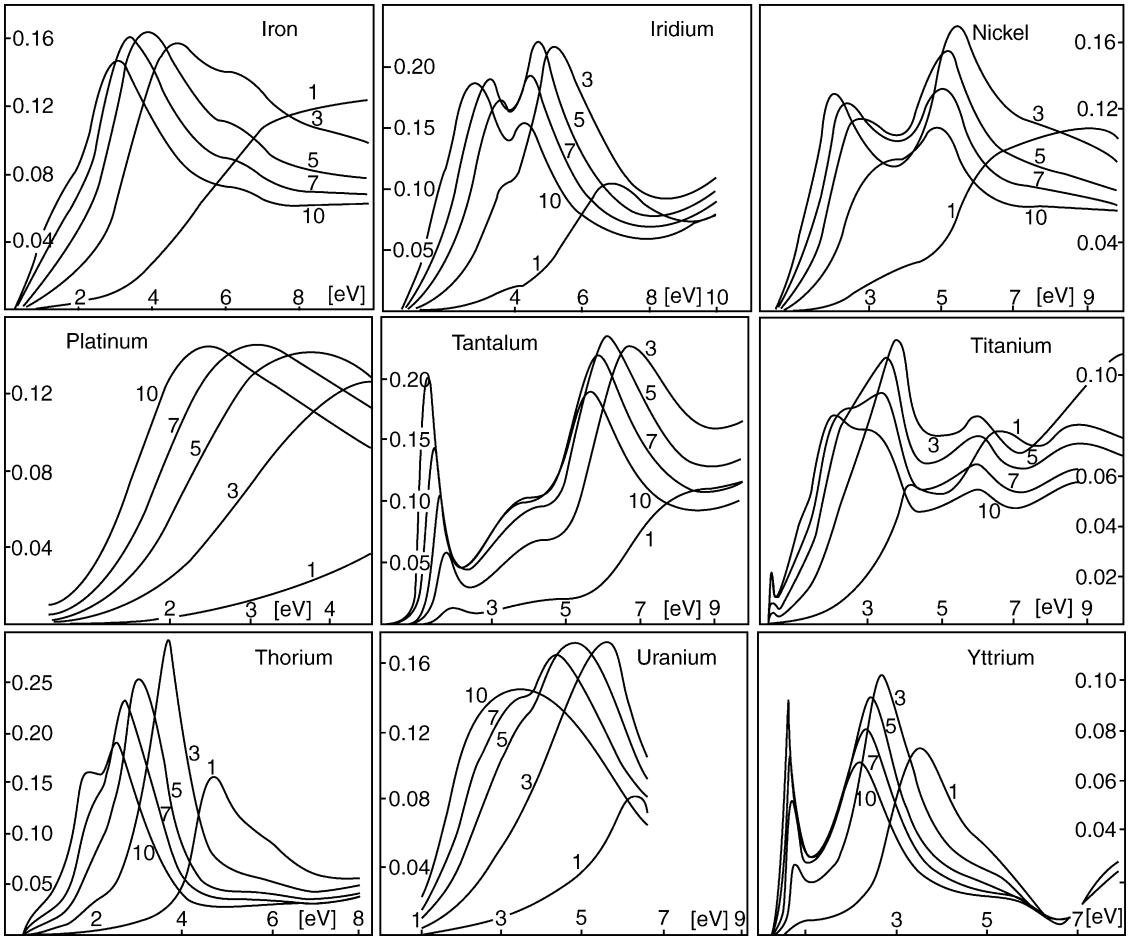

Figure 3 Mie extinction spectra of various particle materials. $2R = 10$ nm. The clusters are embedded in matrix materials with dielectric constants between 1 and 10, which are indicated for each spectrum. Obviously, the peak structure of the spectra strongly depends on the matrix.

Figure 3 gives a compilation of some spectra of general interest determined by evaluating Mie's theory.

Beyond Mie's Theory

Application of Mie's theory to experimental results is disappointing because, in most cases, quantitative coincidence is not obtained. One reason is that the simple assumptions incorporated either in Maxwell's theory or in Mie's derivation are not met by reality.

Mie's theory does not apply, if:

1. particle sizes in a diluted cluster matter sample are not uniform;
2. particle shapes differ from the sphere;
3. $\varepsilon_{\text{matrix}}$ varies with frequency, $\varepsilon_{\text{matrix}}(\omega)$
4. cluster-dependent dielectric functions differ from the according functions of the bulk;
5. the (step-function like) Maxwellian boundary conditions at the particle-matrix interface are not applicable;
6. dielectric functions of particles and/or matrix are nonlinear;
7. surrounding/embedding matrix material is absorbing;
8. particle structures are heterogeneous (core-shell structures, multi-grain clusters, etc); and
9. particles form close-packed aggregates instead of being well-separated, and hence, electromagnetic coupling among particles is important.

Of course, this list may be continued. Regarding realistic samples, it is obvious already from these deviations that quantitative correspondence between experiment and Mie theory usually cannot be expected. But, over time, each of these extra effects has been treated and included into extensions of Mie's

theory, which should therefore be applied, instead of the original theory. In the following several of these effects will be treated in some detail.

Particle Shapes Deviating From the Sphere

Even metals of high structure-symmetry, like the fcc-Au, can yield nanoparticles with low symmetry habits. Figure 4 shows Au nanoparticles with exotic shapes ranging from triangle and hexagonal platelets over fivefold symmetry multitwin-particles to rodlike shapes. The majority of particles are multigrain structures of irregular isometric shapes.

Multishell Particles

In experiments, particle surfaces often react chemically with the surrounding media, thereby forming compound shells. Core/shell structures can be clearly visible in the optical absorption spectra. Figure 5 shows, as an example, the absorption spectra of nanoparticles of Ag core/Au shell and of Au core/Ag shell, respectively with varied shell thicknesses.

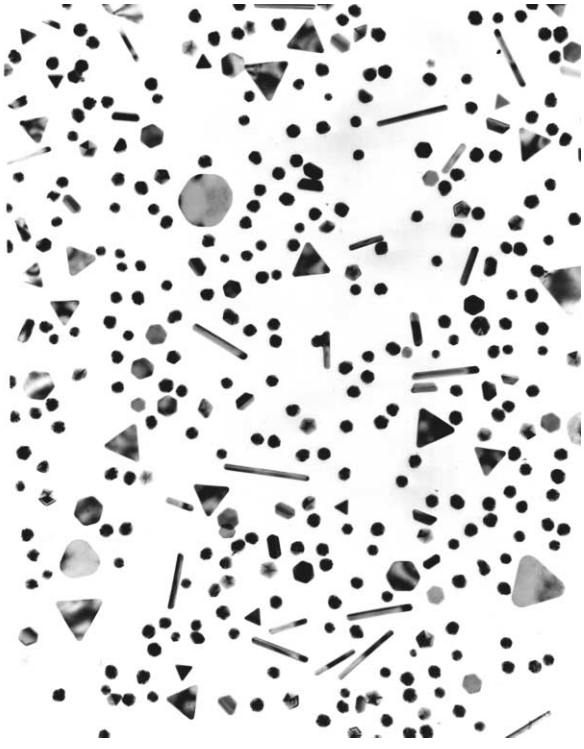

Figure 4 Chemically (Esiguondy method) produced Au clusters with extraordinary variety of different shapes. (Of special interest are the small particles of five-fold symmetry.) Mean sizes of the irregular, almost spherical particles: 36 nm.

Resonances will also occur, e.g., in metal-coated dielectric particles. An example is shown in Figure 6, with extinction spectra of silver-coated titanium-dioxide particles, computed by an extension of Mie's theory.

Aggregates of Nanoparticles with Electrodynamic Particle–Particle Coupling

The optical extinction and scattering spectra of many-particle systems with dense packing forming aggregates (see Figure 4) are strongly influenced by electromagnetic interactions: each particle feels the

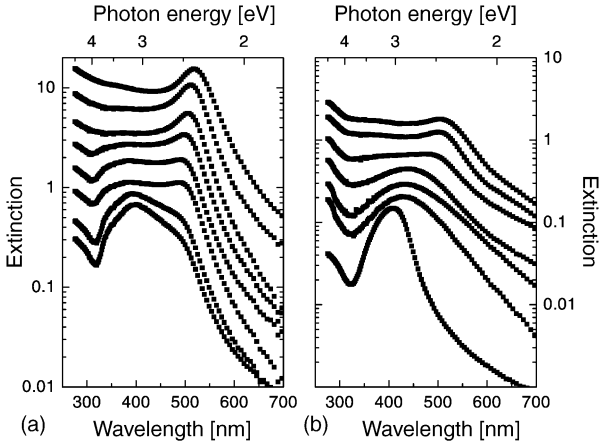

Figure 5 Measured extinction spectra of (a) silver-coated gold particles (gold core $2R = 17$ nm, shell thickness varying from $d = 0$ to $d = 3.6$ nm from top to bottom), and (b) gold-coated silver particles (silver core $2R = 18$ nm, shell thickness varying from $d = 0$ to $d = 5$ nm from bottom to top).

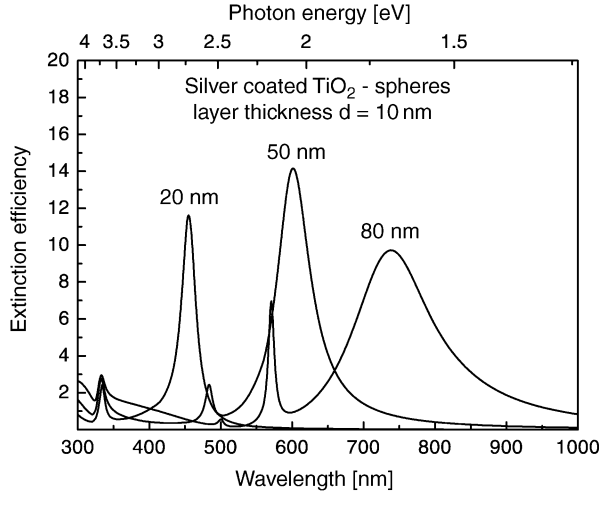

Figure 6 Calculated extinction spectra of spherical silver-coated titanium dioxide particles. The shell thickness is kept constant at $d = 10$ nm, the core sizes amount to $2R = 30$ nm, 50 nm, and 80 nm, respectively, as indicated in the graph.

scattering near fields of all its neighbors, which give rise to splitting, broadening, and shifts of resonances. This is clearly demonstrated with colloidal Ag and Au particles in Figure 7.

The splitting, broadening, and shifts can be assigned to the shape and size of the resulting many-particle aggregates. An example for the influence of the topology of the many-particle system is given in Figure 8 with extinction and scattering spectra of silver particle aggregates of $N = 5$ identical silver particles with $2R = 40$ nm, which were computed by the Generalized Mie Theory (GMT). As a rough rule-of-thumb, such electrodynamic coupling effects of the oscillators only can be ignored if the smallest next neighbor center-to-center distance d_{cc} exceeds $d_{cc} \approx 5 \cdot R$.

Size Effects

The extraordinary practical success of Mie's theory is based upon the fact that this example of classical electrodynamics enables us to compute numerically the optical response for arbitrary realistic particle materials. In contrast quantum theoretical calculations are restricted, beyond the molecule-solid state transition, to jellium and jellium-related hypothetical material.

Classical electrodynamics, being a phenomenological theory to describe light propagation, does not yield information about optical material properties. These enter via the dielectric functions inserted into the Maxwell boundary conditions. They must be taken from elsewhere, such as from experiments or from quantum solid state theory model calculations. This twofold basis of Mie's theory is illustrated in Figure 9.

There are two different sources for particle size dependences of the optical extinction spectra:

1. The electrodynamics: the larger the particles, the larger are the number of contributing multipoles and the influences of retardation effects, both influencing strongly the optical spectra;
2. The optical material properties describing the particle material which, in the nanoscale size region, exhibit size dependences. These size dependences can be treated by corrections entering the bulk material function.

In general, the dielectric function $\varepsilon(\omega)$ of a metal or semiconductor is the sum of susceptibility contributions of the lattice, of the conduction electrons, and of the interband (electron–hole) excitations:

$$\begin{aligned}\varepsilon(\omega) &= \varepsilon_1(\omega) + i\varepsilon_2(\omega) \\ &= 1 + \chi^{\text{lattice}}(\omega) + \chi^{\text{free electrons}}(\omega) \\ &\quad + \chi^{\text{interband}}(\omega)\end{aligned} \qquad [9]$$

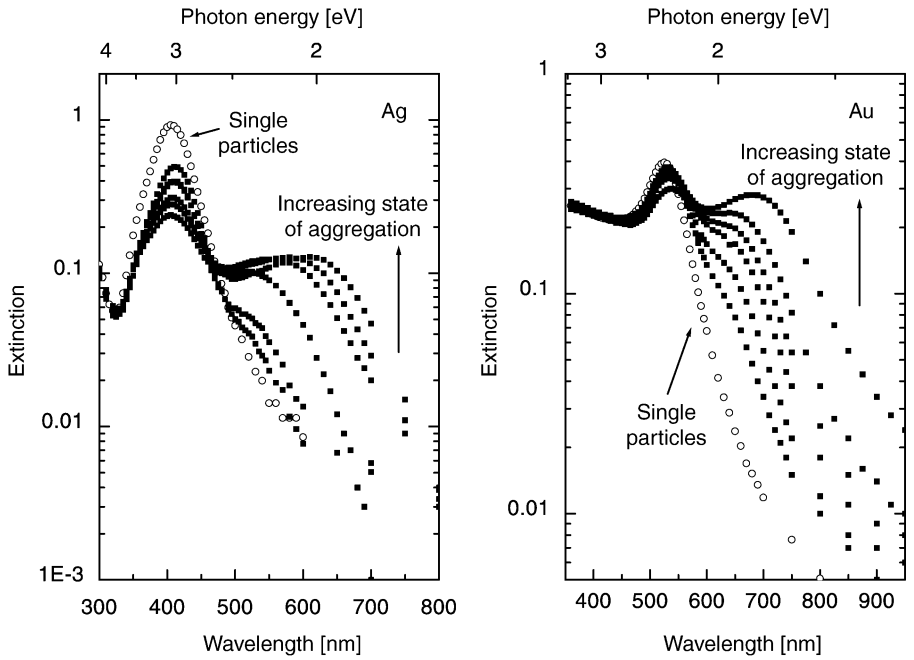

Figure 7 Measured extinction spectra of aggregated samples of (a) silver particles with $2R = 28$ nm, and (b) gold particles with $2R = 38$ nm. The samples contain random distributions of aggregates of various topologies, but with increasing state of aggregation from bottom to top.

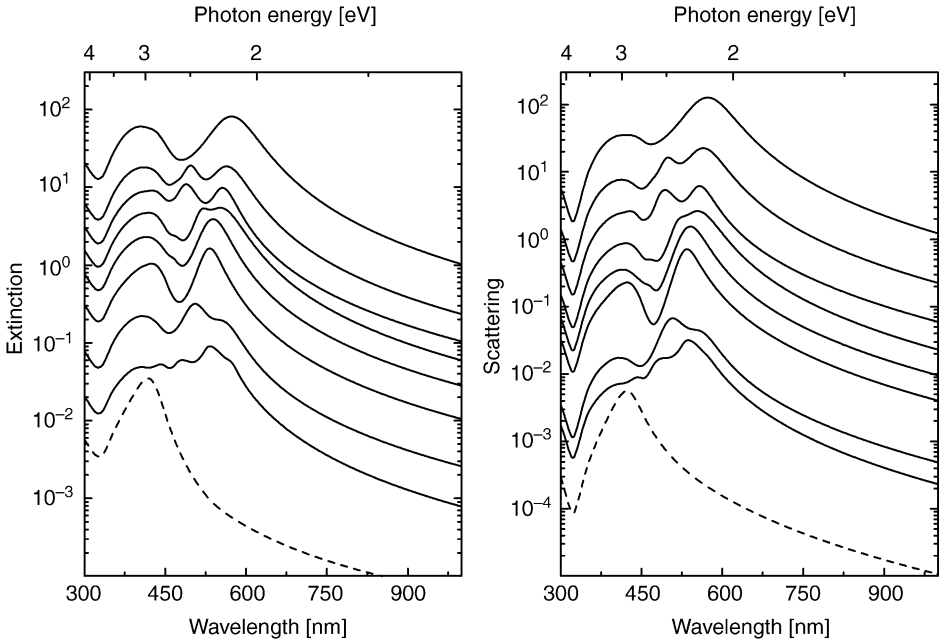

Figure 8 Calculated extinction and scattering spectra of aggregates with $N = 5$ almost touching identical silver spheres of $2R =$ 40 nm. From top to bottom, the spectra belong to the following particle arrangements in the aggregate: ▪▪▪▪▪ ▪▪▪▪ ▪▪▪ ▪▪ ▪ ▪▪▪ ▪▪▪. The dashed line represents the single particle spectra.

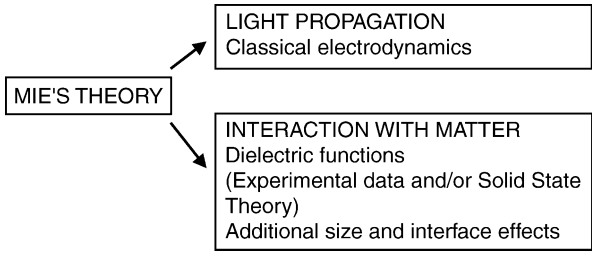

Figure 9 Scheme of the basics of Mie's theory.

A detailed expression was given by Bassani (here, the lattice contributions, mainly important in the IR, were disregarded):

$$\varepsilon(\omega) = 1 - \underbrace{\frac{(ne_0^2/\varepsilon_0 m_{\text{eff}})}{\omega^2 + i\gamma\omega}}_{\text{conduction electrons}} + \underbrace{\chi^{\text{interband}}(\omega)}_{\text{interband transitions}} \qquad [10]$$

with

$$\chi^{\text{interband}} = \frac{2\hbar^2 e^2}{\varepsilon_0 m_{\text{eff}}^2} \sum_{i,f} \int_{\text{BZ}} \frac{2d^3k}{(2\pi)^3} |\mathbf{e} \times M_{\text{if}}(\mathbf{k})|^2 \times \left\{ \frac{1}{[E_f(\mathbf{k}) - E_i(\mathbf{k})][(E_f(\mathbf{k}) - E_i(\mathbf{k}))^2 - \hbar^2\omega^2]} + i\frac{\pi}{2\hbar^2\omega^2} \delta(E_f(\mathbf{k}) - E_i(\mathbf{k}) - \hbar\omega) \right\} \qquad [11]$$

In this equation, the quantity n is the conduction electron density, $\mathbf{k}$ the wavevector of the electrons with norm k, and BZ denotes the Brillouin Zone. The vector $\mathbf{e}$ is the polarization vector of the incident light. M_{if} is the transition matrix element with i = initial and f = final states.

To which degree of approximation a single dielectric function can describe the optical response of a nanoparticle consisting of inner core and surface with differing local optical properties (i.e., polarizabilities), and how this function has to be modelled as an average, is still a problem. An easy, but only approximate answer is to identify terms in the eqns [10] and [11], which may change if the cluster size is reduced down to the nanometer scale, and to introduce correction terms.

In the case of the conduction electrons of eqn [10], these are the electron density n, the effective electron mass m_{eff}, and the relaxation frequency γ. In the terms of the interband transitions (index inter), these are the transition matrix elements M_{if} and the band structure energies of the initial and final states E_i and E_f. All of these quantities change, when the particle size is reduced, in different size regions and to different amounts, and detailed quantum theoretical investigations are required to derive proper correction terms.

The application of the continuum-based dielectric functions and of Mie's theory fail when the molecule-solid state transition region is reached.

The effects of size-dependent dielectric functions upon cluster absorption spectra are demonstrated in the series of absorption spectra of Figure 10, measured on highly diluted heterogeneous systems containing spherical Ag, Au, and Cu particles which were embedded in a glass matrix. If $\varepsilon(\omega)$ were independent of size, then the spectra should be identical, in the investigated particle size region. So, their differences reflect clearly that $\varepsilon = \varepsilon(R)$.

To describe the size effects of the conduction electrons, the relaxation frequency γ of eqn [10] has been modified introducing a parameter that is called A-parameter which also contains size effects and also particle–host interface effects. To explain the electronic size effects in detail, quantum effects have to be considered taking the discretization of the bandstructure into account, but they can also be treated by a simple classical approach: this is the mean free path effect (FPE), assuming the mean flight time of the effective conduction electrons (i.e., those with Fermi energy E_F) between subsequent surface collisions amount to

$$\tau\gamma_{FPE} = A_{FPE}\frac{v_{Fermi}}{R} \qquad [12]$$

The A-parameter is a measure of the effectiveness of the single collision in view of relaxation. Complete 'memory loss' of the drift momentum in each collision would lead to $A_{FPE} = 1$. Taking electron correlation effects and energy relaxation into account, A-values larger than 1 may also be realistic. Values larger than unity also occur in multigrain particles, due to grain boundary 'collisions'.

Various quantum mechanical models of electronic particle size effects result in relations, formally coinciding with the $1/R$-dependence in eqn [12]. Most relevant is the value of A for particles *in vacuo* with clean surface. This value has been determined theoretically and experimentally to $A \approx 0.25$ for Ag particles.

Properties of Internal Interfaces

Structures of Surfaces/Interfaces

Only mathematical interfaces in geometry can, in fact, be two-dimensional planes separating two different volume elements. This is assumed in the frame of Maxwell boundary conditions entering Mie's theory. In real nanostructured matter, however, the interface regions are three-dimensional layers formed by disturbances of atomic and/or of electronic structures, and/or of chemical compositions. In addition, due to the finite wavelengths of the conduction electrons, the according electron density 'spills out' and, as a consequence, we find electron density beyond the geometric surface. It should be kept in mind that these effects hold, with proper changes, for interfaces in nanostructured materials in general. Hence, an understanding of the interface regions is of key importance for all nano-material.

Electronic Interface States

Up to now, this discussion has been restricted to particles with uncovered, 'clean' surfaces. In most practical examples of heterogeneous materials however, the building units are embedded in a host matrix, deposited upon the surface of a substrate, or are in close contact to neighboring crystallites, etc., to stabilize the samples. Then, special electronic

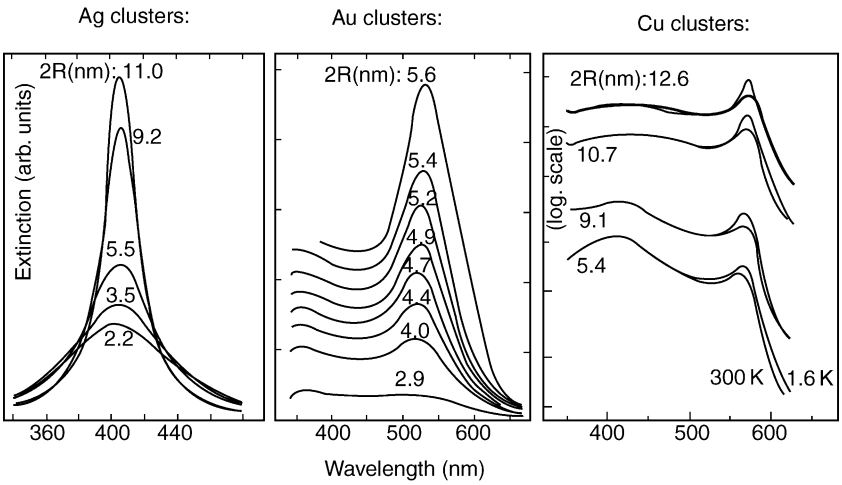

Figure 10 Measured extinction spectra of Ag, Au, and Cu clusters of various mean sizes, grown in glass matrix. In the case of Cu-particles, measurements at 1.5 K are added.

interface states are created by contributions of particle electrons and host electrons, which are (disregarding their density on the surface) similar to adsorbate states.

One might assume that the broad knowledge about these states in surface science, obtained from samples with extended crystallographic planes, should be very useful here. However, the surface of a cluster, in principle, differs from the planar surface of a single crystal by containing a multitude of different local surface structures, atomic sites, and varying atomic coordination numbers. Even if the surface structure is not irregular (as is usual in nanoparticles), the surface consists of several facets of different orientation separated by edges and corners. The coordination numbers of surface atoms, thus, vary strongly (e.g., between 5 at a corner and 9 on a plane), indicating surface sites to have different energies.

We have shown that, if the particles are metallic, the 'particle/host'-interface states give rise to two different electronic charge transfer processes of particle conduction electrons, the static and the dynamic charge transfer. This will be demonstrated qualitatively for metal particles by the example presented in Figure 11.

The Static Interface Charge Transfer and its Effects Upon Mie Resonance Positions

At the left side of Figure 11, the conduction band of the metal cluster close to its surface is shown, which is occupied with electrons up to the Fermi energy E_F. Chemisorption of a free atom (one energy level E_a of which is plotted at the right-hand side) is assumed to occur by approaching the atom to the cluster surface. The resulting energy states are also shown. Let us assume the marked electronic level E_a in the free atom is nonoccupied. During the chemisorption process, this level is shifted and broadened, developing density of nonoccupied states below the particle Fermi energy, which is localized at the three-dimensional interface region. After complete the process is, such a state will be occupied permanently by electrons of the cluster (static charge transfer), and the nanoparticle will have lost electrons, thus its electron density being reduced. The driving impact of this process is the equilibration of the chemical potential in the whole cluster-matrix system.

Now assume we embed a cluster into some surrounding material. Then all those atoms of the latter, which are situated directly at the interface, become chemisorbed at the cluster. Hence remarkable amounts of charges can be transferred into the interlayer region and an electrical double layer is created. As an example, a very strong amount of static charge transfer was observed experimentally when applying solid Fullerite (C_{60} molecules) as embedding matrix for Ag-nanoparticles: here, each C_{60} in direct contact with the Ag particle attracts one electron, forming (C_{60}^-). Hence, in this experiment with 500 atoms large particles, in total about 20% of the conduction electrons of the Ag-particle were transferred into the interlayer. Strictly speaking, such a nanoparticle of the heterogeneous material is no longer a silver particle because of the remarkable changes of electronic properties by static charge transfer.

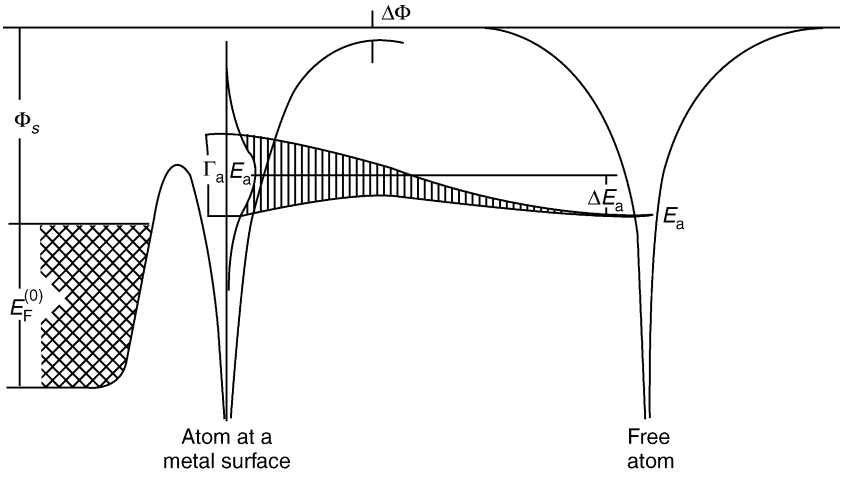

Figure 11 Electron energy scheme for atomic adsorbation at a metal particle surface. The free atom (energy spectrum: right) approaches the particle surface (left; conduction band with Fermi-level E_F). Its energy level E_a is thereby shifted and broadened (including ensemble broadening of many atoms deposited at many clusters). The atoms are assumed to be separated from the metal by a tunnel barrier (see text).

Some consequences are listed in the following:

In a first step, let us assume that the electronic bandstructure is not altered by the charge transfer. Then we expect: (i) changes of level occupation; (ii) changes of Fermi energy and Fermi velocity; (iii) changes of effective masses close to E_F; (iv) changes of surface 'spill out'; (v) additional adsorbate levels and special surface states; and (vi) changes of the optical interband transition edge.

In a second step, we may consider possible changes of electronic bandstructure (e.g., energies) and, finally, also changes of atomic structures (i.e., lattice structures and/or surface structures).

Since plasmon frequencies depend on the conduction electron density, the resulting Mie resonance can monitor and give quantitative information of this effect. We find shifted by the static charge transfer:

$$\Delta\omega_{\text{resonance}} \approx (\sqrt{n_2} - \sqrt{n_1}) \times \sqrt{\frac{e_0^2}{\varepsilon_0 m_{\text{eff}}(2\varepsilon_{\text{matrix}} + 1 + \chi_1^{\text{interband}})}} \quad [13]$$

with n_1 being the conduction electron density in the cluster *in vacuo*, and n_2 being the electron density after contact with foreign material (adsorbate, substrate, or host-matrix). This peak shift of the Mie resonance, however, is superimposed in the experiment by a much larger shift, following simply from the change of Maxwell boundary conditions by the altered dielectric constant of the particle surrounding $\varepsilon_{\text{matrix}}$, when going from vacuum to a matrix material. Hence, the experimental determination of static charge transfer processes is rendered more difficult.

The Dynamic Interface Charge Transfer and its Effects Upon Mie Resonance Widths

After the static charge transfer in Figure 11 has taken place, electrons close to E_F can fluctuate between the cluster and empty adsorbate levels, if present at E_F. The residence times in these levels, which are usually separated from the Fermi sea of the metal cluster by some tunnel barrier, vary statistically. If a plasmon is excited, i.e., mainly a collective, phase ordered motion of all conduction electrons superimposed to their statistical motion, we may assume that, after such electron transfer back and forth, the reminiscence to the primary drift momentum, and the phase of this excitation, has been lost. Thus, the phase relaxation of the plasmon is increased.

The consequences of this dynamic charge transfer effect ('chemical interface damping') have been investigated in detail. Here, we only state that the directly observable main consequence is the broadening of Mie resonances. If the particles are sufficiently small to neglect radiation damping (this is the case for Ag clusters smaller ≈ 15 nm), band broadening is only due to internal energy dissipation and the band width can be modeled quantitatively with the modified relaxation frequency γ in eqn [10] which yields an additive correction term:

$$\Gamma(A, R) \approx \Gamma_0 + \frac{2ne_0^2}{\varepsilon_0 m_{\text{eff}}\omega^3} \times \frac{A}{\sqrt{(\partial\varepsilon_1/\partial\omega)^2 + (\partial\varepsilon_2/\partial\omega)^2}} \frac{v_{\text{Fermi}}}{R} \quad [14]$$

with the A-parameter extended to the additional electronic excitations in the particle/host interlayer:

$$A = A_{\text{size effects}} + A_{\text{interface effects}} \quad [15]$$

The A-parameter of eqn [15] now expresses both the strengths of the particle size effects and of the chemical interface damping, due to statistically varying occupation of interface states near E_F.

An important feature of this model is that the dependence on the kinds of materials is described by specific material parameters ($A_{\text{size effects}}$ and $A_{\text{interface effects}}$), and the direct size dependence effects are given by an $1/R$-dependence, for both the direct size effects and the interface effects. For one fixed cluster size R, the magnitude of $A_{\text{interface effects}}$ directly characterizes the probability of the single temporal charge transfer, including the number and energies of contributing interface states; hence, important properties of the adsorption process can be investigated by determining the A-parameter.

Experimental Results

In the experiments presented in the following, we deal with the interfaces between clusters and a more or less homogeneous solid embedding medium. We selected very small silver nanoparticles of about 2 to 4 nm size with accordingly large ratio of surface- to volume-atoms, in order to optimize the sensitivity of the measurements. Silver is unique in having the most pronounced Mie resonance of all known materials.

In Figure 12 two classes of matrix materials are presented, fluorides and oxides. The absorption spectrum of the free particles with uncovered 'clean' surface (measured in a cluster beam in UHV) is added in both diagrams which is only influenced by size effect. General features are, that embedding in a host medium causes:

- drastic Mie resonance peak shifts toward IR, depending on the dielectric constant of the matrix

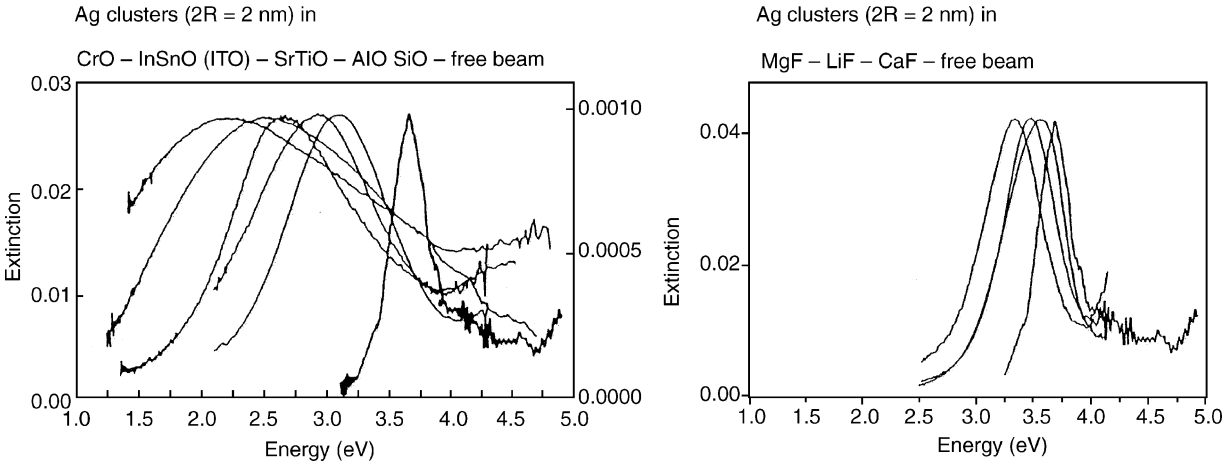

Figure 12 Measured optical extinction spectra of 2 nm Ag nanoparticles, embedded in various different embedding materials. For comparison, the spectrum of the free nanoparticle beam is added. Left side: oxidic materials, right side: fluoridic materials.

$\varepsilon_{\text{matrix}}$, which classically follow from Mie's theory and by comparingly small additional shift due to static charge transfer;

- drastic broadening (exceeding, in some cases, all known size effects), which according to eqn [14], can be described by characterizing values of the *A*-parameter. Recently, these parameters have been experimentally determined for Ag nanoparticles embedded in a broad variety of host materials. Their interpretation is rendered difficult, however, due to inhomogeneous broadening of varying magnitude.

We can immediately judge from Figure 12 that both shift and broadening are larger in the case of oxidic matrices than of fluoridic ones, i.e., oxides possess more interface states close to E_F of the material. In Figure 13, observed peak positions $\hbar\omega_{\max}$ and broadenings expressed in the resulting *A*-parameters, are summarized for a broad variety of different embedding materials.

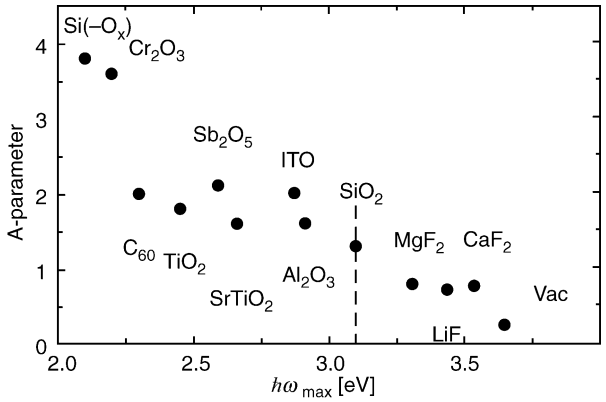

Figure 13 Silver nanoparticles ($2R = 2$ nm) embedded in various solid host matrices: measured Mie peak positions and resonance halfwidths expressed by the *A*-parameters.

Comparison of Plasmon Polariton Lifetimes with Femtosecond Experiments

In the last section, experimental examples were presented to show how fundamental physical properties are changed by forming heterogeneous materials. Because the Mie resonance widths are mainly a consequence of finite plasmon polariton life times τ, (in addition, there are interband contributions, in larger particles radiation damping, and dispersion influence), the latter can be evaluated from measured optical absorption spectra. This supposes the bandwidth to be essentially homogeneous. From a width analysis fitting Mie's theory numerically we obtained for Ag particles, free flying in UHV with uncontaminated free surfaces and 2 nm in size, a plasmon lifetime of $\tau = 6$ fs. Under these experimental conditions, the measured bandwidth is the homogeneous one.

Concerning the size dependences, we can extrapolate to larger particles. The longest lifetimes are expected for 15 nm particles, for which $\tau = 15$ fs was obtained by extrapolating the experimental data for 2 nm particles to this size. The same width analysis was performed for the nanoparticles embedded in matrix materials, and as a result, the lifetimes drastically decrease down to 1–2 fsec. The observed increase of the *A*-parameter, as shown in the previous section, is thus directly correlated to the measured decrease of the plasmon polariton lifetime. Hence, we conclude that the decrease of the lifetime is mainly due to increased phase relaxation caused by the dynamic charge transfer effect.

These results can be compared with recent femtosecond spectroscopy experiments which have recently given much impact on the experimental investigation of the dynamics of Mie resonances in silver and gold nanoparticles. In these experiments data between 6 and 10 fsec were obtained for deposited Ag and Au particles of different sizes and different substrates. Regarding the complexity of the different experiments the correspondence of the data appears convincing.

Obviously the lifetimes evaluated in the frequency domain, from our spectra of particles *in vacuo*, coincide with the lifetimes determined in the time domain. The latter, though, were measured with larger particles deposited on substrates (i.e., not from free particles but including interactions with substrates).

As a concluding remark, it may be pointed out again, that the optical properties and the heterogeneity effects presented here for the model system of nanoparticle/host-matter, are also to be found in other examples of the large field of heterogeneous materials.

List of Units and Nomenclature

Absorption bandwidth	Γ
circular frequency [s^{-1}]	ω
dielectric constant/dielectric function [–]	ε
effective electron mass [kg]	m_{eff}
electric field [$V\,m^{-1}$]	E
(electron) relaxation frequency [s^{-1}]	γ
electron state energies for initial and final state [J]	E_i, E_f
elementary charge [C]	e_0
extinction, scattering, absorption cross section [m^2]	σ_{ext}, σ_{sca}, σ_{abs}
Fermi energy [J]	E_{F}
Fermi velocity of electrons [$m\,s^{-1}$]	v_{Fermi}
intensity [$W\,m^{-2}$]	I
Kronecker energy distribution [J^{-1}]	$\delta(E)$
magnetic field [$A\,m^{-1}$]	H
norm of wave vector of electrons [m^{-1}]	k
number density of conduction electrons [m^{-3}]	n
Riccati-Bessel functions of first kind [–]	$\psi_n(z)$
particle radius [m]	R
(phase-) life time [s]	τ
Planck constant [J_s]	$\hbar$
Riccati-Bessel functions of third kind [–]	$\eta_n(z)$
scalar electromagnetic potentials [V]	Π, Γ
susceptibility [–]	χ
transition matrix element [$kg\,m\,s^{-1}$]	M_{if}
vacuum permittivity [$CV^{-1}\,m^{-1}$]	ε_0
vacuum velocity of light [$m\,s^{-1}$]	c
vacuum wavelength of light [m]	λ
wave vector of electrons [m^{-1}]	$\mathbf{k}$

Lightweight Mirrors

J W Bilbro, George C Marshall Space Flight Center, AL, USA

Published by Elsevier Ltd.

The desire to probe the heavens is as old as humanity; the realization that the human eye could be aided in these investigations is somewhat more recent. In May 1609, Galileo Galilei, while visiting in Venice, heard about the new 'telescope' invented by the Dutch lens-maker Hans Lipershay and decided that it would be useful in his astronomical investigations. He returned to his home in Padua and made his own telescope comprised of 4.2 cm diameter plano-convex and plano-concave lenses. With this telescope, Galileo discovered the satellites of Jupiter; got tenure; had his salary doubled – and the race was on! It did not take too long to realize that 'bigger' was 'better', and from this point forward, there has been a continuous striving to increase collecting area and resolution, thereby enabling the astronomer to 'see' farther and farther into the heavens.

The limitations of refractive optics soon prompted investigations into reflecting optics – mirrors. In 1668, Isaac Newton produced the first reflecting telescope having a 2.5 cm diameter mirror made of speculum (copper (6), tin (2), and arsenic (1)). A little over 100 years later, in 1789, William Herschel constructed his 'Great Telescope', having a 1.22 m diameter mirror made of bronze. Of course as telescopes grew, so did mirror weight. In 1845, William Parsons' 'Leviathan' was built. It had a 1.84 m diameter mirror made of speculum that weighed 3600 kg – a whopping 1354 kg m^{-2}.

Problems with corrosion in speculum and bronze mirrors led to a renewed interest in glass, and the development of highly reflective coatings soon made metal mirrors obsolete. In 1917, the mirror for the Hooker telescope arrived on Mount Wilson. Made by the Saint Gobain glassworks in France from the same material used for wine bottles, the mirror was 2.54 m in diameter, 33 cm thick and weighed over 4000 kg (789 kg m^{-2}).

The increasing weight of larger and larger mirrors produced practical problems for telescope makers and astronomers. Herschel's telescope was so unwieldy that he found it almost impossible to use and returned to smaller telescopes for most of his observations, and the 2.54 m Hooker telescope required a 100 ton mount and drive system. Obviously, if telescope apertures were to increase, steps had to be taken to make mirrors lighter. The first major success in this arena was accomplished for what was to become the Hale Telescope commissioned at the Palomar Observatory in 1948. In 1936, Corning cast a mirror made of a new borosilicate glass blend called Pyrex. The blank was lightweighted by placing hexagonal shaped obstructions in the mold which created corresponding voids in the glass. The finished mirror (**Figure 1**) was 5.08 m in diameter, 61 cm thick at the edge and weighed approximately 13 000 kg (641 kg m^{-2}). Even with this degree of 'lightweighting' the mounting and drive mechanisms still weighed around 182 000 kg.

Although the desire for larger ground-based telescopes provided the initial impetus for developing lightweight mirrors, the advent of the space program and the desire to put telescopes in space became the main driver in the pursuit of 'serious' lightweighting techniques. The cost of launching

Figure 1 5.08 m Pyrex™ mirror made by Corning/Caltech for the Hale Telescope. Reproduced with permission from the Palomar Observatory/California Institute of Technology.

large telescopes into space quickly becomes prohibitive as aperture size increases. Consequently, the current emphasis is on developing ultra-lightweight, deployable telescopes that permit ever-increasing apertures to be placed in orbit. Fortunately, the zero gravity environment of space permits satisfactory operation of such ultra-lightweight telescopes and therefore the extent to which a mirror can be lightweighted is primarily dependent upon the mirror material and the manufacturing techniques utilized.

Manufacturing

Mirror manufacturing can, in some sense, be divided into two general classes, one that removes material (direct generation) and one that deposits material (replication). The two classes have significantly different limitations relative to producing lightweight mirrors. Direct generation encompasses the more traditional methods of mirror manufacturing, blank fabrication, and optical surface generation, i.e., grinding and polishing. Many innovative techniques have been developed over the past decade that have not only made significant strides in improving fabrication times, optical figure, and surface finish, but have also made possible the reduction of weight to unprecedented levels.

Although extremely lightweight mirrors are being fabricated using direct generation, in the end, there are limitations in the fabrication processes that are not present in replication. This process offers the fascinating potential to create mirrors that are only a few molecules thick, thereby bringing a new meaning to the term 'lightweight optics'.

Direct Generation

Mirror blank fabrication

Casting lightweight glass mirror blanks has evolved substantially since 1936. Four 8.2 m diameter Zerodur™ mirror blanks were spun cast for the European Southern Observatory's Very Large Telescope Interferometer. The largest mirror cast to date was the 8.4 m borosilicate mirror cast in a spinning oven for the Large Binocular Telescope on Mount Graham. Although not exactly lightweight by space standards – the blank weighs 15 455 kg (266 kg m^{-2}) – it is substantially less than a conventionally cast solid blank.

It has been postulated that an areal density of around 64 kg m^{-2} probably represents the limit of lightweight glass castings. Therefore, as the demand for lighter and lighter mirrors increased, methods other than casting had to be developed. Investigations in the 1960s indicated that mirrors could be lightweighted to about 180 kg m^{-2} by first fabricating a 'honeycomb' core and then fusing plates on the front and back of the core using a high-temperature fusion process. This process was used to produce the Hubble Space Telescope mirror (Figure 2). Hubble had a 2.5 cm thick face-sheet and backsheet and a honeycomb interior constructed of individual pieces 0.5 cm thick. These pieces were assembled and placed in a large furnace where the temperature was increased until they fused together. The resulting 2.4 m diameter mirror weighed 828 kg (183 kg m^{-2}).

During the 1980s, Frit bonding technology was developed. Unlike the fusion process, Frit allowed the bonding of glass elements at a lower temperature. This allowed the cross-sections of the glass elements to be significantly reduced. The thicknesses of face-plates were typically reduced to around 7 mm and areal densities in the 40–50 kg m^{-2} range became routine. New advances were also made in core manufacturing. Diamond tooling was developed along with computer controlled systems to machine cores from solid blanks. High-pressure water jets were developed that allowed cores to be made much faster than with diamond tooling. In addition, the water jet cutting provided the ability to create very flexible geometries optimized to minimize weight while retaining stiffness. Water jets could machine core walls that could be held to a thickness of around 1.5 mm over a core depth of 20 cm. Computer controlled diamond machining has created even thinner cores (less than 1 mm in thickness) but the process requires longer generation times.

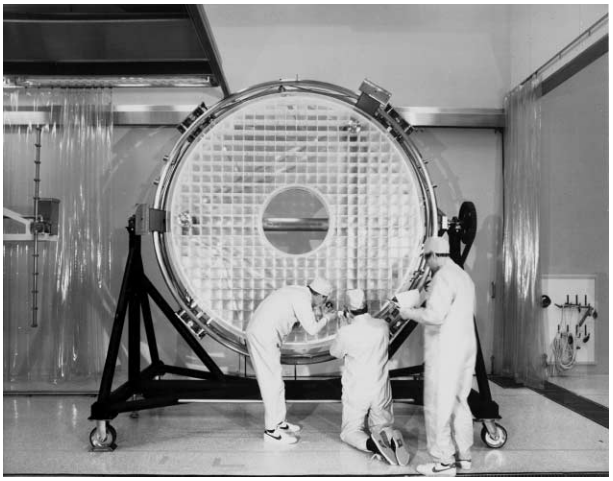

Figure 2 2.4 m ULE™ mirror made by Corning/Perkin Elmer for the Hubble Space Telescope. Photography courtesy of NASA.

Material removal

The evolution in blank manufacturing required a corresponding evolution in the process of material removal. Many new grinding and polishing techniques were developed over the years to more accurately and rapidly generate precision optical surfaces. These included adaptive force grinding, electrolytic in-process dressing (ELID), water jet figuring, computer controlled polishing, stress lap polishing, magneto-rhelogical figuring (MRF), plasma-assisted chemical etching (PACE), ion figuring, and vacuum lap figuring. Most of these processes induce localized forces on the face-sheet in the process of material removal, and for a 'honeycomb' mirror, the face-plate deflects away from the grinding/polishing tool as the tool reaches the center of the cell. This means that less material will be removed in the center of the cell than at the edge of the cell where the core wall holds the face-sheet against the tool. This creates a 'quilted' pattern in the surface that must be removed in subsequent steps. As face-sheets become thinner, quilting becomes more pronounced and the process of removing 'quilting' becomes exacerbated. For a number of years, this was the limiting factor in the development of high-precision lightweight mirrors.

Ion figuring is a noncontact process that has eliminated the problems associated with mechanical material removal. It bombards the surface of the optic with neutralized ions causing atoms to be dislodged. The process creates no deflection of the surface and therefore can remove quilting and other irregularities without generating further distortion in the surface. This has permitted 2–3 mm thick face-plates to be manufactured without concern for quilting effects. Primary limitations now being encountered are in face-plate generation and the various associated handling processes. Great care must be taken to avoid fracture. Spin casting ultra-thin face-plates is being investigated as a means of further reducing problems in the generation process. The 0.75 m mirror made for IKONOS, the high-resolution imaging satellite, represents the state-of-the-art in all-glass lightweight mirrors (28 kg m^{-2}).

Replication

Replication techniques are quite common in low-cost production mirrors and lenses for commercial purposes. However, there are also a number of techniques that hold great potential for precision mirrors as well. Chemical vapor deposition (CVD), plasma vapor deposition (PVD), plasma spray deposition, and electro-forming are all being investigated for producing lightweight precision mirrors. This class of mirror generation does not start with a mirror blank *per se*, rather it replicates a 'mandrel' that has the appropriate surface finish and the inverse of the shape desired in the final mirror. The mandrel can be made very rigid and therefore unperturbed by either gravitational forces or the localized forces generated by grinding and polishing. Extremely thin mirrors with areal densities on the order of 0.1 kg m^{-2} are currently being manufactured using replication techniques. These 'membrane' mirrors are currently being used for solar energy collection; however, recent advances in membrane quality and wavefront correction techniques hold out the promise of producing high-resolution, membrane imaging systems.

The Future?

Theoretically, single-molecule thick mirrors could be manufactured in space using self-replicating nanotechnology systems that 'grow' mirrors according to a mathematical description of the desired optical surface. These 'smart' mirrors could self-correct in the presence of physical disturbances and self-heal when damaged. They could be 'grown' to hitherto unimagined size, being limited only by the availability of raw material. Such mirrors, however, are definitely of the future and should merit re-examination 20 years hence.

Materials

A variety of materials have been developed over the years that have led to lighter and lighter mirrors. Recently, metals are coming back into play as means of fabricating stiff, lightweight mirrors. These metals include beryllium, nickel, nickel alloys, aluminum, and aluminum alloys. Composite materials are also playing a large role in lightweight mirror fabrication, both as a support structure and also as a reflecting surface (with appropriate coatings). Hybrid mirrors comprised of a combination of glass and composites have also been developed, as well as combinations of glass and beryllium. Various forms of silicon carbide have been extensively investigated and lightweight mirrors of pure silicon are being manufactured. Glass still plays a significant role in large lightweight mirrors, and various plastics are under investigation for the production of ultra-thin membrane mirrors.

Glass, Glass Ceramics, and Hybrids

The most common glass/glass ceramic materials used in large telescope mirrors are fused silica, ULE™ (Ultra-Low Expansion) glass, and Zerodur™, a glass ceramic. As was mentioned earlier, there are a variety

of methods available for the manufacture of glass mirrors depending upon the extent of lightweighting desired. Most of the current effort in lightweight mirrors is centered around hybrid mirrors. One method bonds very thin (2–3 mm) glass face-sheets to composite cores to form 'sandwich' mirrors. Another method attaches face-sheets to composite back-plane structures via actuators. In the latter case, the actuators can be used to actively control mirrors to correct for distortions. These mirrors were developed as part of the James Webb Space Telescope technology program, and typically have areal densities on the order of 15 kg m^{-2} (including back-plane structures). An all glass face-sheet and core is shown in Figure 3.

Silicon Carbide

Silicon carbide has long been a promising material for lightweight mirrors. It has many of the desirable properties of beryllium and is nontoxic. Until recently difficulties were encountered in producing mirrors larger than ~0.5 m in diameter. Of late, several manufacturers have produced large (<1 m) lightweight mirrors using different processes; sintering, liquid silicon infiltration and chemical vapor deposition.
